The ultimate bladder neck reconfiguration is complete closure of the bladder outlet. Today, after years of experience, we feel that most, but not all, bladder necks can be made continent. Those that cannot be repaired can be closed. The concept of bladder neck closure was made a viable option in 1980 when Paul Mitrofanoff constructed the continent appendicovesicostomy and combined it with bladder neck closure in patients with neurogenic bladder (Figure 56.22).[124] Duckett and Snyder presented variations of bladder neck closure and continent stomas, and Van Savage et al. presented a series of 46 children with closure of bladder neck.[125,126]

In general, bladder neck closure is a procedure of last resort and is utilized after other more flexible options in bladder neck reconstruction have been exhausted.[127,128] The indications for bladder neck closure are intractable urinary incontinence resistant to maximal medical management and reasonable surgical management. Patients usually have failed previous incontinence surgery or suffer from a primary condition that projects failure. The obvious advantage is complete urethral continence in as many as 96% of patients. Eighty-nine percent have stable upper urinary tracts, and no bladder capacity is lost in the creation of a continence mechanism.[129] Disadvantages include a complete lifelong reliance on an extra-anatomic method of bladder emptying and no pressure pop-off valve. Bladder neck closure does have complications, with one series reporting initial results of 20% with stomal incontinence and 40% with urethral fistulas and persistent urethral leakage.[130] With surgical revision, 85% became completely continent. In reviewing multiple reports, 65% of patients with closed bladder necks require additional surgery for complications, such as fistulas, stones, augmentation, ruptures, and other revisions.

The Mitrofanoff Principle

Mitrofanoff's contribution, now termed the Mitrofanoff principle, has had a profound effect on incontinence surgery in children. His development of alternative continent bladder access through a continent stoma has relieved the necessity for the patient to either void efficiently or catheterize through the reconstructed bladder neck. There have been other alternatives to Mitrofanoff's original use of appendix for extra-anatomic access to the bladder. Other options for continent bladder access include

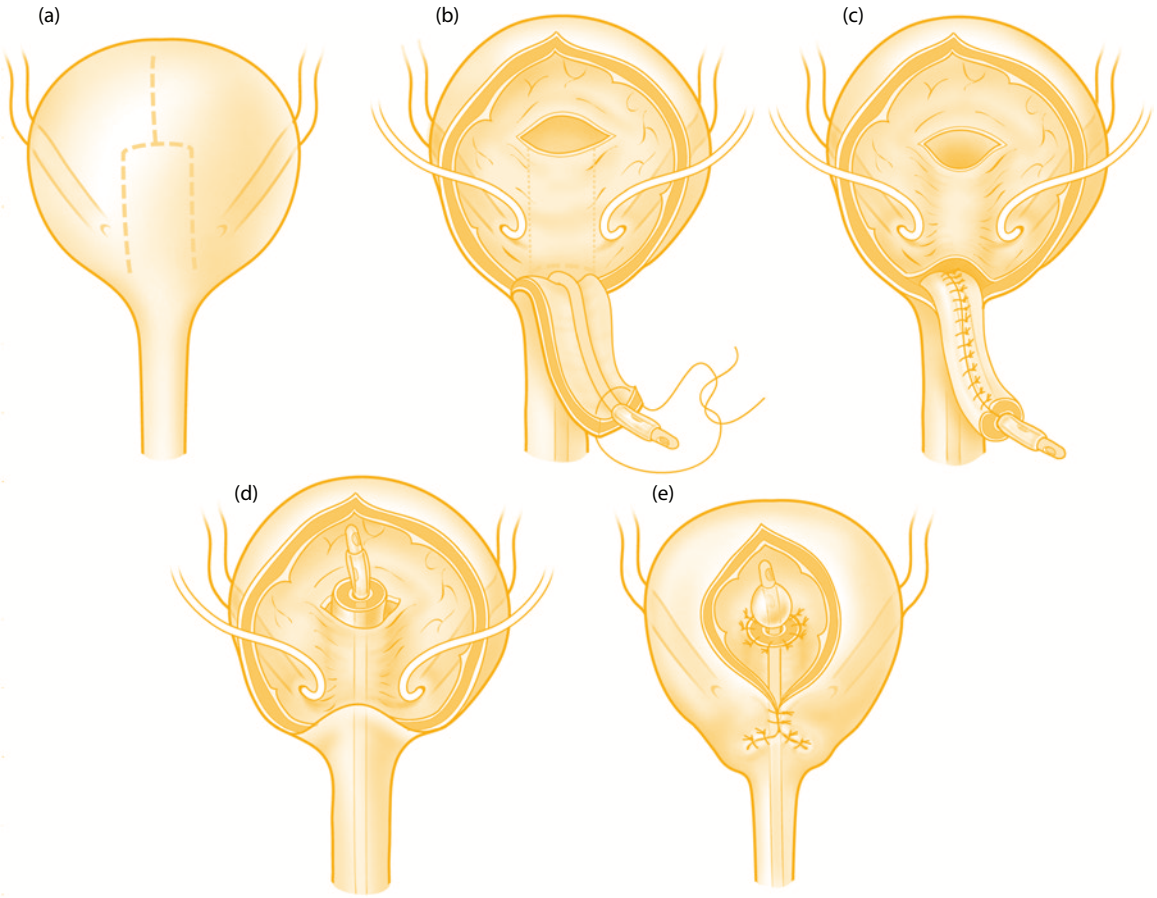

FIGURE 56.19 Kropp also creates a neourethra from a flap of anterior bladder neck and bladder, but unlike Tanagho, Kropp's flap is based on the urethra. The flap is tubularized and then placed in a submucosal tunnel created along the midline of the posterior bladder wall. (a) An anterior urethral-based flap is mobilized. (b and c) The flap is tubularized. A submucosal tunnel is made in the posterior bladder wall. (d and e) The tube is placed in the tunnel.

the ureter, fallopian tube, bladder tubes, and tubularized bowel.[131–133] With the recent interest in the Malone antegrade continence enema (MACE) for patients with neuropathic bowel and bladder, the appendix has been used more often as access to the colon.[134]

Tubularized ileum and Yang–Monti tubes have been the most dependable and flexible method of bladder access for these patients (Figure 56.23).[135] We have developed a longer ileal tube for patients with a greater distance between the bladder and skin (Figure 56.24).[136] Today, an easily accessible, continent, catheterizable access for emptying the bladder is available for almost all patients.

We believe that catheterizable abdominal stomas promote continence by avoiding manipulation of the reconstructed bladder neck. In some cases, they encourage patient compliance with intermittent catheterization because catheterizing through an abdominal stoma is easier and less time-consuming than urethral catheterization for many patients. Regular catheterization keeps bladder pressures low and minimizes stress on reconstruction done at the bladder neck. Stomas allow the surgeon to be more aggressive in creating resistance at the bladder outlet because the urethra will not be needed as the primary access for catheterization. The combination of continent stomas and augmentation has allowed patients who have suffered multiple failed continence surgeries to be salvaged with good results.[137]

INDICATORS FOR SUCCESS

The definition of continence has changed over the years and is open to interpretation by each surgeon.

"Social continence" was felt to be adequate in the past, and if a child used several continence pads per day but was free of diapers, most pediatric urologists considered their treatment successful. Our tolerance of wetness has been modified over the years, perhaps in response to the change in public policy in the 1970s to mainstream the education of children with disabilities. In more modern reviews, surgeons have been more specific in defining successful continence. Dryness, without the odor of urine, has become the expected goal. This evolution of the definition of success makes comparing results from different eras and series difficult.

The effectiveness of procedures to treat the weak bladder outlet cannot be judged easily. Ultimate success is of course based on continence, but also involves other criteria, such as the ability to void and the need for other surgery to attain continence, such as bladder augmentation.

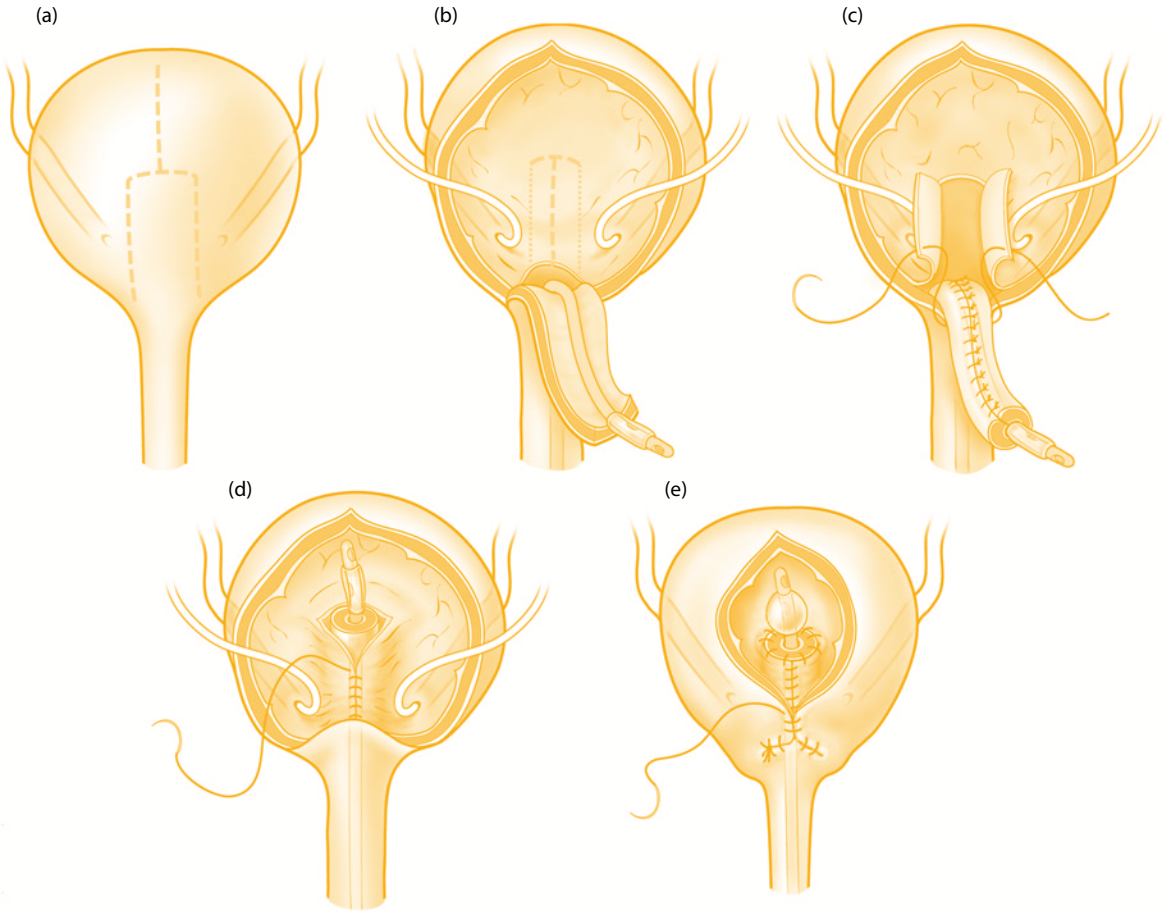

FIGURE 56.20 The Snodgrass variation of the Kropp procedure lays the Kropp tube in a trough instead of a tunnel. Construction of the tube is identical to that of Kropp. (a) A full thickness flap of bladder is isolated from the anterior bladder wall and encompasses the bladder neck. (b) With the anterior flap rotated out of the way an incision is made in midline of the bladder mucosa. (c) The anterior bladder flap is rolled into a tube in continuity with the proximal urethra. Mucosa is mobilized on either side of the midline incision exposing a trough in which the anterior bladder tube will rest. (d) The bladder tube is sewn into the trough and then covered with the bladder mucosa flaps creating a flap valve for continence in patients who are committed to intermittent catheterization. (e) The bladder is closed.

It is unfair to compare procedures that allow voiding with those that prevent voiding by design.

Of the procedures that allow voiding, the YDL procedure, its variations, and the Tanagho repair have been the most successful, allowing 70%–100% of patients to void initially. Voiding after this type of surgery is seldom normal, for these procedures usually produce a fixed resistance at the weak bladder neck. Voiding is often accomplished with abnormally high bladder pressures that are generated by Valsalva's maneuver. These pressures are necessary to overcome the static-increased bladder outlet resistance. Even if the patient is able to void for a period of several years, the detrusor may eventually fail and require intermittent catheterization. Many procedures produce 75% continence rates, but often these rates are dependent on intermittent catheterization and chronic detrusor relaxation achieved with medication or augmentation.

The artificial urinary sphincter would seem to be the best alternative for the patient who can void prior to surgery, as it provides a variable resistance at the bladder neck and should allow voiding at more physiologic pressures. Long-term studies of sphincters in children reveal that most patients eventually require intermittent catheterization because of inadequate emptying due to detrusor failure. The other complications of inevitable reoperation and potential secondary detrusor hyperreflexia are additional considerations with this device. If the patient does have the potential to void over a long period of time, the artificial sphincter is the best option. Around 80% of patients will be continent over a long period of time with the sphincter, although most require intermittent catheterization. Augmentation rates of 30%–35% in long-term selective studies are less than those with other bladder procedures.

Of the procedures that prevent voiding by design and rely on intermittent catheterization, the slings are the most simple and dependable in females and produce 80% continence rates with good durability. The Pippi Salle bladder neck reconstruction produces 80% continence, whereas the Kropp procedure produces the highest continence rates, approaching 100%. Bladder neck closure is also very dependable but leaves the patient reliant on only one bladder access, an extra-anatomic continent stoma, and no pop-off valve.

If one is choosing a bladder neck procedure, one must have specific goals in mind relating to the patient's potential to void. Patients with neuropathic bladders from sacral agenesis, myelomeningocele, and spinal cord trauma have poor potential to void regardless of bladder outlet resistance. Patients with

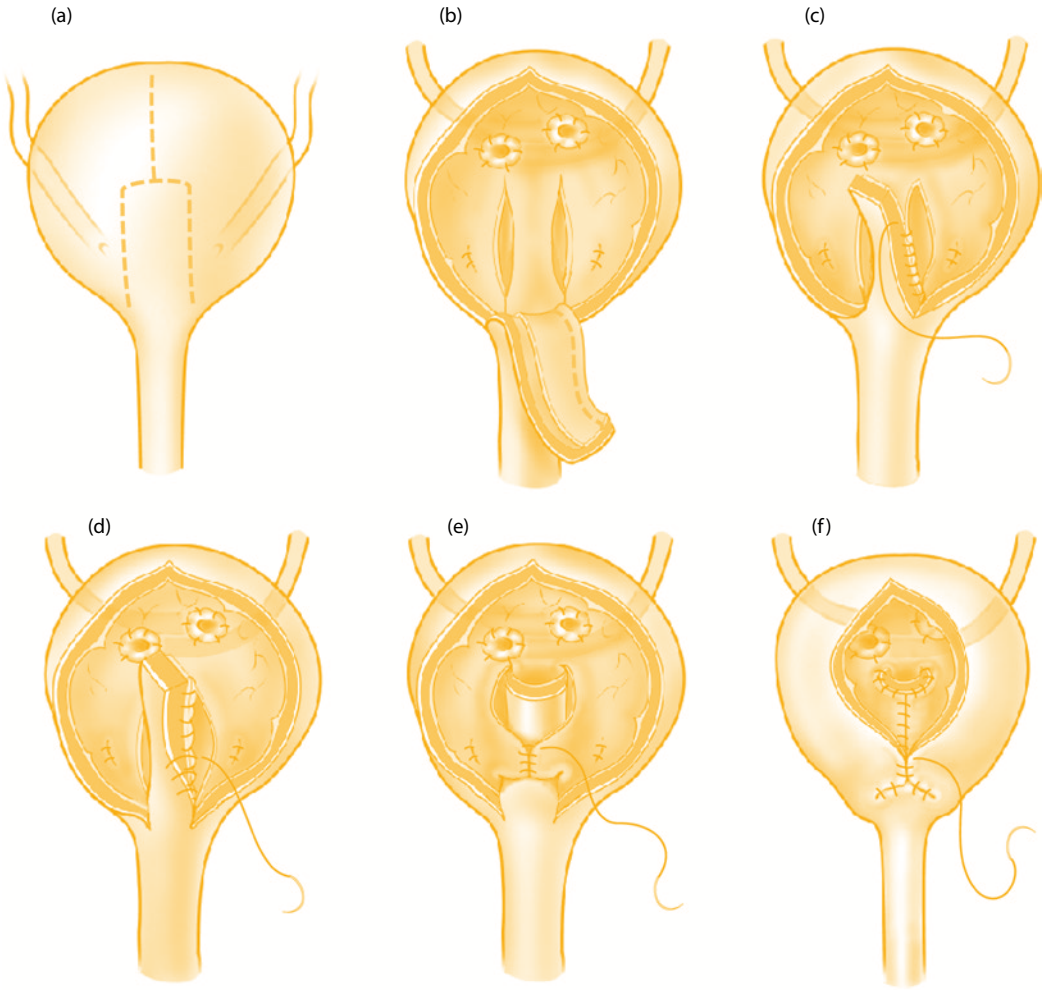

FIGURE 56.21 Pippi Salle creates a neourethra from an anterior and a posterior strip of bladder neck and bladder. The two are sewn together, but only the anterior flap is mobilized completely. The posterior flap is isolated but not mobilized from the posterior bladder wall. The neourethra is then covered with mucosa and some muscle, which is mobilized on each side. (a) An anterior bladder flap is mobilized. (b) A posterior bladder mucosal flap is mobilized. (c) The mucosas of the anterior and posterior flaps are sewn together. (d) The muscles of the flaps are sewn together. (e and f) The bladder mucosa is closed over the neourethra.

epispadias and some with exstrophy have better detrusor function as a group and have the best potential to void.

If the goals of surgery are to have the patient dry and voiding, the artificial sphincter would seem the best choice, followed by the YDL procedure or variations. If the surgical goals are to have the patient dry and to catheterize through the bladder neck and urethra, the Pippi Salle repair or the artificial sphincter allows continence with easy catheterization in most cases. If the goals are to have the patient dry and the bladder neck and urethra are not important for voiding or catheterization because a continent stoma is available, then the Kropp repair and a bladder neck closure are good options.

Another measure of success that has been used to judge bladder neck surgery is the need for bladder augmentation to achieve continence. On the surface, it would seem that the YDL procedure and its variations and the Tanagho procedures are superior because series of these procedures report augmentation rates of 0%–40%. This compares with Kropp's reported augmentation rate of 78%, bladder neck closure of 61%–80%, and Pippi Salle repair rates of 80%. Closer inspections of the series reveal that the patient groups are not comparable. Studies with the lowest augmentation rates (15%–20%) are consistently made up of mostly epispadias, exstrophy, and urogenital sinus patients, whereas the series with high augmentation rates (70%–90%) usually include a significant number of neuropathic bladders. The need for augmentation is much more a function of the underlying condition and the pathophysiology of the detrusor rather than a result of bladder outlet incompetence or corrective surgery.

CONCLUSIONS AND RECOMMENDATIONS

Patients found to have incontinence due to bladder outlet incompetence as demonstrated by leak point pressures, cystograms, or cystoscopic examinations should always be treated with all available medical options needed to improve continence. CIC, anticholinergic medication, α-adrenergic medications, control of constipation, and

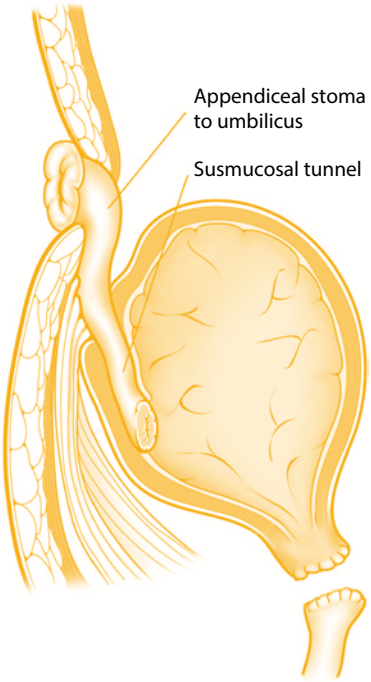

FIGURE 56.22 Mitrofanoff used a continent catheterizable stoma to empty the bladder. By implanting the appendix into the bladder in a continent manner, he allowed efficient bladder emptying without relying on the urethra. This allowed him to close the bladder neck surgically, leaving the appendix as the only access with which to empty the bladder.

control of infection should be utilized. If these methods fail and the patient and family have the sufficient motivation and understanding of what continence procedures require, then the urologist may explore the surgical options.

The patient and family should have a vital role in the decision-making process, and they must understand the consequences of having surgery to increase leak point pressure. The surgeon makes a profound change in the physiology of the urinary tract and, in doing so, depends on the patient and family to perform the management required by this change. Whether it is performing intermittent catheterization, emptying the bladder on schedule with an artificial sphincter, or taking medication, the success of the surgery and the health of the child depend on their willingness and ability to comply.

Once the child, family, and surgeon agree to perform a procedure to increase resistance at the bladder neck, there are many good options. The choice of procedure depends on the goals of surgery and the particular surgeon's preferences. It is important to approach each patient individually. Children with incontinence that requires surgical management are often complex cases, with other health and social concerns. In general, however, we can look at the underlying pathology and goals of surgery and recommend procedures that are good management options.

If the child can void to completion prior to surgery and has a condition that may allow long-term voiding, then the artificial sphincter or the YDL procedure is a good option. The conditions that leave children with relatively isolated bladder outlet incompetence and adequate detrusor function include epispadias, bilateral ectopic ureters,

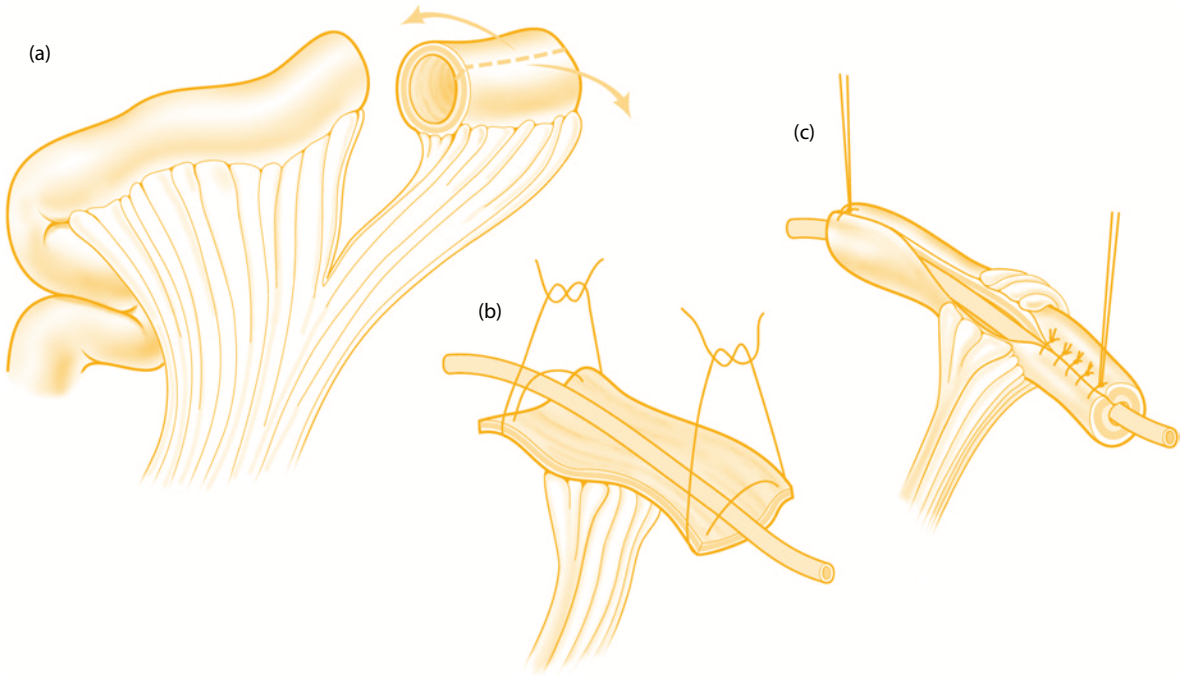

FIGURE 56.23 Monti popularized a concept originally described by Yang, who created a catheterizable tube from small bowel. (a) A 3–4 cm section of bowel is isolated on its mesentery and split on the antimesenteric border. (b) It is then closed along the transverse axis, 90° from the original. (c) This doubles the length of tube produced from a piece of bowel. The tube may then be implanted into the bladder for continent catheterizable access.

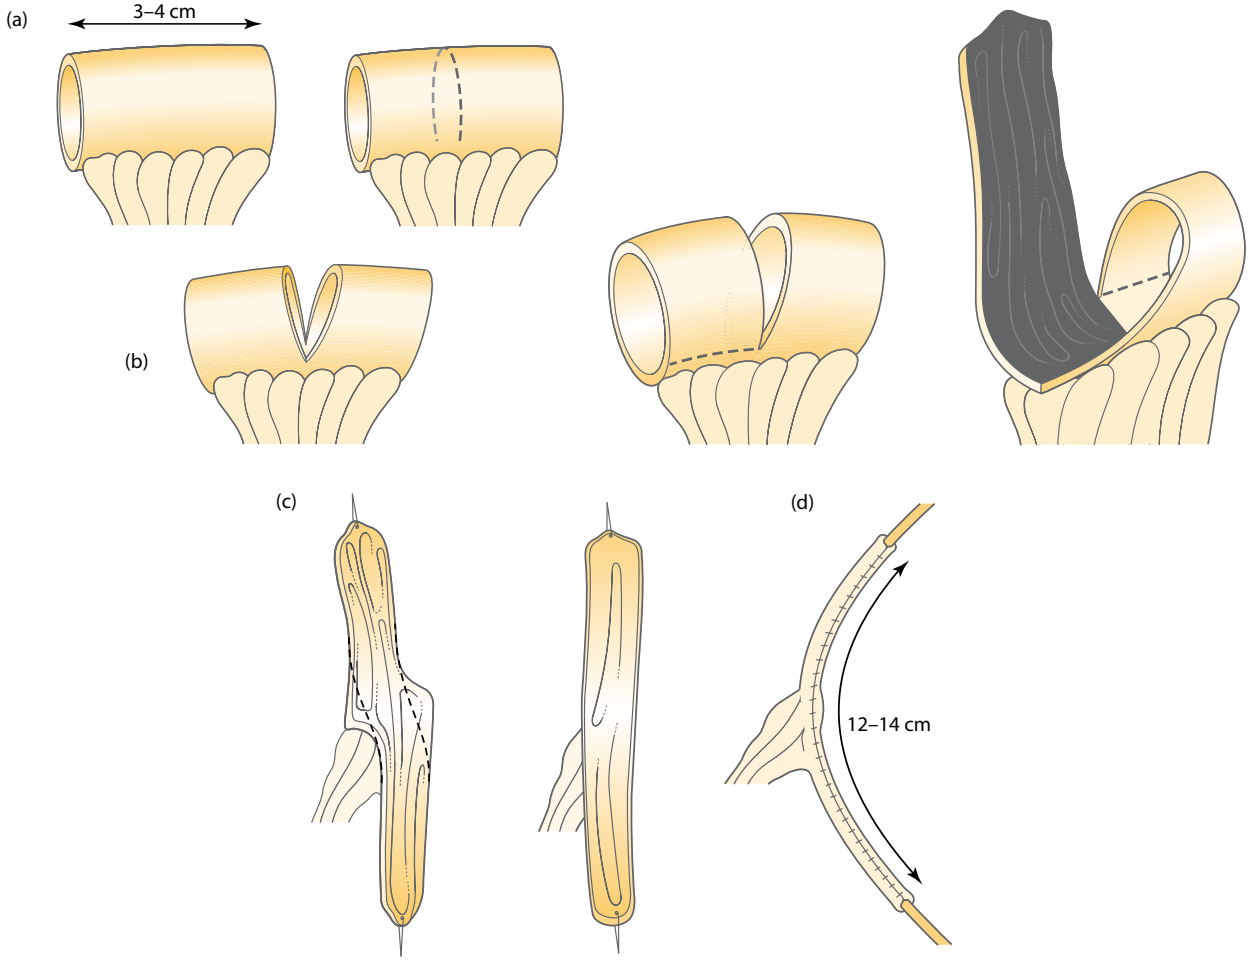

FIGURE 56.24 Casale presented a variation of the reconfigured ileal tube. (a) A 3–4 cm section of ileum is partially split into two rings, leaving the bowel over the mesentery intact. (b) The two rings are then split on opposite sides, allowing the bowel to be unfolded into a much longer flap. (c) Corners of bowel along the mesentery are trimmed off to make the strip uniform in width before it is tubularized. (d) The longer tube allows more flexibility in placement of the anastomosis, mesentery, and stoma.

some surgical injuries to the bladder neck, and urogenital sinus anomalies. As a rule, artificial sphincters should not be used if there has been prior bladder neck reconstruction, such as in exstrophy closure, because of the risk of erosion. The rare child with pure stress incontinence may be treated with suspension of the bladder outlet using any of the procedures used in adult stress incontinence, such as the McGuire or Raz procedures. Slings may be used in children who void, but they should be applied loosely.

Patients with exstrophy are still treated with the YDL procedure or one of the variations. New urodynamic data suggest that procedures such as the YDL procedure, which surgically alter the trigone, may lead to worsening of detrusor function. Kaefer et al.[138] studied epispadias patients and Diamond et al.[139] reviewed exstrophy patients before and after bladder neck surgery, and both studies showed that most patients suffer a deterioration of filling and voiding dynamics. Most bladders developed high pressures, increased contractility, and diminished capacity, whereas some bladders increased in size and developed poor contractility. Only 25% of 30 exstrophy patients maintained normal detrusor function after their bladder outlet resistance was surgically increased. We have yet to determine whether the detrusor functional changes observed are the result of surgical trauma to the bladder or increased demands on the bladder to retain urine and cycle, or are predetermined by different levels of dysfunction inherent in each exstrophy bladder.

The newest development in exstrophy surgery is to perform the entire repair, including closure, bladder neck reconfiguration, and urethroplasty, as a single procedure in the newborn period.[140] Multiple reports have shown that while complete primary repair of exstrophy can be successful, many patients need additional bladder neck reconstruction to attain continence, and there are potential complications that are less common in staged repairs in some surgeon's hands.[141]

At the time of bladder neck repair, it has been our practice to add a continent umbilical urinary stoma.[142,143] This allows the child to void per urethra and also offers easy access to check residual urine or to perform intermittent catheterization without violating the repaired bladder outlet if the child cannot void adequately. We believe that the surgeon should elevate and suspend the bladder neck and urethra at the same time as a bladder outlet reconfiguration, such as the YDL procedure, is performed.

In patients who cannot void adequately prior to surgery and who have poor potential for good detrusor function,

there are more options. These children, for the most part, have neuropathic bladders from myelodysplasia or other neurologic conditions. They will be dependent on CIC to empty the bladder. In girls, the fascial sling has become the treatment of choice because of its simplicity and reliability. In boys, there are many options, but we currently use the YDL, Pippi Salle, or Kropp procedures. If the plan calls for intermittent catheterization through the repaired bladder neck in a boy, the Pippi Salle procedure is preferred because it is easy to catheterize. At this time, almost all patients have the simultaneous creation of a continent catheterizable abdominal stoma. This allows easy access to the bladder, and there is no need to worry about routine catheterization or catheter trauma to the repaired bladder outlet.

The majority of children with neuropathic incontinence at the bladder outlet also have bladders with limited detrusor function and storage capacity. Most children today undergo a simultaneous augmentation cystoplasty to create a large, low-pressure storage reservoir. There is no question that augmentation alone will improve continence in this patient population even if the bladder outlet is weak.[144] In our experience, augmentation alone has not provided reliable continence even in patients with reasonable bladder outlet resistance. For this reason, we believe that in most cases of reconstruction for incontinence, the surgeon should maximize both bladder outlet resistance and the storage capacity of the bladder.

In writing the second revision of this chapter, I again am impressed by the change in emphasis on surgical treatment of severe anatomic and neuropathic incontinence. Many factors are at work here, including years of less than perfect results and a drop in the number of new patients with these conditions due to in utero diagnosis and termination, along with the effects of folic acid supplements. It is also a fact that pediatric urologists do less open surgery, especially around the bladder, and our residents and fellows have less experience in training.

New work in this field is directed toward less aggressive surgical intervention, such as slings, wraps, and injection therapy. There have been few advances in the area of major bladder outlet reconstruction in the past 8 years, and if anything, this surgery has become less radical, as in the modifications of the YDL procedure.

Procedures to improve resistance at the incompetent bladder outlet have been advanced greatly by the development of associated procedures, such as bladder augmentation over the past 25 years. Two singular contributions in this field came from Lapides, with his concept of CIC, and Mitrofanoff, whose novel idea to create a continent catheterizable stoma allowed a nonurethral method of bladder emptying. Finally, the predictors of success in bladder outlet reconstruction remain unchanged despite any new advances. They are sufficient resistance at the bladder outlet, a low-pressure reservoir of adequate size, and a reliable means to empty the bladder efficiently.

CHAPTER 57

Bladder Augmentation: Current and Future Techniques

Bradley P. Kropp, Dominic Frimberger, and Earl Y. Cheng

INTRODUCTION

The surgical management of the child with a neuropathic bladder can be a formidable task, but major advances in surgical technique have been made in recent decades. The ability to augment the capacity of the bladder with a piece of reconfigured bowel, in conjunction with clean intermittent catheterization (CIC), has dramatically altered our ability to form a compliant urinary reservoir that protects the integrity of the upper urinary tract and promotes urinary continence. Conventional enterocystoplasty uses detubularized segments of small or large bowel. Despite the functional success of intestinocystoplasty, clinical experience has demonstrated that numerous complications can result from the incorporation of small and large bowel and their associated heterotopic epithelium into the urinary tract. To avoid some of these deleterious side effects of the use of bowel for bladder augmentation, several procedures have now been developed to augment the bladder without the use of bowel, including gastrocystoplasty, autoaugmentation, seromuscular enterocystoplasty, and ureterocystoplasty. In addition, recent advances in tissue engineering techniques have increased the possibility of regenerating new bladder tissue that is clinically useful for augmentation purposes. This chapter reviews the relevant surgical anatomy and physiology, advantages and disadvantages, surgical techniques, and clinical results of conventional enterocystoplasty and each of the alternative procedures that avoid the use of bowel. These are summarized in Table 57.1. Since the care of the child with a neuropathic bladder can be complex and requires individualization that is dependent on the desires of the patient and family, familiarity with each of these procedures is extremely important for the pediatric urologist when considering augmentation cystoplasty.

Many different surgical techniques have been developed over the years by many dedicated surgeons aiming to increase the health and life quality of their patients. Not every technique is suitable for every patient, and careful selection is necessary to avoid failure and reoperations, frustrating for patients, families, and surgeons alike. Every new approach aims to minimize complications of previous techniques while improving or at least achieving the same functional outcome. In order to avoid complications, conservative and minimal invasive therapies have been developed with mixed results. However, bladder augmentation using intestinal segments, with all its problems, still has the most durable long-term functional outcomes and possibly satisfaction rates. The authors of this chapter recommend careful study of the various described procedures in order to allow the surgeon to choose the best-fitting procedure for an individual patient.

INDICATIONS AND PREOPERATIVE ASSESSMENT

Enterocystoplasty is performed when there is a need to enlarge and/or decrease the storage pressure in the native bladder, when the native bladder becomes an inadequate reservoir owing to abnormal bladder wall dynamics. This can result from a host of conditions, including spina bifida, spinal cord trauma, posterior urethral valves (PUVs), dysfunctional voiding, radiation, and infectious or other chronic inflammatory processes. Wiener et al. reported that 3403 patients with spina bifida received enterocystoplasty between 1998 and 2005. During that same time period, 772 ileal loop diversions were performed in spina bifida patients. Their data demonstrated that younger male patients with private insurance were more likely to have an enterocystoplasty than urinary diversion.[1] Enterocystoplasty is intended to relieve high-pressure and low-capacity characteristics. There are two major indications for enterocystoplasty. The first is the presence or risk of upper tract deterioration secondary to a poorly compliant bladder. The second indication is when the bladder is a causative factor in urinary incontinence. All patients who are being considered for enterocystoplasty should be thoroughly studied with preoperative urodynamics and initially treated by medical alternatives, such as anticholinergic medications and/or intermittent catheterization. It is extremely important that patients understand that, in most instances, enterocystoplasty will not result in normal voiding and a lifelong commitment to intermittent catheterization will be required.[2]

Lapides's landmark studies in the early 1970s, demonstrating that intermittent catheterization can be performed safely and effectively in children,[3,4] have had the

TABLE 57.1 Advantages and disadvantages of procedures for bladder augmentation

Procedure	Advantages	Disadvantages
Intestinocystoplasty	Extremely compliant tissue Availability of tissue Proven long-term clinical efficacy	Heterotopic epithelium Mucus Infections Stones Hyperchloremic metabolic acidosis Malignant transformation Spontaneous rupture
Gastrocystoplasty	Moderately compliant tissue Easily definable submucosal plane for reimplantation Minimal mucus and stone formation Acid buffering in renal insufficiency patients	Hematuria dysuria Hypochloremic hypokalemic metabolic alkalosis
Autoaugmentation	Preservation of native urothelium Avoids bowel Technically less demanding procedure Extraperitoneal procedure Does not preclude future conventional enterocystoplasty	Inability to predict success preoperatively
Seromuscular enterocystoplasty	Preservation of native urothelium Muscle-backed mucosa	Technically more demanding procedure Factors that predict success preoperatively not well defined
Ureterocystoplasty	Preservation of native urothelium Muscle-backed mucosa Compliant tissue Avoids bowel	Limited patient population Large surgical incisions

single greatest impact on the ability to perform enterocystoplasties in children. If a patient is not dedicated to performing lifelong intermittent catheterization, then a noncontinent form of urinary diversion should be chosen instead of enterocystoplasty.

The goals of enterocystoplasty are to change the native bladder environment by reducing storage pressure and increasing volume. A thorough preoperative evaluation will help to determine which type of augmentation is most appropriate and beneficial for each child. Major factors that must be addressed before proceeding with enterocystoplasty include (1) assessment of renal function, (2) absence or presence of reflux and/or ureteral dilatation, (3) determination of outlet resistance, (4) history of bowel dysfunction, (5) need for a continent catheterizable stoma, (6) physical and mental capacity to perform intermittent catheterization, and (7) previous urinary diversion. Since there is currently no perfect bladder augmentation applicable to all children, all the above factors must be considered in order to make the most suitable and best choice for the patient and his or her family.

Renal Function

Renal function can be assessed by measurement of serum creatinine, using one of several methods to calculate estimated creatinine clearance; 24-hour urine collection; or estimation of the glomerular filtration rate via a radioisotope renal scan. The authors prefer to obtain a serum creatinine and nuclear renal scan before any type of bladder augmentation if the renal ultrasound is abnormal. The information obtained from this assessment may make one segment of bowel or an alternative procedure more attractive or appropriate than others. For example, in a patient with chronic renal insufficiency, a gastrocystoplasty is often a better choice than intestinocystoplasty because fewer urinary wastes are absorbed and electrolyte disturbances, such as metabolic acidosis, are reduced.

Reflux and Ureteral Dilatation

The presence of reflux and/or massive ureteral dilatation is an important preoperative determinant. When massive ureteral reflux is present, the exact bladder capacity and compliance may be difficult to assess. Occlusion of the ureteral orifices with balloon catheters can be helpful in assessing these parameters. An anesthetic is usually required to place these catheters. Although this technique has been reported, the authors have not found this procedure to be very helpful and therefore rarely perform it.

Reflux has been reported to resolve spontaneously after enterocystoplasty.[5–8] Antireflux surgery should be considered at the time of reconstruction, especially if reflux occurs at low intravesical pressures. In patients who have low- to moderate-grade reflux in association with high intravesical pressures and poor bladder compliance, enterocystoplasty alone, without ureteral reimplantation, can be considered, as the reflux tends to resolve with reduction of intravesical pressure. Recently, endoscopic subureteric injection with dextranomer/hyaluronic acid copolymer has been shown to correct reflux with a high degree of success. Thus, in cases of mild to moderate reflux that occurs at elevated pressures, the authors are more likely to proceed with augmentation without concomitant open reimplant surgery. If the reflux does not

resolve after augmentation, then endoscopic correction can be performed. Alternatively, endoscopic correction can be considered at the time of augmentation, especially in cases where concomitant bladder neck procedures that may limit endoscopic access are being performed.

In patients where there is ureteral dilatation in the absence of reflux, a very low-pressure reservoir must be constructed so that adynamic ureters can propel the urine into the bladder. Although not well documented in the literature, clinical experience strongly suggests that dilated ureters with walls that do not coapt are not capable of generating a peristaltic wave of greater than 40 cmH_2O. Thus, dilated ureters are likely to require very low intravesical pressures, well below 40 cmH_2O, for proper efflux of urine into the bladder.

Preoperative assessment of native bladder wall dynamics can be extremely difficult in patients who have a neuropathic bladder with an open bladder neck and low outlet resistance. In these patients who leak from an empty bladder, cyclical filling and distension of the bladder do not occur. The bladder has not been stretched under physiologic conditions. When performing preoperative urodynamics in these patients, a balloon catheter can be snugged down into the bladder neck to prevent leakage and bladder capacity, and compliance can be evaluated. This technique has been reported to be a good predictor of the need for future augmentation.[9] However, Kronner et al.[10] demonstrated that preoperative urodynamics in such patients do not necessarily correlate well with eventual bladder outcome. They concluded that preoperative assessment of bladder capacity and compliance could not reliably predict which patients would eventually require enterocystoplasty after outlet resistance had been increased. Since preoperative urodynamics do not appear to be accurate in patients with an open bladder neck, the decision to perform an enterocystoplasty in conjunction with a bladder neck procedure should be based on preoperative discussions regarding the risks and benefits of immediate versus delayed enterocystoplasty.

Previous Urinary Diversion

As with patients with low outlet resistance, those with a defunctionalized bladder secondary to previous urinary diversion who are being considered for undiversion or transplantation are also difficult to assess preoperatively with regard to the need for bladder augmentation. In patients with a vesicostomy, urodynamics can be performed by occluding the vesicostomy with the balloon from the urodynamic catheter. For the same reasons previously described for patients with a poor outlet, interpretation of these urodynamic findings and assessment of their significance may be difficult. In PUV patients who have previously had urinary diversion and subsequently undergo renal transplantation, there are good data showing that the native bladders reexpand and regain function irrespective of preoperative urodynamic findings.[11–13] Currently, there are few data on outcomes in patients with neuropathic bladders associated with spina bifida after primary closure or undiversion without enterocystoplasty.

In the defunctionalized bladder not associated with spina bifida, some authors feel that bladder cycling may help to determine whether a bladder is adequate for closure without augmentation.[12,13] A gastrotomy button placed in the vesicostomy to facilitate bladder cycling can be used in these patients.[14] The authors' experience has been that preoperative bladder cycling can be helpful in some patients, at least in increasing bladder capacity. However, urodynamic results remain difficult to interpret in many. In general, we favor undiversion without augmentation when there is doubt as to whether augmentation will be required. Secondary enterocystoplasty can always be performed in patients in whom the bladder does not eventually attain adequate bladder compliance and capacity following undiversion or transplantation. It should be emphasized that this approach is only recommended for patients with a defunctionalized bladder not associated with spina bifida, since such patients usually do poorly following vesicostomy closure. Reliable follow-up also needs to be ensured in all patients following undiversion.

Bowel Function

A thorough evaluation of bowel function, including a history of constipation or diarrhea, must be carried out prior to enterocystoplasty. Postoperative bowel dysfunction can occur in up to 50% of patients who have undergone enterocystoplasty.[15] In addition, King[16] found that removal of the ileocecal segment in children with spina bifida causes severe diarrhea in approximately 10% of patients. However, in a more recent series of 63 patients who underwent ileal cecal cystoplasty, bowel complication was found to be only 3%.[17] Nevertheless, before undertaking any type of urinary reconstruction that involves the use of a bowel segment, discussion with the patient and family should include potential gastrointestinal complications. The type of augmentation should be chosen with these potential complications in mind.

Ability to Catheterize

Since most patients who undergo enterocystoplasty will not be able to void completely and will require lifelong intermittent catheterization, one should consider the formation of a catheterizable stoma at the time of the augmentation. This is especially important in patients who are sensate or are in wheelchairs. Clinical experience has shown that when both the native urethra and a catheterizable stoma are present, the majority of patients will choose to use the catheterizable stoma. In addition, assessment of the physical and mental capacities of the patient and family must be undertaken to make sure that they will be able to perform intermittent catheterization on a regular schedule.

Families want to believe that their child will become continent after enterocystoplasty and that the kidneys will be protected. However, the amount of time and effort that will be required is often not appreciated preoperatively. Therefore, all must understand the risks and benefits of enterocystoplasty prior to surgery and the lifelong commitment to a relatively rigorous schedule of intermittent catheterization. Since there are many potential problems associated with failure to catheterize, including spontaneous bladder rupture and death, urinary reconstruction

should be deferred until the patient has the physical and mental maturity needed to care for himself or herself.

Alternative Therapies

Botulinum Toxin

The intravesical injection of botulinum toxin (Botox) is a good temporary measure to enhance bladder capacity and decrease intravesical pressures.[18] Botox is injected into the detrusor muscle endoscopically using a cystoscope under anesthesia. It is generally very well tolerated, and the effects last for several months. The procedure is, however, not Food and Drug Administration (FDA) approved. Botox injection can be repeated safely, but due to its temporary effect, it is not a final measure and will possibly require additional procedures later.[19]

Transurethral Electrical Bladder Stimulation

The technique begins with detailed bladder capacity measurements, followed by refilling the bladder via an electrocatheter. Various electric parameters, such as intensity of current and frequency, can be adjusted to the individual patient. Bladder stimulation therapy will provide volitional voiding in less than 10% of patients but can be an effective form of treatment for up to 60% of patients. The beneficial effects are generally permanent, but the therapy is very labor-intensive and requires a very dedicated family.[20]

Sacral Neuromodulation

Sacral neuromodulation (InterStim) can improve bladder function either by consistent stimulation of the efferent fibers of the sacral nerve roots or by providing rhythmic contractions of the pelvic floor.[21] The device consists of a pacemaker, placed in the area of the buttocks, and a neurostimulator lead that is tunneled under the skin to electrically stimulate the S3 nerve root. A prospective, randomized study enrolled 42 patients with spina bifida and compared urodynamic outcomes and incontinence. The implanted group demonstrated significantly improved leak point pressures.[22] Further studies will be necessary to evaluate the true advantage for patients with spina bifida.

Xiao Procedure

The Xiao procedure is a neurosurgical technique in which a new neuronal loop is created unilaterally between the ventral roots of L5 and S3. The originators of this method first reported their successes in spinal cord–injured adults, showing that via percutaneous electrical stimulation or scratching of a skin dermatome, a detrusor contraction could be initiated with promising results in increased bladder control.[23,24] A study in the spina bifida population of 20 children demonstrated 17 (85%) with increased bladder storage capacity and emptying functions. This included the ability to sense fullness and to initiate bladder emptying with L5 dermatome stimulation and eventually achieving dryness after 6 months. However, 5 of the 17 children with bladder success also had signs of partial loss of L5 motor function. In the three patients who had no improvement, two were noted to have significant scarring in the spinal canal due to their previous surgeries, and therefore had inadequate neural rootlet identification.[25] In 2010, Peters et al. published their 1 year results in the first U.S. trial on nine patients. Most patients had an improvement in bowel function, but none achieved complete urinary continence. Two patients could stop CIC, and antimuscarin medication was safely stopped in all. Temporary weakness of lower extremity muscle groups occurred in 89%, and one child had persistent foot drop. The authors concluded that more patients with longer follow-up are needed before the procedure can be universally recommended.[26] To our knowledge, only two centers in the United States, one in Detroit and one in Tampa, are currently offering the procedure.

Bladder Neck Procedures

The bladder neck can either be competent or have little resistance, requiring a bladder neck procedure to avoid postoperative urine leakage. Bladder neck procedures aim to tighten the bladder outlet either by creating a muscular channel or by placing a sling to tighten and elevate the bladder neck region. Both procedures create a controlled obstruction to prevent urine flow under low pressures but allow urine leakage if the intravesical pressures become too high. Since most patients do not have an adequate native bladder, providing them with a sufficient, low-pressure-reservoir simultaneous bladder augmentation is often necessary. However, Snodgrass and Barber reported the possibility of performing a bladder neck procedure without augmentation.[27] The group observed that in their patients, the bladder usually will eventually gain enough compliance to prevent unsafe intravesical pressures that could harm the upper tracts. As with all major congenital conditions, various management protocols exist and are defended by their proponents compassionately. These controversies and educated discussions are highly desirable since they spark more research and advance the field.

INTESTINOCYSTOPLASTY

Small Bowel

Currently, ileum is the most commonly used bowel segment for enterocystoplasty. The abundant supply of small bowel, easy workability, mobility, reliable blood supply, and compliance of the reconfigured ileum have led most reconstructive surgeons to choose ileum over other bowel segments. Although the jejunum can be used for urinary reconstruction, the high incidence of metabolic complications (hyponatremic, hypochloremic, and hyperkalemic acidosis) associated with use of this segment makes it less desirable, and thus it is rarely used. The major contraindications to the use of ileum are a history of short gut syndrome, inflammatory bowel disease, pelvic and/or abdominal radiation, and significant renal insufficiency. Under these conditions, alternative segments, such as the stomach, are more appropriate.

Anatomy and Physiology

The proximal two-fifths of the small bowel proper is jejunum, and the distal three-fifths is ileum. The coils of the midileum usually lie in the pelvis, while the terminal 30 cm of the ileum, the most commonly used portion for

enterocystoplasty, usually rises out of the pelvis to lie in close relationship to the cecum and the ascending colon.

The mesentery of the small bowel attaches to the posterior abdominal wall. The "root" of the small bowel mesentery runs obliquely across the abdomen. As the root of the mesentery runs obliquely from left to right, it crosses, in order, the abdominal aorta, the vertebral column, and the third portion of the duodenum. The midportion of the small bowel has the longest mesentery, whereas the segments of the small bowel closest to the cecum and the duodenojejunal flexure have the shortest. Therefore, in patients in whom the mesentery is short, a segment of ileum 30 cm or more above the ileocecal valve will be the most mobile and will reach the furthest into the pelvis.

The arterial supply to the entire small bowel is derived from the superior mesenteric artery (Figure 57.1). There are usually 12–16 branches of the superior mesenteric artery running to the jejunum and ileum and entering the small bowel at its mesenteric border. The ileocolic artery is the most distal segment of this vessel. It is found in the right lower abdominal quadrant, where it gives off branches that supply the terminal ileum, the cecum and appendix, and the proximal ascending colon. Venous drainage of the small bowel occurs through multiple mesenteric channels that coalesce to form the superior mesenteric vein. It is this abundant and redundant blood supply that makes the use of different segments of ileum available for urinary reconstruction.

The small intestine is innervated from the autonomic plexuses grouped around the "takeoff" of the superior mesenteric artery from the aorta. These plexuses include preganglionic parasympathetic nerves from the vagus, as well as postganglionic sympathetic fibers from the celiac plexus. The submucosa of the small intestine contains the nerve plexus of Meissner. Between the longitudinal and circular muscle of the small bowel is the intramuscular myenteric (Auerbach's) plexus, consisting of nonmyelinated nerve fiber plus numerous ganglion cells.

The bowel wall is made up of an outer serosal coat, two layers of muscle (outer longitudinal smooth muscle and inner circular smooth muscle), a submucosal layer, and a mucous membrane composed of a single layer of columnar epithelial cells. Since the muscle and epithelial layers are relatively thin, the plane between these layers is difficult to establish surgically; therefore, tunneling procedures for ureters and catheterizable stomas may be quite difficult in the small bowel.

The physiology of the small and large intestine involves an intricate balance of water and electrolyte shifts. The major mechanisms of intestinal transport of water and electrolytes are illustrated in Figure 57.2. Water and electrolyte movement varies throughout the length of the bowel. These changes can be accounted for by both structural and functional differences between the small and large bowel. The major structural difference between the small and large bowel involves the "tight" junctions that join the epithelial cells (Figure 57.2). These tight junctions have characteristic permeabilities and ionic conductance that form the basis for paracellular ion and water movement.[28] Because such junctions are tightest in the colon and more permeable or leaky in the proximal small bowel, paracellular movement may account for a significant portion of water and electrolyte transport in the small bowel, and not play as important of a role in the colon.

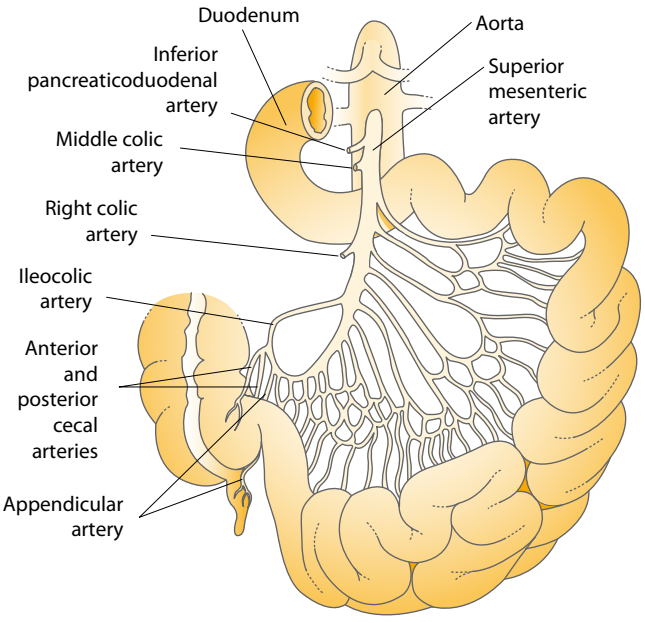

FIGURE 57.1 Arterial blood supply to the small intestine. The portion of the ileum with the longest mesentary that is commonly used for intestinocystoplasty is around 20–30 cm proximal to the ileocecal valve. (Adapted from Lindner H. *Clinical Anatomy*. Norwalk, CT: Appleton and Lange, 1989. With permission.)

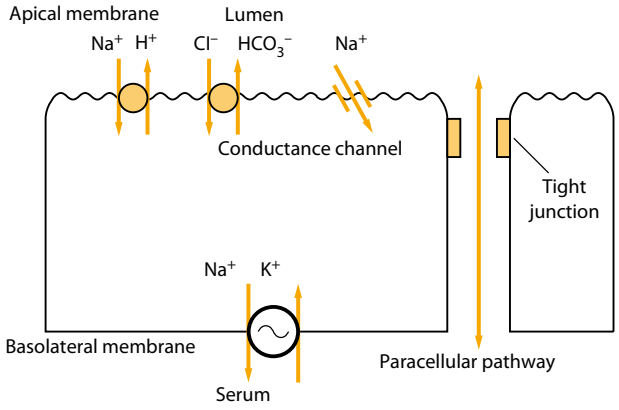

FIGURE 57.2 Intestinal transport mechanisms. Sodium absorption in both the small and large bowel is transcellular and occurs via a Na^+–H^+ exchanger on the apical membrane and a Na^+–K^+ pump on the basolateral membrane. The colon has an additional pathway of entry for Na^+ via conductance channels, which allows for noncoupled sodium absorption. Chloride and bicarbonate transport are coupled, which is pertinent in the development of metabolic acidosis following intestinocystoplasty. Water and electrolyte movement also occurs via paracellular pathways associated with tight junctions between the cells. Paracellular movement occurs more in the ileum than in the colon owing to leakier tight junctions. (Adapted from Lindner H. *Clinical Anatomy*. Norwalk, CT: Appleton and Lange, 1989. With permission.)

Although paracellular movement accounts for some of the bidirectional water and electrolyte transport, most of these shifts are thought to occur via transcellular mechanisms that occur through the intestinal absorptive cell. A characteristic example of the intestinal absorptive mechanism is the Na^+–K^+-ATPase enzyme, which is located on the basolateral membrane. This pump maintains low intracellular sodium concentrations, and thus creates an electrochemical gradient for sodium absorption, as well as passive transport of other electrolytes and water.

Sodium entry in the small bowel is accomplished by way of an Na^+–H^+ countertransport system in the apical membrane. In addition, a significant portion of the sodium entry into the colon also occurs via electrogenic Na^+ conductance channels that allow for noncoupled sodium absorption. The presence of this channel in the colon probably accounts for its ability to transport Na^+ and water against large gradients.

Chloride is absorbed throughout the entire small and large bowel. Bicarbonate is absorbed in large quantities in the jejunum but secreted in the ileum and colon. Chloride absorption in exchange for HCO_3^- secretion plays a large role in the transport of these electrolytes in the ileum and colon. Na^+–H^+ exchange and Cl^-–HCO_3^- exchange occur together. The net result is the electroneutral absorption of Na^+ and Cl^-.

Metabolic acidosis may develop whenever urine is in contact with ileal or colonic mucosa. The mechanism by which this hyperchloremic metabolic acidosis occurs is thought to be directly related to ammonium (NH_4^+) reabsorption that can occur along the entire small and large bowel. It is likely that the inhibitory effect of ammonium on Na^+–H^+ exchange allows ionized ammonium transport where it substitutes for sodium in the Na^+–H^+ exchanger.[29] The result of this ammonium absorption is increased Cl^- absorption in order to maintain electrical neutrality. This leads to hyperchloremia and eventual metabolic acidosis. Although the exact physiologic mechanisms of electrolyte transport continue to be defined, it must be remembered that the major function of the intestine, regarding this transport, does not change when intestine is used for urinary reconstruction. Continued fluid and electrolyte fluxes account for the majority of the physiologic problems associated with the use of intestine in the urinary tract.

Advantages and Disadvantages

Ileum is the most commonly used bowel segment for bladder augmentation. The advantages that are obtained with use of the ileum are (1) large quantity available, (2) ease in handling and reconfiguration, (3) predictable and abundant blood supply, (4) most compliant segment of the bowel, (5) moderate mucus production compared with colon, (6) less severe metabolic complications than the colon or stomach, and (7) fewer gastrointestinal complications than the cecum.

The disadvantages in using ileum include (1) occasional short mesentery that cannot reach the pelvis, (2) possible development of diarrhea and vitamin B_{12} deficiency when the most distal ileum is used, (3) difficulty with creation of submucosal tunnels, and (4) metabolic acidosis, as well as (5) bowel obstruction, (6) stone formation, (7) mucus production, (8) urinary tract infections (UTIs), and (9) tumor formation, all of which are risks with large bowel segments as well. These complications will be discussed later in the chapter.

Large Bowel

Through the early 1980s, the cecum and sigmoid colon were more commonly used than the ileum for enterocystoplasty. However, because of the shorter mesenteries, increased mucus production, and difficulty with configuration associated with the large bowel, the ileum has come to be the preferred segment of bowel for enterocystoplasty for most surgeons. Nevertheless, detubularized large bowel is still used for simple bladder augmentation in select patients.

Anatomy and Physiology

Anatomically, the large bowel can be divided into five sections: (1) the cecum and vermiform appendix, (2) the ascending colon and the hepatic flexure, (3) the transverse colon and mesocolon, (4) the splenic flexure and descending colon, and (5) the sigmoid colon.

The colon is 1.4–1.7 m in length. Its diameter is greatest on the right side, and gradually decreases as it approaches the sigmoid colon. The diameter of the sigmoid colon is often no wider than a loop of terminal ileum. The large bowel is made up of five distinct layers: serosa, muscularis externa, submucosa, muscularis mucosa, and mucosa. The outer serosal coat is a component of the peritoneum and normally completely covers the cecum, the appendix, and the transverse and sigmoid colon segments. The muscularis externa of the large bowel is composed of a complete inner circular and incomplete outer longitudinal layer of smooth muscle. The submucosa is composed of areolar tissue and lies between the muscularis externa and the muscularis mucosa. This layer contains the blood and lymphatic vessels supplying the bowel and is also the most important layer when developing an anastomosic site. The thin muscularis mucosa is made up of circular and longitudinal smooth muscle. The mucosa is composed of a layer of simple columnar epithelium containing goblet cells and is smooth and devoid of villi.

The muscle layers of the colon are notably different from those of the stomach, small intestine, and rectum. Longitudinal smooth muscle covers the large bowel incompletely. The longitudinal fibers are arranged in three narrow but distinct bands called teniae coli. The teniae of the cecum and ascending colon have a constant position relative to the bowel circumference. One band lies on the ventral surface of the colon, while the other two lie medial and lateral to the ventral band. The teniae of the transverse colon are less constant in position. Near the rectosigmoid junction, the teniae become quite indistinct. The unique anatomy of the teniae facilitates reimplantation of the ureters, appendix, and catheterizable stomas to create a reliable flap valve continence mechanism. The deep circular muscular coat of the colon wall is visible between the longitudinal muscle fibers of the teniae. Contractions of the colon produce a pouching or saculations of the bowel between the teniae. These pouchings, or

haustra, are randomly distributed and are easily noted on gross examination and visible on x-ray studies.

Cecum and Vermiform Appendix

The cecum measures approximately 6 cm in length and lies caudal to the entrance of the ileum into the colon. It is the thinnest portion of the colon. The cecum is normally mobile. In more than 90% of individuals, it is completely covered with peritoneum and possesses no mesentery. In some patients, such as children with spina bifida and ventroperitoneal shunts, the cecum can become fused with the posterior abdominal wall. This in turn causes foreshortening of the peritoneal attachments, resulting in the cecum becoming more superiorly located in the right colic gutter.[30]

The terminal 14 cm of ileum, the cecum, the appendix, and the ascending colon are supplied by the ileocolic artery, which is the terminal segment of the superior mesenteric artery. The ileocolic artery ends just proximal to the ileocecal junction and then divides into four major branches. The most superior branch, the colic artery, passes to the ascending colon, anastomosing with the descending branches of the right colic artery initiating the right colic portion of the marginal artery of Drummond or mesenteric arcade (Figure 57.3).

The three bands of teniae coli originate at the base of the appendix. The appendix varies in length from 2 to 20 cm, with an average of 9 cm. In the majority of patients, the appendix is held in position by the posterior inferior ileocecal fold. In about 5% of patients, the mesentery of the appendix runs directly from the posterior peritoneum in the region of the ileocecal junction onto the midportion of the appendix, at which point it is usually joined by the appendicular artery, a branch of the ileocolic artery. The appendicular artery arises either as a branch of the posterior cecal artery or directly from the main ileocolic trunk. It may also arise from the ileal branch of the ileocolic artery. Regardless of its site of origin, the appendicular artery will usually pass dorsal to the most distal segment of the terminal ileum before it enters the mesoappendix.

Ascending Colon and Transverse Colon

The ascending colon occupies most of the right side of the abdominal cavity and extends from the cecum to the hepatic flexure. The blood supply to the ascending colon comes from the colic branches of the ileocolic artery, the right colic artery, and the right branches of the middle colic artery. The right colic artery is the most variable vessel in the colon and is absent in 5%–7% of people. The transverse colon receives blood from the left colic artery; however, the major supplier is the middle colic artery, which is a more direct branch of the superior mesenteric artery.

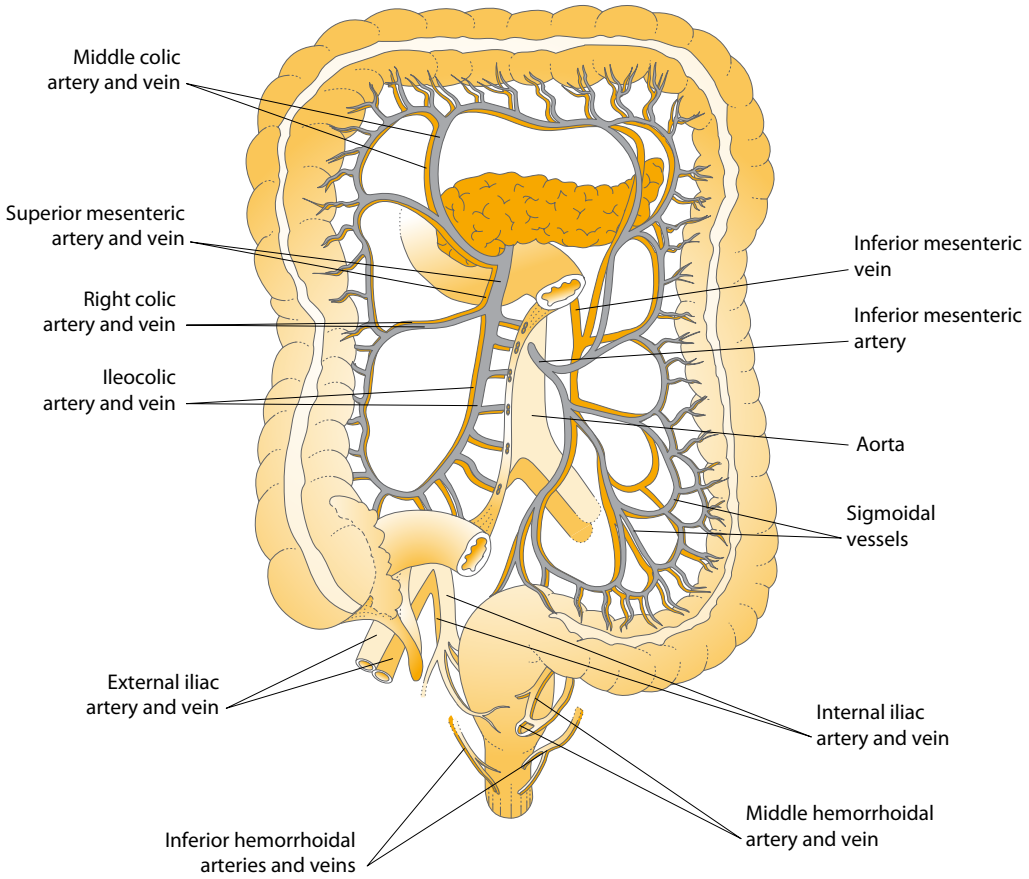

FIGURE 57.3 Arterial blood supply to the large bowel. Preservation of the marginal artery is extremely important when isolating portions of the colon for intestinocystoplasty. (Adapted from Lindner H. *Clinical Anatomy.* Norwalk, CT: Appleton and Lange, 1989. With permission.)

Sigmoid Colon

The sigmoid colon frequently has an S shape, and is divided into a fixed superior and a mobile inferior portion. The fixed portion of the sigmoid colon begins at the level of the iliac crest. The mobile portion of the sigmoid colon begins at the medial border of the left psoas major muscle and ends where it joins the rectum. The length, location of loops, degree of redundancy, relationship to other structures, and mobility of the sigmoid colon are markedly variable. It is very common in the spina bifida population to encounter sigmoid colon so enlarged and redundant that the mobile portion crosses the midline and lies anterior to the cecum.

The inferior mesenteric artery is the major vessel to the left transverse colon, the splenic flexure, the left colon, the sigmoid colon, and the rectum. The left colic artery is the first branch of the inferior mesenteric artery and runs in the direction of the superior half of the descending colon. The ascending branch of the left colic artery runs superiorly and parallel with the left colon, contributing to the marginal artery of Drummond. The descending branch of the left colic artery supplies the fixed segment of the sigmoid. The sigmoid arteries, which are second branches of the inferior mesenteric, supply the lower portion of the descending colon, the sigmoid colon, and a small segment of the upper rectum.

Advantages and Disadvantages

The ileocecal segment and cecum have been used extensively in reconstructive urology. One major advantage of these segments is utilization of the portion of bowel that has the largest diameter, resulting in a capacious and compliant reservoir that often fits the bladder base neatly. It has a well-defined blood supply that is reliable. The modified ileocecal valve can also be used as an antireflux or continence mechanism.

The major disadvantage in using the ileocecal segment is related to the loss of the ileocecal valve in the intestine. Patients with neurologic disorders or short gut may have an increased incidence of diarrhea and difficulty with fecal continence following removal of this segment from the intestinal tract. In addition, it is not available in the cloacal exstrophy population, who have little or no hindgut. The ileocecal segment also reabsorbs urinary wastes, which may result in hyperchloremic acidosis. Finally, cecum usually produces more mucus than the ileum, which can lead to increased infections and stone formation.

The major advantage in using sigmoid colon is the redundancy that is present, especially in the spina bifida population. The mobile portion of the sigmoid is so redundant in such children that it often lies in the right lower quadrant. It can be easily opened and reconfigured into a U shape to increase compliance. The thicker muscle can be used to create an antireflux ureteral anastomosis, as well as for placement of a tunneled continent catheterizable stoma, such as the appendix.

The major disadvantage in using the sigmoid colon is the reduced ability to create a large-capacity, compliant reservoir. The diameter of the sigmoid may be only as large as the ileum. In this circumstance, a segment of colon at least 20–28 cm is required to create an adequately sized reservoir. This amount of sigmoid colon can occasionally be difficult to obtain in the non–spina bifida population. Mucus production from the sigmoid is increased compared with the small bowel. This may increase the potential for the development of UTI and bladder stones. In the Indiana series, the highest spontaneous perforation rate occurred among those with sigmoid cystoplasties.[31] However, this has not been observed in other large series. Finally, hyperchloremic acidosis is more common when the sigmoid colon is used, compared with other bowel segments. Frequently, patients will need lifelong alkalizing agents, but this is also true after cecocystoplasty or ileocystoplasty.[32]

Surgical Technique

The goals of bladder augmentation are to provide a large-capacity, low-pressure urinary reservoir. Hinman[33] and Koff,[34] in particular, have documented the importance of detubularization and reconfiguration of the small and large bowel to facilitate maximum gains in capacity and compliance. Detubularization of bowel segments prevents synchronous contractions of the circular muscle of the gut. Since the radius of the reservoir is directly related to the volume, a greater radius in the augmented bladder translates into a larger low-pressure reservoir. The diameter of the reconfigured bowel segment increases with the number of folds that are incorporated during the reconfiguration (Figure 57.4). Regardless of the bowel segment used

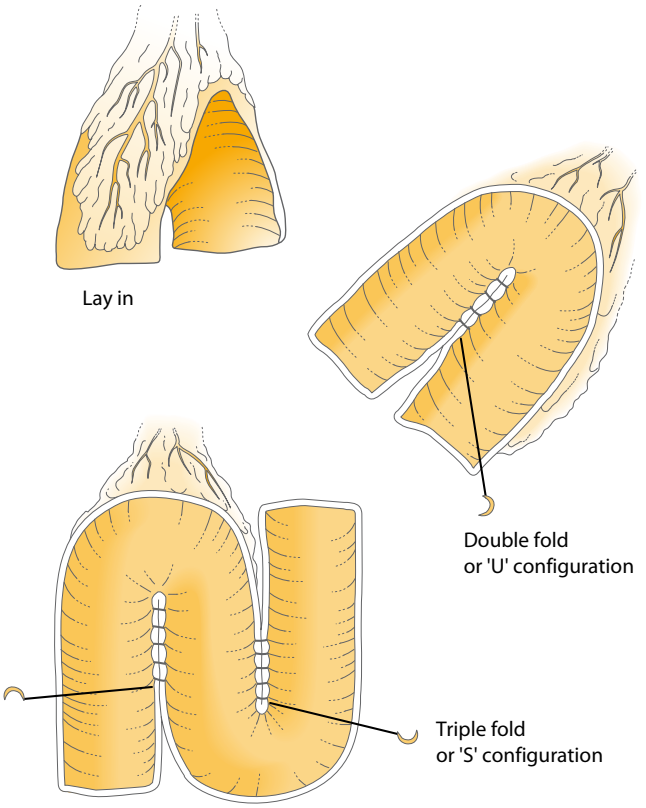

FIGURE 57.4 The detubularized ileum can be reconfigured in numerous ways. Each additional fold increases the potential radius of the augmented bladder. (Adapted from Rink RC, Adams MC. Augmentation cystoplasty. In Walsh PC et al., eds., *Campbell's Urology*, 7th edn., Philadelphia: WB Saunders, 1998, 3167–89. With permission.)

for augmentation, detubularization and reconfiguration should always be employed for both minimally invasive and open techniques, described below.

Ileocystoplasty

Enterocystoplasty is very reliable in lowering storage pressures and expanding the capacity of the noncompliant bladder. Ureteral implantations and procedures to increase outlet resistance can safely be undertaken at the same time. However, not every augmentation is completely successful. This may be related to the bladder having a great tendency to re-form itself, turning the augmentation into a diverticulum with a relatively small opening. To prevent this, the bladder should be bivalved ("clamshelled") from the bladder neck ventrally to the trigone posteriorly. Alternatively, when the bladder is small and thick walled, the "star" modification can be performed (Figure 57.5).[35] The star procedure involves opening the bladder in the sagittal plane. A second incision is then made in the coronal plane. If ureteral reimplantation or bladder neck reconstruction is being performed, the second incision is not made until after these procedures are completed. The authors will also occasionally employ an upside-down U-shaped or Boari flap modification for the initial bladder opening when a catheterizable stoma is being positioned at the umbilicus. In severely diseased bladders from tuberculosis, schistosomiasis, interstitial cystitis, and rarely bladder exstrophy, supratrigonal bladder excision is sometimes necessary, as in neuropathic bladders, when the walls are very thick. Whatever type of bladder opening is used, the goal is the same: to provide a wide bladder plate to which the bowel segment can be sewn, thus preventing a narrow anastomosis or hour-glass deformity that might result in the augmentation becoming a diverticulum.

When using ileum for enterocystoplasty, the segment chosen should be at least 15 cm proximal to the ileocecal valve to prevent vitamin B_{12} malabsorption, diarrhea due to malabsorption of bile salts, and potential injury to the blood supply to the cecum. Guidelines on the length of the ileum required to obtain the appropriate size and shape of the augmentation vary.[34,36] Most commonly, an ileal segment between 20 and 35 cm in length is used. However, a slightly longer segment may be required in an older child or an individual with a severely diseased and contracted bladder.

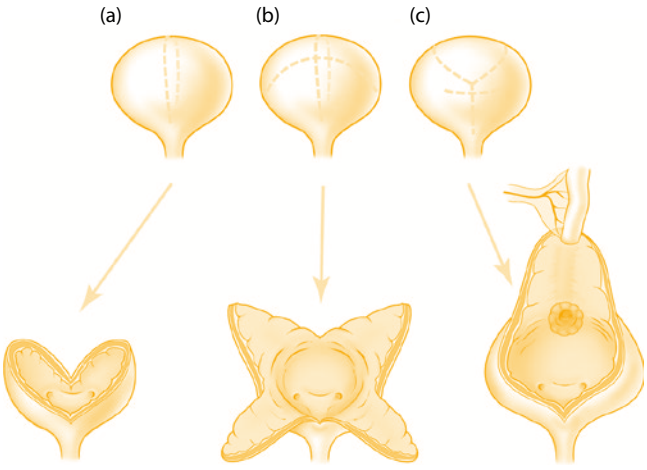

FIGURE 57.5 The native bladder can be opened in several ways: (a) bivalved in a clam-like fashion with full extension of the incision into the bladder neck to prevent an hourglass deformation of the augmented bladder, (b) the star modification, and (c) a U incision to create a flap of bladder that can be used for tunneling when creating a continent catheterizable stoma to the umbilicus.

Prior to harvesting the ileal segment, it is important to ensure that the mesentery reaches well down into the pelvis. Extensive mobilization of the mesentery is sometimes required if it is foreshortened. This is most common in the spina bifida population, often secondary to spinal abnormalities and the intraperitoneal adhesions that occur from the ventriculoperitoneal shunt. Once the appropriate bowel segment has been selected, the bowel is divided between straight clamps. The authors prefer to perform a single-layer hand-sewn ileoileostomy. A two-layer hand-sewn or stapled anastomosis can also be used. Closure of the mesenteric window with interrupted permanent sutures then completes the anastomosis. The isolated ileal segment is detubularized along its antimesenteric border after thorough intraluminal irrigation with normal saline. The ileal segment is then reconfigured into a U, S, or W (Figure 57.6).

After opening the native bladder as described above, the reconfigured bowel segment is anastomosed to the bladder with a full-thickness absorbable suture beginning at the posterior apex of the opened native bladder. Once the posterior aspect of the running, locking anastomosis has been completed, a second running, locking suture beginning at the bladder neck apex is begun and carried along the lateral aspect to meet the previous suture. Before final closure of the anastomosis, a suprapubic tube is brought out through the native bladder wall. After completion of the augmentation, the bladder is inflated and a watertight anastomosis confirmed by irrigation. A Penrose or closed suction drain is usually left in place along the posterior and anterior aspects of the bladder. The bowel is then examined to confirm its integrity, and the abdomen is closed in an anatomic fashion using heavy, running, absorbable sutures.

Ileocecocystoplasty and Cecocystoplasty

The ileocecal segment and cecum have frequently been used for augmentation cystoplasty. The cecum alone is rarely used. Simple detubularization and reconfiguration can be performed. The terminal ileum can be detubularized and incorporated into the cecal segment to increase total volume (Figure 57.7). Continuity of the bowel is reestablished with an end-to-side ileocolostomy. The reconfigured ileocecal segment is then anastomosed to the bivalved bladder with a single or double layer of running, locking, absorbable suture. Alternatively, the terminal ileum can be used for ureteral replacement when the ureters are short or the ileum can be tapered and used as a continent catheterizable stoma.

Sigmoid Cystoplasty

The sigmoid colon easily reaches the bladder and can be used for augmentation cystoplasty. It is especially valuable when reimplantation of ureters or a catheterizable stoma

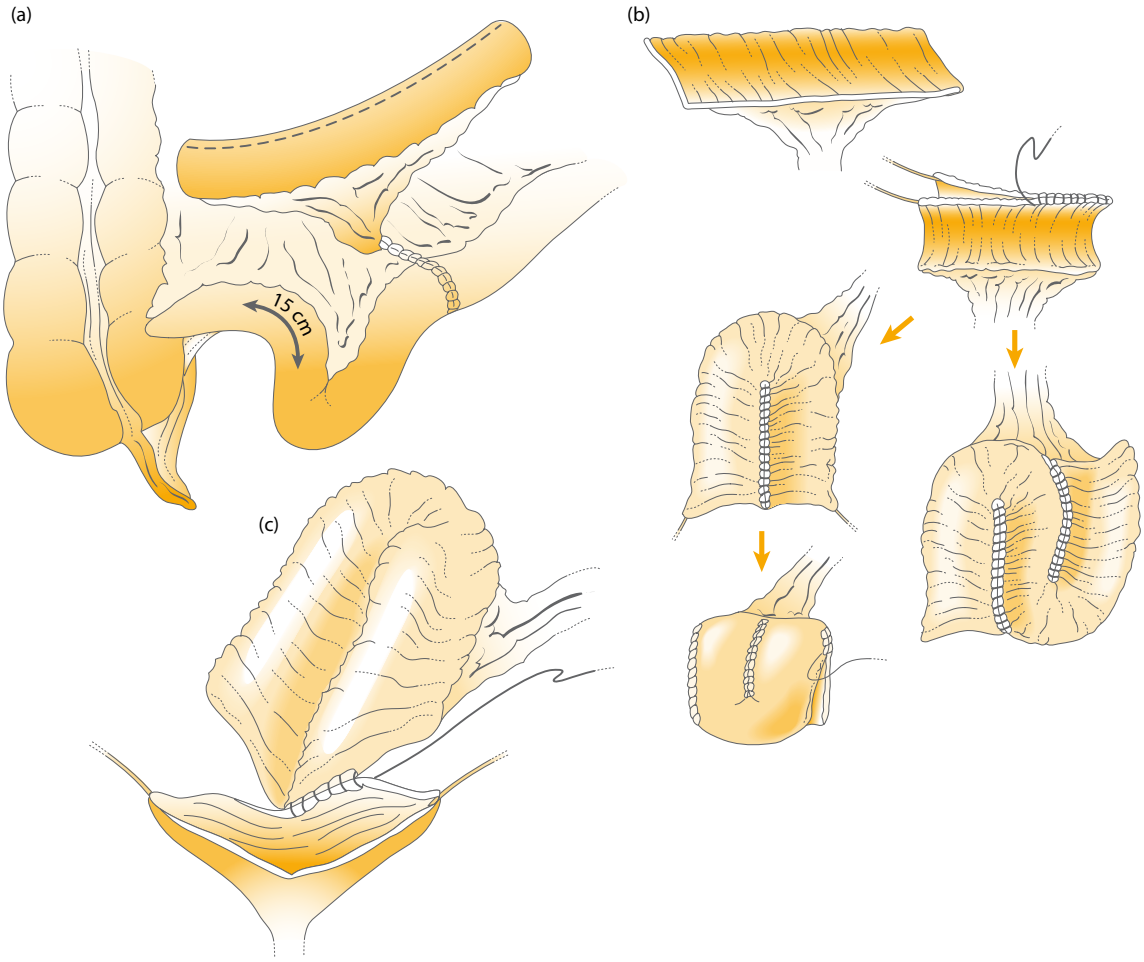

FIGURE 57.6 Ileocystoplasty. (a) A dependent portion of the ileum that is 20–30 cm long and a minimum of 15 cm proximal to the ileocecal valve is isolated and detubularized. Bowel continuity is reestablished with an end-to-end ileoileostomy. (b) Depending on the size of the ileal segment, it can be reconfigured and folded in several ways, including the U, S, and W (not illustrated) configurations. In addition, the edges of the reconfigured bowel can be sewn together to create a cup patch. (c) The anastomosis of the reconfigured bowel to the native bladder begins in the posterior apex of the opened bladder. (Adapted from Rink RC, Adams MC. Augmentation cystoplasty. In Walsh PC et al., eds., *Campbell's Urology*, 7th edn., Philadelphia: WB Saunders, 1998, 3167–89. With permission.)

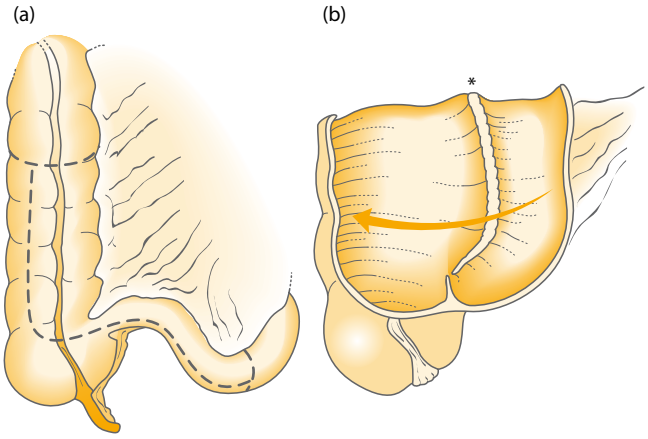

FIGURE 57.7 Ileocecocystoplasty: The ileum and cecum are isolated as a single unit (a) and reconfigured to form a "cup" for augmentation (b). * = suture line between the ileum and cecum. (Adapted from Rink RC, Adams MC. Augmentation cystoplasty. In Walsh PC et al., eds., *Campbell's Urology*, 7th edn., Philadelphia: WB Saunders, 1998, 3167–89. With permission.)

is not possible in the native bladder because the sigmoid musculature can easily be separated from the muscosa facilitating tunneling. Twenty centimeters of sigmoid is usually sufficient to achieve an adequate capacity after the segment is reconfigured. It is important to detubularize the sigmoid in order to prevent high-pressure coordinated contractions. Several techniques of sigmoid reconfiguration have been described (Figure 57.8). The authors prefer the U or S configuration because of simplicity and the possibility of significant contractile activity that may result from the method described by Mitchell[37] (Figure 57.8c). When the sigmoid segment has been isolated, colon continuity is reestablished with a single-layer, hand-sewn, end-to-end colocolostomy. The reconfigured sigmoid segment is then anastomosed to the native bladder in a similar fashion as described for ileum.

Postoperative Care

Following enterocystoplasty, parenteral antibiotics are continued for 48 hours unless the intraoperative urine culture is positive. Then, a full 7 days of culture-sensitive coverage

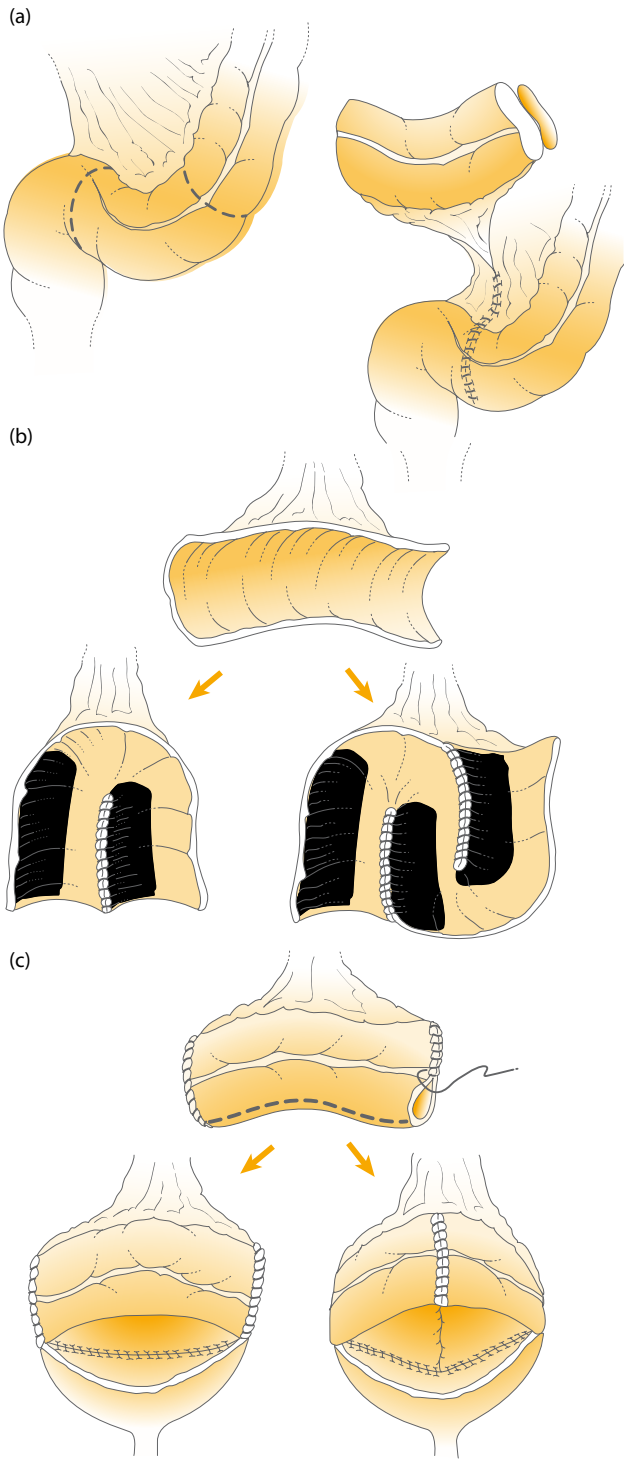

FIGURE 57.8 Sigmoid cystoplasty. (a) A portion of the sigmoid colon is isolated. (b) The sigmoid can then be reconfigured in a similar fashion as is performed for ileocystoplasty, with detubularization and folding back on itself. (c) Alternatively, the colonic segment can be closed at both ends, opened along the antimesenteric border, and then anastomosed to the bladder. This latter method is less optimal owing to the persistence of high intraluminal pressures following augmentation. (Adapted from Rink RC, Adams MC. Augmentation cystoplasty. In Walsh PC et al., eds., *Campbell's Urology*, 7th edn., Philadelphia: WB Saunders, 1998, 3167–89. With permission.)

is used. A nasogastric tube is left in place overnight and removed on the morning of postoperative day 1. Urinary drainage is maintained through the suprapubic tube and a secondary catheter through either the native urethra or the appendicovesicostomy (when performed). Diligent observation is needed during the immediate postoperative period to ensure that obstruction of the catheters does not occur secondary to blood clots or mucus. Daily bladder irrigations are important to decrease mucus buildup in the bladder, which can lead to infection, stone formation, and inefficient emptying. Bladder irrigations can begin immediately after surgery with 30 mL three times a day. This is increased to 60 mL twice a day after discharge. Both the suprapubic tube and secondary catheter are left to gravity drainage for 2–3 weeks. The suprapubic tube is then plugged and the patient begins intermittent catheterization. Before this, a cystogram can be performed to ensure adequate healing and the absence of extravasation; however, it is not absolutely necessary. Adequate emptying of the bladder with catheterization can be confirmed by checking residual urine via the indwelling suprapubic tube. Once the patient demonstrates proficiency at performing intermittent catheterization, the suprapubic tube is removed. Daily irrigations to clear the bladder of mucus are then recommended. Patients are told to catheterize every 2–3 hours during the daytime and once at night for the next few weeks. The time interval between catheterizations is gradually lengthened depending on the compliance of the augmented bladder and the gradually increasing storage volumes. In general, adequate stretching of the augmented bladder occurs within 6 months so that most patients need only catheterize approximately four to six times during the day to stay dry and maintain safe filling pressures. If a patient is going to attempt spontaneous voiding, one should wait until at least 3 months after surgery and then follow postvoid residuals to ensure adequate emptying. Radiographic imaging of the augmented bladder and the upper urinary tract is performed approximately 3 months postoperatively.

Results of Ileocystoplasty and Colocystoplasty

Bladder Capacity and Compliance

The most common preoperative urodynamic finding in the pediatric patient with a neuropathic bladder in need of bladder augmentation is a small-capacity, poorly compliant bladder with or without evidence of hyperreflexia and bladder instability. Both small and large bowel segments, when detubularized and reconfigured, have been found to provide adequately compliant tissue for enterocystoplasty that ameliorates or eliminates these adverse characteristics.[38] Flood et al.[39] reported on 22 augmentation cystoplasties performed over a period of 8 years. Mean age at surgery was 37 years, with a range of 2–82 years. The major indication for augmentation cystoplasty was reduced bladder compliance. A detubularized ileal augmentation was performed in 67% of the patients; 30% had a detubularized ileocecocystoplasty, and the remainder had detubularized sigmoid augmentation. Mean follow-up was 37 months. Bladder capacities increased from a preoperative

mean of 108 mL to 438 mL postoperatively. Excellent or improved results by all parameters were achieved in 95% of these patients.[39] Kilic et al.[40] reported on 30 children who underwent intestinocystoplasty. Sigmoid was used in 11 cases, ileum in 6, and ileocecum in 2. Postoperative evaluations revealed a mean postoperative capacity of 237 mL in the colonic group, 240 mL in the ileal group, and 250 mL in the ileocecal group. Mean compliance was 20.6 mL/cmH_2O in the colonic group, 21.6 mL/cmH_2O in the ileal group, and 25.5 mL/cmH_2O in the ileocecal group. They concluded that ileal, ileocecal, and colonic augmentations all provided high-volume reservoirs of similar compliance. Quek and Ginsberg reported long-term results on 26 patients with neurogenic voiding dysfunction who underwent enterocystoplasty. Mean follow-up in these patients was 8.0 years. Ninety-six percent of the patients had near or complete resolution of urinary incontinence. Mean total bladder capacity increased from 201 cc to 615 cc. They concluded that bladder augmentation provides durable clinical and urodynamic improvement for patients with neurogenic bladder dysfunction.[41]

It is apparent that all segments of intestine, when appropriately reconfigured, can adequately increase the capacity of the native bladder. However, enterocystoplasty does not guarantee that the bladder will be free of hyperreflexia. Robertson et al.[42] reported the persistence of hyperreflexia in 23% of patients after enterocystoplasty and documented regular phasic contractions in 77% of the augmented bladders despite bowel detubularization. It should be mentioned that in a majority of the patients in this series, an ileocecal segment was used. Recently, Pope et al.[43] reported on 19 of 323 patients who had undergone primary enterocystoplasty but required a secondary augmentation owing to the persistence of high pressures. Twelve of the 19 patients had colocystoplasties (14% of the total colocystoplasties), 4 had gastrocystoplasties (10% of the total gastrocystoplasties), and 2 had undergone ileocystoplasty. Cecum was used in one (1%). It is apparent in this large series that colocystoplasties are more likely to allow high storage pressures to persist. However, it must be noted that not all the colocystoplasties were completely detubularized but instead reconfigured after the ends were closed, with the colon opened along the antimesenteric border. Given this, it is difficult in this series to compare colon with ileum that was reconfigured into an S or W shape. Nevertheless, these studies emphasize the importance of careful functional and urodynamic follow-up in patients after enterocystoplasty, since some will require anticholinergics or secondary augmentation due to failure of the original procedure to improve bladder capacity and compliance adequately.

In summary, it appears that both small and large bowel, when detubularized, can be used for cystoplasty to provide a compliant and large-capacity reservoir. However, the large bowel may retain increased contractile activity despite detubularization.[31,38] It appears that detubularized ileum has less energetic phasic contractions than colon, and therefore has potentially less risk for persistent high storage pressures.[43] Given these advantages of ileum over colon, it is the authors' preference to use ileum whenever possible when performing simple enterocystoplasty.

Metabolic Issues

Electrolytes

The major function of intact small and large bowel is to absorb food, fluid, and electrolytes. When urine is stored in the bowel for prolonged periods, there is increased absorption of urinary solutes, which increases the risk of metabolic derangement. Koch and McDougal[44] hypothesized that ammonium reabsorption plays a key role in the development of hyperchloremic metabolic acidosis in patients following intestinocystoplasty. In support of this hypothesis, Stampfer and McDougal[29] demonstrated in a rat model that ammonium inhibits the sodium–hydrogen exchanger, resulting in ionized ammonium transport where it substitutes for sodium in the exchanger. This then leads to the increased absorption of chloride to maintain electrolyte neutrality, resulting in the development of hyperchloremic metabolic acidosis. In patients with normal renal function, serum electrolytes are usually unaffected by enterocystoplasty.[45–47] However, in patients with impaired renal function, metabolic acidosis can be profound. Careful preoperative evaluation and judicious use of bowel is recommended in patients with chronic renal insufficiency.[48] A gastric segment or cutaneous diversion may be safer. Owing to the electrolyte problems that can often develop in patients with significant renal insufficiency, the authors recommend gastrocystoplasty rather than conventional enterocystoplasty in this patient population.

Bone Growth

Impaired bone growth and demineralization are major concerns related to prolonged acidosis. Demineralization occurs secondary to the increased excretion of titratable acid (bony buffers). These concerns have received a large amount of attention in the last decade. Hochstetler et al.[49] demonstrated in a rat model that animals with ileocystoplasty, when given an acid challenge, developed bone demineralization and decreased bone growth that can be corrected with bicarbonate therapy. Current basic science literature demonstrated that enterocystoplasty in rats impairs neither skeletal growth nor bone quantity, but leads to significant loss of bone mass when combined with resection of the ileocecal segment.[50,51] This same group has also reported histomorphometrically that bone loss occurs after enterocystoplasty in the rat model.[50,51]

The more recent clinical literature has not clarified the true incidence or effect on bone growth. Mundy and Nurse[52] reported an average of 20% reduction in growth potential in three of six children who had colocystoplasties. However, no decrease in growth potential was noted in 10 children who had ileocystoplasties. They concluded that bone growth impairment was more likely after colocystoplasty than after ileocystoplasty. Two other reports demonstrated no impairment of bone growth or demineralization in children and adults after urinary reconstruction with various bowel segments.[47,53] However, two series have demonstrated variable degrees of reduction in bone mineral density in children with enterocystoplasties.[54,55] Finally, four other series have not demonstrated any effects of bone growth.[56–59] Interestingly, two of these reports are in bladder exstrophy patients; both of them

report growth retardation in this population with or without augmentation.[56,57] Further longitudinal studies will be required to clarify this issue. Therefore, until such studies are available, close observation for the development of acidosis and the treatment of any electrolyte abnormalities following intestinocystoplasty with bicarbonate therapy is recommended.

Bowel Dysfunction

Bowel dysfunction is known to occur occasionally after enterocystoplasty. Diarrhea can develop after resection of large segments of ileum, removal of the ileocecal valve, and extensive colonic resections. The incidence of bowel dysfunction following enterocystoplasty in all patients, including adults, has been reported to be between 10% and 54%.[15,60,61] In the spina bifida population, the incidence is approximately 20%. Since the overall incidence of bowel problems in children with spina bifida is further increased when the ileocecal valve is removed, one should try to avoid the use of ileocecal segments for augmentation in this patient population. Osmotic diarrhea has been theorized to occur after removal of the ileocecal valve, which results in a decreased transit time within the intestine.[62] It should be noted that these original data were not supported in a recent report by Husmann and Cain,[17] in which only 3% of their 63 ileal cecal cystoplasty patients had worsening of their bowel function. Despite this encouraging recent report, the authors feel that careful preoperative screening of patients with spina bifida with regard to their bowel habits is extremely important.

The diarrhea that develops postoperatively can be osmotic or secretory in nature. Secretory diarrhea is thought to occur because of decreased resorption of bile salts and subsequent fat malabsorption resulting in steatorrhea. Barrington et al.[63] reported on 14 patients who developed bowel difficulties after enterocystoplasty. They showed a direct correlation in many of these patients between their diarrhea and interruption of the enterohepatic circulation of bile acids. They also found that these patients can be identified by using bowel frequency charts and can be treated with anion-exchange resins.

Vitamin B_{12} Deficiency

Concerns regarding the development of vitamin B_{12} deficiency following small bowel resection or the use of small bowel for urinary reconstruction are well documented. The distal ileum is the major site of vitamin B_{12} absorption. It has previously been reported that up to 35% of patients will develop vitamin B_{12} deficiency following the construction of a Kock pouch, which uses about 80 cm of the small bowel.[64] Stein et al.[53] reported on 51 children who had undergone such reconstructions, but no significant drop in vitamin B_{12} levels was noted following surgery. From the older published data, it appears that the use of shorter segments of ileum, about 35 cm, as used for the Camey type 1 enterocystoplasty and conventional ileocystoplasty in children, did not place the patient at significant risk for vitamin B_{12} deficiency, even in the long term.[46] However, the Indiana group reported on more than 500 bladder augmentations and showed that there was a statistically significant correlation between follow-up time and serum B_{12}.[273] There conclusion was that pediatric patients who have undergone ileal enterocystoplasty are at risk for development of vitamin B_{12} deficiency. It was felt that the highest risk begins at 7 years postoperatively, and the risk increases with time. In a follow-up study, the same group demonstrated that oral vitamin B_{12} was effective in the treatment of vitamin B_{12} deficiency in patients with prior ileocystoplasty.[274]

It does appear that these patients are at some risk for vitamin B_{12} deficiency, and therefore the authors recommend harvesting small bowel segments that are at least 15 cm away from the ileocecal valve. The B_{12} receptor sites are clustered in the most terminal portion of the ileum, and this segment should be avoided. It is further recommended that vitamin B_{12} levels should be obtained yearly postoperatively. Oral administration of vitamin B_{12} is recommended when serum B_{12} levels reach the low normal levels (200–300 pg/dL). Alternatively, a vitamin B_{12} injection can be given prophylactically 3 years after enterocystoplasty. There is no evidence that the use of sigmoid colon for augmentation places patients at risk for vitamin B_{12} deficiency.

Mucus Production and Stone Formation

Mucus production and bladder stone formation are both complications related to the use of the gastrointestinal tract for urinary reconstruction. All segments of bowel produce mucus. However, mucus production from the ileum is less than that from the colon.[65] This has been confirmed clinically by several authors.[31,66] Mucus in the urinary tract is associated with an increased risk of infection.[67] Mucus production also increases during an acute infection, resulting in poor bladder emptying, especially when small catheters are used to drain the bladder.[36] Clinically, mucus production appears to decrease over time following ileocystoplasty. This is probably because of villus atrophy that occurs in the ileum. Colonic epithelium does not appear to undergo this type of change. Significant mucus production in colonic augmentations continues throughout the life of the patient.

The risk of stone formation after enterocystoplasty ranges between 7% and 52%.[68–73] The usual stone composition reported is magnesium ammonium phosphate (struvite), although several other stone compositions have been reported. Since the majority of stones are struvite in origin, it appears that chronic bacteriuria with urease-producing organisms may have a contributory role. However, it is also clear that the presence of mucus has an important role in the development of bladder stones following intestinocystoplasty. Mucus may serve as a biofilm that can harbor bacteria and promote further growth in a protected environment. Khoury et al.[74] have also demonstrated that the mucus from stone formers has increased levels of calcium, phosphate, and magnesium, and an increase in the calcium-to-phosphate ratio, compared with nonstone formers. This increased calcium-to-phosphate ratio may be clinically important in predicting which patients are at risk for stone formation. Given these findings, it appears that mucus has strong lithogenic properties and is a nidus for stone formation. Daily irrigation of the augmented bladder to prevent excess mucus buildup can be an effective measure to reduce the risk of stone formation in the

augmented bladder. Hensle et al.[75] recently reported that an irrigation protocol consisting of saline twice a week (240 mL) and gentamicin sulfate solution once a week (240–480 mg gentamicin/L saline, at 120–240 mL per irrigation, depending on patient age and reservoir size) significantly reduced the number of reservoir calculi from 43% to 7%. However, Brough et al.[69] did not observe a decreased incidence of stone formation when they instituted a regular bladder washout program in children following intestinocystoplasty.

Palmer et al.[73] identified an additional risk factor for the development of bladder stones in the augmented bladder. They noted the presence of hypocitraturia in some of their stone-forming patients. Treatment with oral potassium citrate returned urinary citrate levels to within normal values, and no recurrent calculi were then seen. Woodhouse and Robertson[272] have also reported that a metabolic screen in their augmented patients demonstrated that 80% of patients have risk factors for at least three different types of stones. All the patients were found to have an increase in urinary pH and hypocitraturia.

Bladder calculi in the augmented bladder are amenable to both open surgery and endoscopic management.[68,72,73,76,77] Neither procedure appears to have a clear advantage at this time. An open procedure is usually simpler when the stones are large, although new energy sources for the endoscopic treatment of stones, such as the holmium laser, may enhance the ability to manage bladder stones noninvasively. Miller and Park[78] have also described a method of using a laparoscopic entrapment sac percutaneously to control the loss of multiple fragments. This method has been used by the authors and has been highly successful. Treatment of bladder calculi needs to be individualized. Factors that should influence the surgical approach include the number and size of calculi, the previous bladder outlet procedure, the availability of endoscopic equipment, the availability of energy sources, and the surgeon's experience with endoscopic techniques.

Infections

Bacteriuria following enterocystoplasty is the rule since these patients are being intermittently catheterized. If the bladder is not emptied completely, symptomatic UTI may result. It is not known whether one type of bowel segment is at greater risk for the development of UTIs than another. Hirst[79] reported the presence of bacteriuria in 50% of sigmoid augmentations, whereas only 25% of ileocystoplasties had bacteriuria at any one time. In a series of 231 augmentation patients, Rink et al.[31] reported a symptomatic UTI rate of 22.7% following ileocystoplasty, 17.3% following sigmoid cystoplasty, 12% following cecocystoplasty, and 8% following gastrocystoplasty. They reported an overall 14% incidence of febrile UTIs with no statistical difference in the incidence between the various bowel segments. It appears that all augmented bladders are at risk for infection.

Tumors

Many fear that there may be an increased risk of malignancy in bladders after enterocystoplasty, as is the case after conventional ureterosigmoidostomy. Adenocarcinoma is the predominant tumor that develops after ureterosigmoidostomy, found most frequently at the site of the ureteral orifice. The latency period for tumor formation in the ureterosigmoidostomy patients ranges between 3 and 53 years, with a mean of 26 years. It is estimated that there is a 7000-fold increased risk of developing adenocarcinoma following ureterosigmoidostomy. It is with great trepidation that we enter the new millennium with hundreds of children having received enterocystoplasties without knowing whether there is an increased risk for the development of cancer. Filmer and Spencer[80] reported on 14 patients with tumor formation in the augmented bladder. Nine of these patients had ileocystoplasty, and colon was used in five. The exact etiology and pathogenesis of these tumors are unknown, but they seem analogous to those of cancers occurring after uterosigmoidostomy. Nurse and Mundy[81] studied 34 patients who had undergone augmentation cystoplasty or colonic substitution cystoplasty. A high incidence of histologic abnormalities in the intestinal segment was reported to occur along the anastomotic suture line and in the remaining bladder. Such abnormalities were directly correlated with heavy mixed bacterial growth in the urine and high levels of urinary N-nitrosamines. Woodhams et al.[82] have reported that there is no diurnal or long-term variations in urinary N-nitrosamine levels. They also found that levels were consistently higher in patients with inflamed or infected cystoplasties, those using intermittent self-catheterization, and those not taking antibiotic prophylaxis. Shokeir et al.[83] and Ali-El-Dein et al.[84] demonstrated that all bowel segments exposed to urine, regardless of their position (bladder or ureteral substitution), are at risk for malignant changes, and that urine cytologies may be a useful diagnostic tool in this setting. Barrington et al.[85] reported on four patients who developed tumors in augmented bladders. All the tumors were adenocarcinomas and were located on the bladder side of the anastomosis. It was concluded that these tumors were derived from the native urothelium. It was also demonstrated that transitional epithelium could undergo intestinal mucosal-like changes throughout the exposed native urothelium, including the renal pelvis, which was observed in one patient who had vesicoureteral reflux (VUR). Soergel et al.[86] reported 3 new cases of transitional cell carcinoma (TCC) from the Indiana augmentation database of 483 cases. Mean time from augmentation to TCC was 19 years. None of these patients had any additional risk factors. Thus, it is felt that development of bladder cancer is a real issue, and that all patients should undergo endoscopic surveillance beginning 10 years after initial surgery.

In 2009, Husmann performed an extensive review of the literature and found a total of 20 cases of bladder cancer following augmentation for congenital anomalies.[87] He reported that the incidence of cancer developing per decade following surgery was 1.5% for ileal and colonic and 2.8% for gastric bladder augmentations. Like all the reports of bladder cancer in this population, the majority presented with advanced and high-grade disease.

Austin et al. brought a new twist to the topic of risk of bladder malignancy in the spina bifida population when they reported eight additional spina bifida patients who developed bladder cancer between 1995 and 2005.[88] Mean age at presentation was 41, and only one patient

had previously undergone an enterocystoplasty. They combined their 8 patients with the previously reported 11 spina bifida patients, and only 7 of 19 had undergone bladder augmentation. This report demonstrated that all spina bifida patients, regardless of prior augmentation, appeared to be at increased risk for bladder cancer. In 2010, Higuchi et al. followed up on a similar theme of increased cancer risk for congenital bladder abnormalities.[89] Utilizing an extensive registry of patients with bladder abnormalities, they reported that there was no difference in the incidence of bladder cancer in patients with augmentation compared with a similar population without augmentation. They were able to demonstrate irrespective of augmentation status, patients on chronic immunosuppression for renal transplantation had a significantly higher incidence of bladder cancer. They concluded that bladder augmentation did not appear to increase the risk of bladder malignancy over the inherent cancer risk associated with the basic congenital bladder abnormality.

Previously, it was recommended that routine endoscopic surveillance for bladder tumors begin 7–10 years after augmentation.[86] However, this topic of surveillance became controversial based on three reports regarding the utility and cost–benefit of this type of program. Hamid et al. recommended it was not necessary to perform yearly cystoscopies in patients with augmented bladders, at least in the first 15 years, as cystoscopy had been unable to detect any cancers in this group.[90,275] They did recommend a complete workup, including cystoscopy and computed tomographic (CT) scan, of any patient that developed hematuria, suprapubic pain, or recurrent unexplained UTIs. In 2011, the Boston Children's Hospital group reported on the cost-effectiveness of screening spina bifida patients with cystoscopy and cytology.[91] They utilized a Markov model to compare two screening strategies. They concluded that annual screening for malignancy among the enterocystoplasty population was unlikely to be cost-effective at commonly accepted willingness-to-pay thresholds. Finally, Higuchi et al.[89] reported on the results of their screening program of 65 enterocystoplasty patients that were more than 10 years removed from their original enterocystoplasty. They concluded that annual surveillance endoscopy and cytology should be discontinued secondary to the low incidence of malignancy, lack of proven benefit, and enhanced cost containment.[90]

Enterocystoplasty is not the only group that appears to be at increased risk for bladder cancer. Two recent reports of metastatic transitional cell carcinoma arising after autoaugmentation have been published.[92,93] In both of these reports, the patients presented with gross hematuria 11 and 14 years, respectively, out from their initial autoaugmenation. Both patients eventually died of metastatic disease.

The issue of potential malignancy in augmented bladders and now the entire congenital bladder anomaly population cannot be overlooked or ignored. This is a potentially disastrous complication for children in whom one hopes to provide a surgically reconstructed bladder that will last for life. Future research is needed to determine the true risk of tumor formation, which children are at greatest risk, and whether premalignant changes can be detected endoscopically or with urine markers or cytology. Although the incidence of tumor formation following enterocystoplasty is unknown, lifelong urologic follow-up is required. Whether yearly cystoscopic evaluation and urine cytologies from the augmented bladder should be considered remains controversial. However, there is no controversy regarding the need for a prompt and complete workup for any congenital bladder patient that presents with a history of gross hematuria.

Perforation

Many complications can occur following enterocystoplasty. However, no complication is more potentially devastating or life threatening than unsuspected spontaneous bladder perforation. Although the exact incidence of perforation is not known, nearly every large series of enterocystoplasties includes at least one patient.[65,94–100] Among these reports, seven deaths have been directly attributed to such perforation.[101] Most of these deaths were due, at least in part, to delay in diagnosis. Therefore, a high index of suspicion is needed in any patient with a history of enterocystoplasty who presents with abdominal and/or shoulder pain.

It is not known whether one type of bowel is particularly prone to perforation after cystoplasty. Rink[37] reported a higher incidence of spontaneous perforations in sigmoid cystoplasties. He initially felt that the sigmoid colon was inherently at greater risk for perforation, but he now feel that this higher incidence may be more directly related to his initial technique of sigmoid detubularization. Others have reported that the highest incidence of perforation occurred when ileum was used.[95] DeFoor et al. believe that gastrocystoplasty may be at a lower risk for perforation.[102] However, it appears that no segment of bowel, tubularized or detubularized, is immune from this complication.

The etiology of bladder perforation is unknown. Initially, perforations were thought to be either linked to traumatic catheterization or a consequence of failure to catheterize on a timely basis.[96,99] However, perforation has been reported in patients who do not perform intermittent catheterization.[98] Another contributing factor in bladder perforation may be vascular compromise in the bowel wall. Crane et al.[103] reported that specimens from perforated bladders demonstrated histologic evidence of bowel wall ischemia. Also supporting the theory of bowel wall ischemia is an arterial perfusion study in a canine augmentation model, where a decrease in blood flow to the bowel wall was seen when the reservoir was overdistended and intravesical pressures were increased.[104] The perfusion change was most striking at the antimesenteric border in the detubularized bowel. In addition to overdistension, high pressures due to bladder hyperreflexia may lead to an increased risk of perforation. Bauer et al.[95] noted the presence of postoperative hyperreflexia in 40% of their patients who suffered a spontaneous perforation.

Some authors have suggested that a low urethral resistance is protective against both the high pressures associated with bladder hyperreflexia and failure to empty the reservoir on a timely basis.[94] However, Jayanthi et al.[105] reported on 28 patients who underwent complete bladder neck ligation in conjunction with enterocystoplasty with a catheterizable stoma. In this series, the one bladder

perforation that occurred was associated with blunt trauma and was not spontaneous in origin. Therefore, achieving total urinary continence surgically without a pop-off valve mechanism does not in itself increase the risk for spontaneous rupture.

There does not appear to be one single etiology or risk factor that makes some more prone to bladder perforation than others. Multiple factors are probably involved. Repetitive overdistension secondary to poor compliance, bladder hyperreflexia, and chronic infection all appear to place the augmented bladder at increased risk for spontaneous perforation.

The diagnosis of bladder perforation can be difficult at times, and a high index of suspicion is required to make the diagnosis quickly. Most pediatric patients who undergo enterocystoplasty are neurologically impaired. Lower abdominal sensation is diminished. Therefore, the clinical presentation may be nonspecific. Nausea, vomiting, fever, oliguria, and possibly referred pain to the shoulder secondary to diaphragmatic irritation may be presenting complaints.[106]

On physical examination, the abdomen is distended, with pain and irritation above the level of anesthesia. It may be difficult to distinguish pyelonephritis from a spontaneous bladder perforation. Thus, a standard or CT cystogram is recommended in any patient with an augmented bladder who presents with the above symptoms. Although the diagnostic role of a cystogram has been questioned in the past,[99,100] it is the most specific diagnostic radiographic test.[95,98] Braverman and Lebowitz[107] have recommended fluoroscopy during the filling phase to make sure that the bladder is completely distended in order to diagnose the perforation accurately. Residual contrast in the abdomen after the bladder has been drained establishes the diagnosis. Alternatively, an abdominal CT scan can be diagnostic and is helpful in demonstrating the extent of the extravasation.

When spontaneous perforation of the augmented bladder is suspected clinically and/or confirmed radiographically, immediate treatment is required. Catheter drainage, fluid resuscitation, and broad-spectrum antibiotics should be started immediately. In a stable patient, nonoperative management with catheter drainage, antibiotics, and serial physical evaluations may be all that is needed.[108] This nonoperative approach should be used only in selected patients in whom a small rupture is suspected. In the majority of patients, immediate exploration and closure of the bladder leak is safer. Intra-abdominal lavage, and irrigation and placement of intra-abdominal drains should then be done. Finally, all patients with an augmented bladder must be educated on the potentially lethal complications associated with delay in diagnosis of a spontaneous perforation. They should be instructed to inform a treating physician that they have an augmented bladder, and are at some risk for bladder perforation.

Obesity

An association has been reported in the adult literature between obesity and surgical complications, with increased wound infections being documented most commonly.[109–111] In their review of 1853 patients undergoing resection for gastric carcinoma, Bickenbach et al. reported increased postoperative complications for patients with a body mass index (BMI) of more than 25. Although there was no difference in overall survival, the rate of wound infections (8.9% vs. 4.7%) and anastomotic leaks (11.8% vs. 5.4%) was twice as high in the obese patients.[112] In the orthopedic literature, higher rates of infection and reoperation and additionally less improvement from their baseline were found in obese patients (BMI of more than 30) after surgery for degenerative spondylolisthesis.[113] Patients with myelodysplasia are often prone to obesity due to their mostly nonambulatory status and decreased energy requirements.[114] Donovan et al. reviewed the complication rates of patients with myelodysplasia who underwent bladder augmentations with creation of catheterizable stomas, with a mean follow-up of 39 months. Patients were categorized based on BMI as normal weight (<85th percentile), overweight (85th–95th percentile), or obese (>95th percentile). Obesity was found in 33% of patients, with a significant association between the presence of complications and weight category. Patients who were normal weight or overweight experienced complications in 40%, while obese patients demonstrated complications in 75%. As one of their study limitations, the authors acknowledged the difficulty of measuring BMI in myelodysplasia patients due to variations in height with spinal and lower extremity malformations.[115] The problem of adequately measuring the energy needs and BMI levels in children with myelodysplasia is currently being investigated in a multidisciplinary study at the Children's Hospital in Oklahoma City.

Quality of Life

The decision to proceed with augmentation of the bladder and other associated reconstructive procedures in children with a neurogenic bladder can be a complicated one. When the decision is based purely on the finding of upper tract deterioration, the decision is relatively straightforward since there is a definitive need to perform surgery to preserve renal function. However, in contrast, when the decision is being made for continence reasons, it can be difficult since it is not entirely clear what effect the surgery will have on the overall quality of life of the patient. This is especially true in individuals with spina bifida, where other forms of disability may impact their life more than bladder and bowel incontinence issues. As reconstructive surgeons, we are pleased when a patient that is wet becomes dry after lower urinary tract surgery. However, the perception of how surgical correction of incontinence truly impacts the patient's life may not necessarily be the same for the patient, parents, or surgeon. In a retrospective analysis of 36 patients with spina bifida, MacNeily et al. examined whether lower urinary reconstruction improves health-related quality of life (HRQOL). They did not find that there was a significant increase in the HRQOL score in these patients after surgery compared with age-matched controls.[116] In a follow-up prospective trial from the same institution, 31 patients with spina bifida were evaluated before and after surgery. Once again, no significant improvement in HRQOL domains was noted postoperatively.[117] However,

patient's self-assessment of improvement in continence postoperatively did not correlate well with that of the investigators, which may explain the lack of improvement in HRQOL. Additional studies in HRQOL in this unique patient population highlight the differences that can occur in HRQOL scores between patient reports and those from their parents.[118] The authors' own experience, as well as that of others that perform lower urinary tract reconstructive surgery, suggests that there are definite improvements in overall quality of life following reconstructive surgery in appropriately chosen patients. This disparity in experience from different institutions may relate to the appropriateness of the survey tools utilized to assess HRQOL, patient selection, investigator bias, and the tools to assess continence. Nevertheless, it is important that families be counseled about these quality of life issues preoperatively. Future studies will hopefully better clarify the true impact that bladder reconstructive surgery plays in patients' lives and those of their families, as well as specific patient characteristics that can better predict a positive result.

SURGICAL ALTERNATIVES TO INTESTINOCYSTOPLASTY

As discussed above, bladder augmentation with small and large bowel segments may result in electrolyte abnormalities, UTIs, mucus production, stones, and tumor formation. Most long-term complications are attributable to the presence of intestinal mucosa in a urinary tract reservoir for urine storage. In an effort to avoid the unwanted effects of enterocystoplasty, several alternative surgical procedures have been developed. These include gastrocystoplasty, ureterocystoplasty, autoaugmentation, and seromuscular enterocystoplasty.

Gastrocystoplasty

Gastric tissue was first reported to be applied to the urinary tract in 1956, when Sinaiko[271] described the use of a stomach segment for urinary diversion. Leong and Ong[119,120] subsequently reported the successful use of stomach for augmentation of the bladder in both dogs and humans. More recently, Mitchell and colleagues have modified Leong's original techniques for gastrocystoplasty and popularized its use in pediatric patients.[121,122] Since then, experience from multiple institutions over the past two decades indicates that the use of the stomach is feasible and effective in augmenting the neuropathic bladder. However, widespread use of stomach tissue as an alternative to intestine has been limited by the findings that the hematuria–dysuria syndrome (HDS) can be problematic in many patients (especially those that are sensate), and that in the long term, gastrocystoplasty does not appear to result in a reservoir that is as capacious and compliant as that which is achieved with conventional intestinocystoplasty. Regardless, the use of stomach tissue can be very advantageous and appropriate in some patients. For example, in patients with renal insufficiency and metabolic acidosis, gastrocystoplasty helps to buffer the adverse effects of the acidosis due to its ability to secrete acid into the urine. Thus, in select patients, the use of stomach for augmentation is a viable and appropriate alternative to the use of intestine.

Anatomy and Physiology

Anatomically, the stomach can be divided into five parts: the lesser curvature, greater curvature, fundus, body, and antrum. The layers of the gastric wall include the outer serosal coat, a muscular coat, the submucosal layer, and the epithelium. The muscular coat consists of smooth muscle fibers oriented in a longitudinal, circular, and oblique fashion. The epithelium of the gastric mucosa consists of a single layer of tall columnar epithelial cells and smaller acid-secreting cells. Loose areolar tissue in the submucosa lies between the mucosal and muscular layers. This loosely arranged layer allows technically simple separation of the mucosa from underlying muscle, permitting implantation of ureters in an antireflux fashion and tunneling of continent catheterizable stomas.

The entire arterial supply of the stomach is based on branches of the celiac artery, including the gastric, splenic, and hepatic arteries (Figure 57.9). The right and left gastroepiploic arteries supply the greater curvature and are pertinent for use in gastrocystoplasty. The gastroepiploic arteries arise from the right gastric and splenic arteries, respectively. They usually do not anastomose directly but are connected through small arterial branches.

The main physiologic function of the stomach is to digest food mechanically and chemically. Given this, the muscle of the stomach functionally contracts in a manner that is different from the rest of the intestinal tract in that it acts to churn its contents, as opposed to moving the bolus of food along a peristaltic wave. This unique pattern of contractility may be the cause of the phasic contractions that are seen in the augmented bladder following gastrocystoplasty.

The stomach chemically digests food through the secretion of acid. The exact mechanisms responsible for the control of acid secretion from the stomach are still not completely understood. Current evidence suggests that parietal cells, which are mainly located in the body of the stomach, secrete acid in response to gastrin that is released from G cells located in the antral mucosa. G cells, in turn, are stimulated to release gastrin by direct contact of the mucosa with food, antral distension, and vagal stimulation. Acid secretion can also be stimulated by acetycholine and histamine. The latter is important in that acid secretion from gastric segments following gastrocystoplasty can be inhibited with H_2 receptor blockers.

In addition to the stomach's ability to secrete chloride, other metabolic properties of importance include its barrier function to ammonium and chloride reabsorption. The combination of hydrogen ion and chloride secretion predisposes patients to the development of hypochloremic, hypokalemic, and metabolic alkalosis following gastrocystoplasty. However, this secretion of acid is beneficial in patients who have chronic acidosis associated with renal insufficiency.

Advantages and Disadvantages

Surgically, the stomach is relatively thick and easy to work with. Use of the stomach for bladder augmentation has clear advantages in patients with renal insufficiency owing to its ability to secrete acid. This allows for buffering of systemic acidosis and reduces the need for bicarbonate supplementation. The resultant acid urine also appears to decrease the incidence of bacteriuria. In comparison with other intestinal segments, there is decreased mucus production and stone formation. The inherent musculature of the gastric segment may offer an additional advantage over small and large bowel by increasing the possibility for spontaneous voiding. This may result in more efficient emptying, less residual urine, and decreased need for intermittent catheterization.[123,124] Lastly, gastrocystoplasty can potentially be accomplished laparoscopically, which offers significant advantages in more rapid patient recovery following surgery.[125]

The main disadvantage of gastrocystoplasty that currently limits its widespread use in children with neuropathic bladders is the high incidence of HDS. This is most troublesome in patients who have a sensate urethra and perineum. Given this, caution should be exercised in selecting patients who are sensate and are at risk for incontinence (i.e., bladder exstrophy) when other enteric segments are available. This also applies when considering gastrocystoplasty in a patient with end-stage renal disease in need of transplantation, since ulcer formation and perforation of defunctionalized bladders have been reported.[126]

Postoperative studies suggest that gastrocystoplasty results in a less compliant and capacious reservoir than that usually achieved with conventional enterocystoplasty. Gastrocystoplasty may therefore be less useful in patients with a very small, noncompliant bladder plate.[40,127]

Surgical Technique

The original gastrocystoplasty, as described by Leong and Ong,[119,120] used the antrum of the stomach. Since incorporation of antral tissue may increase cyclical secretion of acid because of antral distension during bladder filling, more recent forms of gastrocystoplasty[121,128] favor utilization of a wedge taken from the greater curvature of the stomach that incorporates more body and less antrum (Figure 57.10). Depending on the individual vascular supply, this wedge of tissue may be based on either the right or left gastroepiploic artery. There is usually a vascular window between these arteries that defines which artery is dominant. Since the right gastroepiploic artery is longer and dominant in the majority of cases, this is more commonly used. A 10–15 cm length of stomach along the greater curvature is chosen, with special care taken to minimize inclusion of antral tissue. Branches of the gastroepiploic artery that are not directly supplying the wedge to be harvested are ligated. The wedge of stomach is isolated with the use of bowel clamps or an automatic stapler. The authors prefer the latter. The apex of the gastric wedge should be at least 1 cm below the lesser curvature to prevent injury to the vagus nerve and the right gastric

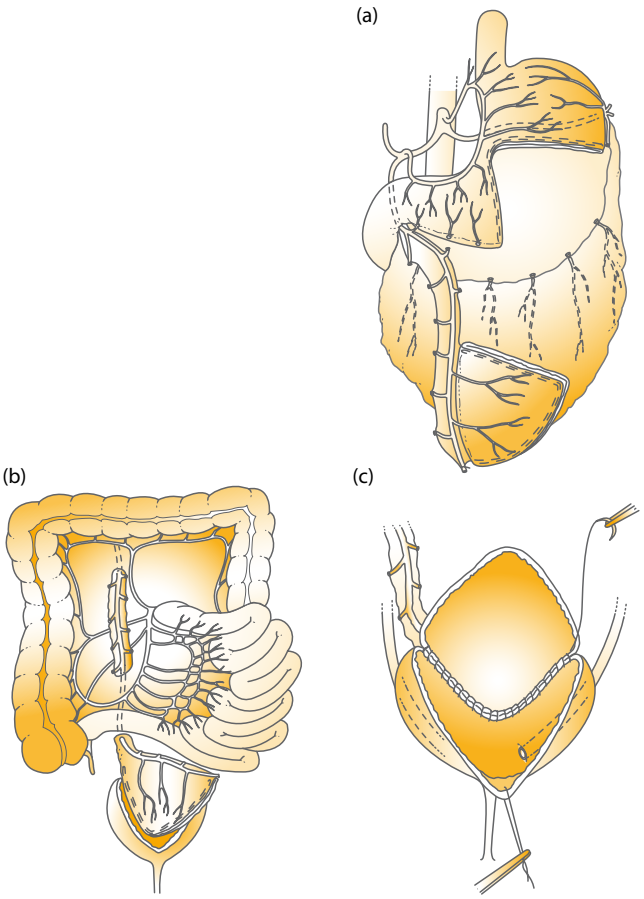

FIGURE 57.10 Gastrocystoplasty. (a) A wedge of stomach is isolated along the greater curvature of the stomach with its blood supply based on either the right or left gastroepiploic artery. (b) The flap is brought through the mesentaries of the small and large bowel or retroperitonealized following complete mobilization of the small and large bowel. (c) The flap is then anastomosed to the bivalved bladder.

vessels. Before isolation of the gastric wedge, it is advisable to ligate branches of the right gastric artery near the apex of the wedge, since failure to do this can result in significant blood loss.[129] A flap of greater omentum must also be mobilized along with the gastric wedge. The stomach is then closed in two layers. Alternatively, Raz et al.[130] have described a technique using an automatic stapler to harvest a gastric segment along the greater curvature of the stomach without opening the stomach.

Once the gastric segment is isolated, it is retroperitonealized by bringing it through the mesenteries of the transverse colon and small bowel. Special care should be taken to close these defects in the mesentery to prevent internal intestinal herniation. Alternatively, the right colon and duodenum can be mobilized up to the root of the small bowel mesentery, which allows placement of the gastric segment and its trailing vascular supply entirely in the retroperitoneal space. After the segment has been relocated inferiorly into the pelvis, it is rotated 90° to straighten the mesentery and vessels. The staples are then removed and the posterior tip of the stomach is sutured to the posterior aspect of the bivalved bladder using a running, interlocking 3-0 polyglactin suture.

Postoperatively, the augmented bladder should be adequately drained with a suprapubic tube and urethral catheter. A nasogastric suction tube is maintained for 3–5 days postoperatively. Following removal of the nasogastric tube and resumption of oral intake, the patient should be encouraged to eat small, frequent meals for the first few weeks to months.

Results

The urodynamic results of gastrocystoplasty are somewhat variable. Some authors report that it is useful in increasing capacity and compliance, similar to large and small bowel.[131] In studies that have analyzed both preoperative and postoperative urodynamics, gastrocystoplasty has been shown to increase bladder capacity by approximately 150%–200%.[132–134] However, it should be noted that there is a wide range of results reported with regard to increased bladder capacity following gastrocystoplasty.[40,128,131,133–135] In a recent series comparing the urodynamic findings and clinical outcomes following augmentation with stomach versus intestine, it was shown that both stomach and intestine are efficacious in improving compliance, but that the use of ileum and colon results in a higher-volume reservoir. Intestinal segments appear to expand more readily following augmentation than does the stomach.[40] Some of the differences in the literature regarding improvements in capacity and compliance following gastrocystoplasty may in part be explained by the variable amounts of stomach that have been harvested in individual patients. However, less volume expansion seems inherent to gastric segments when compared with the ileum and colon.

A unique postoperative urodynamic finding after gastrocystoplasty is the presence of low-amplitude, rhythmic contractions during bladder filling. These contractions are usually less than 30 cmH_2O.[121,135] However, contractions greater than 30 cmH_2O have been noted to be present in 10% of patients.[133–135]

Taken together, experience with gastrocystoplasty demonstrates that it is clearly an effective procedure in providing improvements in bladder compliance and capacity. However, in comparison with the ileum and colon, the stomach often results in a reservoir that is less capacious and perhaps less compliant.

HDS is unique to gastrocystoplasty. HDS is defined as the presence of pain in the bladder, suprapubic, or genital area; coffee-brown or bright-red hematuria in the absence of infection; skin irritation or excoriation; and painful urination or pain with catheterization. HDS occurs in up to one-third of patients and is the major factor that has limited the more widespread use of gastrocystoplasty in children requiring enterocystoplasty. In the largest series to date with long term follow-up, Plaire et al.[136] reported that 24% of patients following gastrocystoplasty had some element of this syndrome. Other retrospective series have reported the incidence of HDS to be as low as 2% and as high as 50%.[32,131,137] The disparity in these numbers likely relates to the variable makeup of the patient populations in each study. Also, longer-term follow-up may result in an increased incidence of complications.[138] In all studies evaluating HDS following gastrocystoplasty, a uniform finding is that HDS is much more prevalent in patients

who have a sensate urethra and perineum, whereas it is less common in patients who are insensate, as in patients with a neuropathic bladder secondary to spina bifida or spinal cord injury. Despite the relatively high incidence of HDS following gastrocystoplasty, most patients respond well to either H_2 receptor blockers or hydrogen ion pump blockers, such as omeprazole.[139] In some patients, alkaline irrigation of the bladder can also be used effectively.[140] A small percentage of patients may be refractory to all forms of conservative medical management, necessitating conversion to a different form of augmentation or diversion.[141]

The etiology of HDS is not entirely clear. Bogaert et al.[142] demonstrated that the gastric mucosa in the augmented bladder is stimulated in the same way as the native stomach. With this in mind, some authors have proposed that hypergastrinemia may be a causative or major contributing factor in patients with HDS. The association of hypergastrinemia and HDS has been demonstrated in several patients.[134,139,143–145] Despite this association, there has never been a direct correlation between this syndrome and aciduria and/or hypergastrinemia.[131,137]

Another potential complication associated with the use of stomach is peptic ulcer disease of the gastric patch with subsequent perforation.[126] It has been postulated that *Helicobacter pylori* infection may be an important etiologic factor in patients who develop ulcerative changes in the gastric portion of the augmented bladder.[146] Although patients are at significant risk for the development of HDS following gastrocystoplasty and other related complications associated with acid secretion by the stomach segment, it is rarely necessary to remove the gastric patch. Medical management of these problems is usually successful.

The beneficial effects of gastrocystoplasty in patients with reduced renal function and systemic acidosis are well documented.[121,123] However, the metabolic losses of acids and chloride may be overabundant, resulting in significant hypochloremic, hypokalemic, and metabolic alkalosis in some. This metabolic imbalance has been severe enough to warrant hospitalization in up to 7% of patients with gastrocystoplasty.[131,132] The precise mechanisms responsible for the development of a severe form of hypochloremic, hypokalemic alkalosis have not been precisely or sequentially elucidated. Significant risk factors appear to be recent viral illness associated with vomiting and other gastrointestinal losses, urinary concentrating defect,[121] renal insufficiency,[147] and the absence of acidosis prior to gastrocystoplasty.

As is the case with HDS, the development of hypergastrinemia following gastrocystoplasty has been postulated, although not definitively proven, to play a significant etiologic role in the development of metabolic alkalosis.[139,143,145] Clinical management of patients with hypochloremic, hypokalemic alkalosis includes aggressive intravenous rehydration with normal saline, replenishment of sodium and chloride, and use of H_2 receptor blockers. Once again, it is unusual to have an electrolyte abnormality that is so severe and unresponsive to medical therapy that removal of the gastric segment becomes necessary.

In comparison with conventional enterocystoplasty with small and large bowel, the incidence of bacteriuria and mucus production, and the development of bladder stones are significantly less following gastrocystoplasty.[71,121,135,148,149] The combination of decreased mucus, acidic urine, and the potential for spontaneous voiding (thus eliminating the need for intermittent catheterization) may be responsible for this decreased incidence.

Composite Gastrocystoplasty and Intestinocystoplasty (Gastrointestinal Composite)

As seen in the previous discussion regarding intestinocystoplasty and gastrocystoplasty, use of single enteric segments for augmentation has unique individual advantages and disadvantages. Since some of the metabolic effects of gastrocystoplasty are directly opposite of those with intestinocystoplasty, it has been proposed that some of these metabolic effects could buffer each other if both enteric segments are placed in combination. This concept was first introduced by Lockhart et al.[150] Ideally, the advantages of each segment could be retained and maximized with concomitant reduction of many of the undesired side effects. Namely, the stomach could still be retained for reimplantation of catheterizable tubes and ureters, while incorporation of a piece of ileum could reduce the side effects of increased acid secretion in the bladder (HDS) and enhance the urodynamic effects that are achieved with the use of stomach alone. Over the last decade, several reports have now demonstrated that gastrointestinal composite augmentation is feasible and advantageous in select patients.[151–154] The composite augment can be constructed either primarily or as a secondary procedure following a previous augmentation with a single piece of stomach or bowel. The size of each individual gastrointestinal segment can be varied depending on the individual metabolic and urodynamic needs of each patient. Austin et al.[153] have demonstrated that the beneficial reduction in acid load in patients with renal insufficiency can still be maintained with the gastrointestinal composite augmentation, while the buffering effects of the incorporated intestine help to reduce the incidence of HDS. In addition, the incidence of bacteriuria and stone formation is lower in composite reservoirs than in intestinocystoplasty alone, presumably in part due to the lessened mucus production from the gastric segment. Although technically demanding, gastrointestinal composite augmentation appears to be a viable and improved form of augmentation in select patients with short bowel syndrome, metabolic acidosis, and renal insufficiency.

Autoaugmentation

Autoaugmentation, also known as vesicomyotomy and vesicomyectomy, was introduced by Cartwright and Snow.[155,156] This is a novel approach to bladder augmentation that aims to enlarge bladder capacity and improve bladder compliance without using a patch graft or opening the bladder. In essence, this procedure creates a large bladder diverticulum by removal of the bladder muscle from the dome. The most important advantage for this procedure is the avoidance of intestinal epithelium with its associated complications. The native urothelium is preserved. The major drawback of autoaugmentation is that experience has failed to identify the most

appropriate patients for this procedure. Mixed results have been obtained clinically with regard to symptomatic and postoperative urodynamic improvement in the autoaugmented bladder. Evaluation of the available data indicates that there is no direct correlation between preoperative urodynamic findings and success. Therefore, it continues to be a procedure that can work well in some patients while it fails in others. Nevertheless, it appears that this procedure is best suited for patients with reduced compliance in combination with a near-normal preoperative bladder capacity.[157–159]

Despite the problems in predicting surgical success preoperatively, it seems reasonable to consider autoaugmentation as an option in some patients in whom conventional enterocystoplasty is needed and there is a desire to avoid the use of bowel. However, patients need to be aware of the relatively high failure rate of autoaugmentation in comparison with conventional eneterocystoplasty. Patients that should be excluded from consideration for autoaugmentation include those with failed bladder exstrophy repair, multiple previous bladder operations, and very small bladder capacities. Autoaugmentation in these children is more difficult technically, and results in general have been poor.[157,159]

Anatomy and Physiology

Autoaugmentation preserves the native bladder urothelium. The metabolic and physiologic properties of this urothelium following autoaugmentation are not well studied, although available data suggest that no significant changes occur. Following autoaugmentation, the mucosal herniation has been shown in both experimental animals and humans to have evidence of collagen deposition, neovascularity, variable inflammatory changes, and occasional muscle fibers.[159–161] No significant metaplastic or dysplastic changes in the native urothelium have been reported.

Advantages and Disadvantages

The primary advantage of autoaugmentation over conventional enterocystoplasty is preservation of the patient's native urothelium in the augmented segment. This avoids the complications associated with enterocystoplasty related to the presence of heterotopic epithelium in contact with the urine noted previously. However, this alone does not seem to eliminate the risk of bladder cancer.[92,93] Technically, autoaugmentation is an extraperitoneal procedure that can be performed through a Pfannestiel incision and avoids the complications of transperitoneal bowel surgery. Although autoaugmentation is usually performed without a formal cystotomy, other bladder procedures, such as ureteral reimplantation and appendicovesicostomy, can be carried out (intravesically or extravesically) at the same time. Lastly, it is important to note that autoaugmentation does not preclude further augmentation procedures if unsuccessful.

The main disadvantage of autoaugmentation is the inability to predict which patients will do well with this technique. An additional concern is the theoretical risk of bladder rupture that has been demonstrated in animal studies.[162,163] Although perforation of the autoaugmented bladder has been reported in only one patient to date,[164] the overall increased risk of bladder rupture compared with other types of bladder augmentation has yet to be defined.

Surgical Technique

Patients should receive a full bowel preparation preoperatively and be counseled on the possible need to perform an alternative type of augmentation if intraoperative findings dictate that autoaugmentation is not technically feasible. Specifics regarding the technique of autoaugmentation have been well described by Snow and Cartwright.[159] The procedure is usually performed through a Pfannenstiel incision and is done extraperitoneally. Once the bladder is mobilized, the peritoneal covering is entirely detached. Snow and Cartwright advocate the performance of intraoperative urodynamics, both before and after the autoaugmentation. Although not definitive, intraoperative urodynamics can be useful in making an assessment of potential success. It also assists in establishing the maximum volume following autoaugmentation to which the bladder can be safely distended during the immediate postoperative period.

Once initial intraoperative urodynamics is completed, the bladder is filled and a needle-tipped electrocautery is used to divide the detrusor musculature from the underlying epithelium (Figure 57.11). This is usually started ventrally in a vertical fashion. The plane between the underlying epithelium and the overlying muscle is then

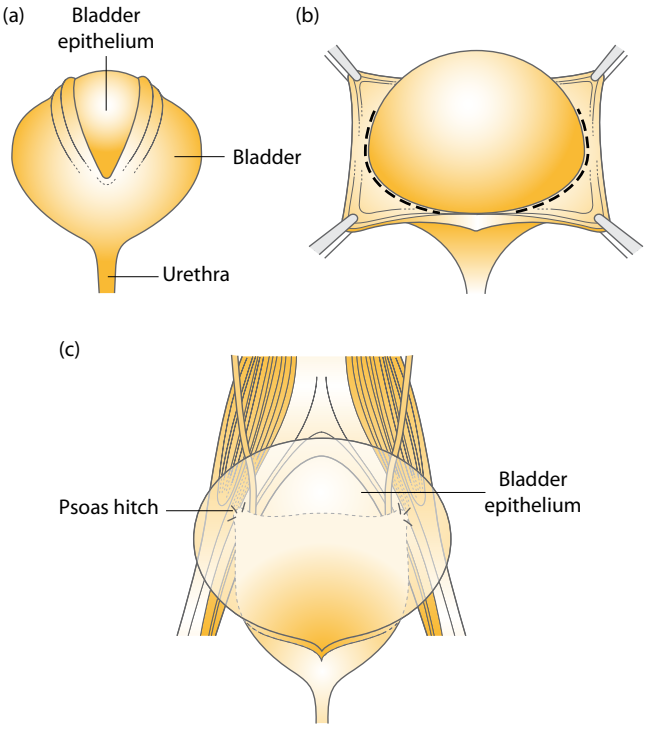

FIGURE 57.11 Autoaugmentation. (a) The detrusor muscle is incised in the midline and a plane is established between the muscle and the underlying mucosa. (b) This plane is further developed, and a large mouth diverticulum is created. (c) The remaining detrusor muscle is fixed posteriorly to prevent its coaptation. (Adapted from Cartwright PC, Snow BW. *J Urol* 1989;142:1050–3. With permission.)

identified and further developed using both blunt and sharp dissection. Special care is taken to avoid tears in the urothelium, since this can be difficult to repair in some cases and urinary extravasation postoperatively is associated with inflammation. Inability to distend the bladder postoperatively may result in contraction. When perforation does occur, it should be repaired with fine, absorbable suture. Removal of overlying muscle fibers continues until the detrusor musculature is removed from at least one-half of the bladder. Optimally, as much musculature is removed as possible. At this juncture, intraoperative urodynamics is repeated once again. If there is minimal to no improvement in bladder capacity and/or compliance, autoaugmentation should be abandoned and conventional enterocystoplasty undertaken following excision of the redundant bladder epithelium.

After autoaugmentation is completed, either one can excise the detached detrusor musculature or the remaining lateral bladder muscle can be attached to the psoas muscles. However, neither of these steps has been found to be essential for success.[159,165] Postoperatively, a urethral catheter and Penrose drain are left in place. Suprapubic tubes are avoided, as the bladder should be watertight. Experience has shown that bladder distension during initial healing is important for surgical success. This can be accomplished either by intermittent distension of the bladder to the capacity that was determined appropriate intraoperatively or by maintaining catheter drainage with constant bladder distension at an intravesical pressure of 20–40 cmH_2O. The catheter can generally be removed in 1–2 weeks. It is recommended that a cystogram be performed before catheter removal to exclude urinary extravasation.

Recently, several authors have demonstrated that technically successful bladder autoaugmentation can be accomplished laparoscopically.[166–169] Although a laparoscopic approach is feasible, further experience is necessary to determine whether this approach is clinically successful and cost-effective.

Results

The efficacy of autoaugmentation in improving bladder capacity and compliance has been varied. Cartwright and Snow[157] have reported follow-up of greater than 1 year in 30 patients, 19 of whom had a neuropathic bladder secondary to spina bifida. All patients had preoperative urodynamic evidence of reduced bladder compliance and detrusor hyperreflexia. While clinical success has been dramatic in some, the overall results have been less impressive. One-third of the patients had a significant increase in bladder capacity, an additional third were unchanged, while one-third had loss of capacity. Evaluation of bladder compliance revealed that 60% had an improvement in compliance by greater than 50% compared with preoperative measurements, 20% had a 20%–50% improvement, and the remainder did not change significantly. Following autoaugmentation, the majority of patients remained on intermittent catheterization, although 20% demonstrated the ability to void spontaneously. Seven of these 30 patients have required secondary enterocystoplasty.

Snow and Cartwright[159] have reevaluated preoperative parameters in these patients in an effort to identify specific factors that would help to prognosticate eventual outcome following autoaugmentation. Unfortunately, they were unable to identify any such factors. However, certain generalizations can be made from this analysis. Autoaugmentation appears to be poorly suited to patients with a history of bladder exstrophy or multiple prior bladder operations, since in these patients it is difficult to develop a plane between the bladder muscle and mucosa. Results have also been relatively poor in these groups. The ideal candidate is the patient with a near-normal bladder capacity but reduced compliance.

Since the original publications describing the autoaugmentation technique, several other centers have reported their experiences with autoaugmentation in children. Stothers et al.[170] performed autoaugmentations in 12 pediatric patients. They observed a mean increase in bladder capacity of 40% and a mean decrease in leak point pressure of 33%. Skobejko-Wlodarska et al.[171] have reported on the use of autoaugmentation in 21 children with spina bifida and found a modest increase in bladder capacity in two-thirds of patients and significant improvements in bladder compliance in another two-thirds. Two recent series with long-term follow-up in children with myelomeningocele have demonstrated less favorable results.[172,173] Both studies demonstrated that a majority of patients were considered surgical failures due to a lack of clinical and/or urodynamic improvement and a high incidence of patients requiring subsequent enterocystoplasty.

Finally, in a long-term functional outcomes assessment of autoaugmentation, Aslam and Agarwal reported on 33 patients with a mean follow-up of 148 months. A total of 10 of the 18 patients with idiopathic detrusor overactivity (55.5%) and 6 of the 15 patients with neurogenic detrusor overactivity (40%) showed marked improvement in symptoms. An overall success rate of 48.5% was achieved. The conclusion of this study was that autoaugmenation offers a reasonable long-term success rate to patients undergoing surgical treatment for refractory detrusor overactivity.[174]

The experience with autoaugmentation in the adult population appears to be more predictable and consistently favorable than the results described thus far in children. Stohrer et al.[175,176] reported on 50 adult patients from their spinal cord injury center. In patients with neuropathic hyperreflexive bladders that were refractory to medical therapy, bladder autoaugmentation was found to increase mean bladder capacity from 121 to 406 mL, with concomitant improvements in bladder compliance. Leng and colleagues[177] recently compared the efficacy of enterocystoplasty with autoaugmentation in adults. They reported on more than 60 patients undergoing either autoaugmentation or conventional enterocystoplasty. There were no significant differences in postoperative urodynamic parameters between enterocystoplasty and autoaugmentation in patients with refractory detrusor instability, interstitial cystitis, radiation cystitis, and other forms of neuropathic bladder. An important finding was that enterocystoplasty was uniformly superior to autoaugmentation in patients with a history of myelodysplasia. The overall improvement in the results of autoaugmentation in adults may be related

to differences in the bladder disease processes and patient population. Autoaugmentation is mostly performed in children with a neuropathic bladder from congenital causes, while in adults the neuropathic bladder is usually an acquired condition. It may be that autoaugmentation is more successful in adults because surgery is undertaken earlier in the disease process, prior to irreversible histologic and functional changes in the bladder wall.

Seromuscular Enterocystoplasty

Seromuscular enterocystoplasty involves the use of a demucosalized flap of the colon, stomach, or ileum. The removal of the gastrointestinal mucosa results in a denuded seromuscular flap that can be either (1) used alone as an augmentation flap that is subsequently reepithelialized with native urothelium from the native bladder, or (2) used in conjunction with autoaugmentation in which the seromuscular is placed over the exposed bladder mucosa of an autoaugmented bladder. The use of a demucosalized segment of bowel for bladder augmentation was first described by Shoemaker in 1955.[178,179] He was able to show that seromuscular bowel flaps, when placed into the bladder wall with the denuded side either inward or reversed, such that the serosa faced the lumen of the bladder, were reepithelialized by urothelium. Unfortunately, subsequent long-term studies in small and large animals have consistently demonstrated that seromuscular bowel segments alone scar and contract.[180–183] Histologic evaluation suggests that the scarring is due to the trauma associated with the demucosalization process and/or a prolonged inflammatory response in the denuded bowel before the reepithelialization of the seromuscular flap from the native bladder urothelium occurs.

The intention of seromuscular enterocystoplasty is to combine the advantages of conventional enterocystoplasty while preserving the native urothelium of the bladder. This procedure ideally results in a muscle-backed augmentation flap that is lined with urothelium. Contraction of the seromuscular flap is hopefully avoided by either rapid regrowth of native urothelium over the demucosalized surface or adherence of the native urothelium to the demucosalized gastrointestinal segment (when combined with autoaugmentation). Numerous animal studies have demonstrated that seromuscular enterocystoplasty with or without autoaugmentation can successfully augment the bladder with elimination of the complications related to retained intestinal epithelium.[184–188] However, clinical experience thus far has been mixed and varied. Early experience with this procedure suggested that the success may be limited by the same factors that give rise to inconsistent results with autoaugmentation. More recent modifications of the technique, including improved methods for demucosalization and constant distention of the seromuscular flap during the initial postoperative period, have demonstrated that more reliable results are possible. Further experience with long-term follow-up is needed to better determine the factors that are important in predicting success and whether this type of augmentation remains stable without future fibrosis, loss of compliance, and/or metaplastic changes. Nevertheless, seromuscular enterocystoplasty represents an intriguing advancement in bladder augmentation techniques whose appropriateness for routine use in children is currently being defined.

Anatomy and Physiology

Seromuscular enterocystoplasty has been accomplished with stomach, ileum, and colon. The metabolic consequences of seromuscular enterocystoplasty are presumed to be minimal, since the native urothelium is kept intact. This assumption is supported in part by animal studies.[187] Histology from these studies reveals that the urothelium covering the seromuscular flap appears normal.[188,189] Whether late metaplastic changes will occur in the bladder urothelium when it is placed in direct contact with a seromuscular segment of bowel is not known. It has been well documented that stromal–epithelial interactions in other individual organs are important for normal cell growth and function.[190,191] The stroma of the bowel segment may adversely affect the overlying growth and function of the bladder urothelium in the long term.

Advantages and Disadvantages

The advantages of this procedure are similar to those of autoaugmentation, with the most important being preservation of the native urothelium. This avoids the aforementioned complications associated with the interposition of heterotopic intestinal epithelium in the urinary tract. Since it has been shown that partial reepithelialization of the seromuscular segment with enteric epithelium can occur, it is not clear that these problems will totally be avoided. This is especially important when considering the long-term risk of tumor formation, since the presence of any intestinal mucosa is clearly worrisome. An advantage of seromuscular enterocystoplasty over autoaugmentation alone is the provision of adequate muscle backing of the augmented segment. This may potentially reduce the risk of scarring and fibrosis and may lessen the risk of spontaneous perforation.

There are currently two major disadvantages to this procedure. It is a technically demanding procedure and much more labor-intensive than conventional augmentation cystoplasty or autoaugmentation alone. In addition, clinical experience is limited, and the available published results are mixed with regard to postoperative urodynamic improvements. Postoperative distension of the augmented bladder appears to be an important factor for the success of this procedure. Thus, some authors have advocated routinely increasing bladder outlet resistance with seromuscular enterocystoplasty and the avoidance of concomitant intravesical procedures when possible.[158]

Surgical Technique

Seromuscular enterocystoplasty is initially begun by isolating a segment of the stomach, ileum, or colon (Figure 57.12). The isolated segment of the stomach or bowel is then detubularized. The most difficult and technically demanding portion of this procedure is demucosalization of the flap. The plane of dissection and whether the submucosa should remain with the seromuscular flap is a point of contention. It has been suggested by some authors that the muscularis mucosa (which is contained

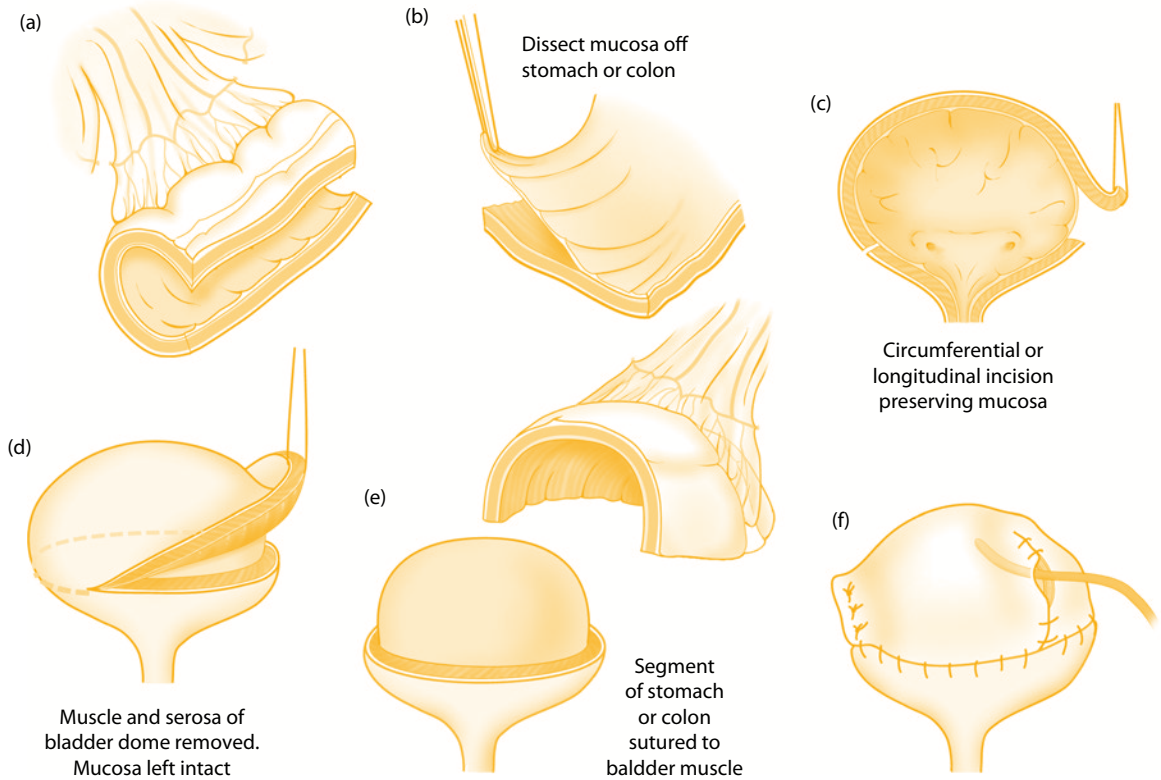

FIGURE 57.12 Seromuscular enterocystoplasty. (a) A portion of the stomach or colon is isolated. (b) The mucosa is removed with sharp dissection. (c and d) An autoaugmentation is then performed, resulting in an exposed diverticulum of bladder mucosa. (e) The demucosalized flap of the stomach or colon is laid on top of the exposed mucosa and anastomosed to the edges of bladder muscle. (f) A drain can be placed in between the flap and the mucosa to facilitate adherence of the two surfaces. (Adapted from Buson H. et al., *Urology*, 1994;44:743–8. With permission.)

in the submucosa) needs to be removed, in addition to the enteric mucosa, to prevent regrowth of intestinal mucosa and flap contracture,[192] while others have argued that preservation of the submucosa with the flap is necessary to prevent flap contracture during the immediate postoperative period.[193] Once the plane of dissection is established, removal of the mucosa can be accomplished with sharp dissection and intermittent use of electrocautery. Usually, the mucosa can be progressively peeled away from the underlying muscle once the proper plane has been established. Occlusion of the arterial blood supply during this dissection can be done to decrease blood loss and facilitate visualization.[194] Since some have postulated that the trauma of demucosalization is a factor that contributes to flap contracture, alternative methods of mucosa removal have been developed, including the use of an argon beam laser.[195] Alternatively, the bowel segment can be distended with a Foley balloon prior to detubularization and the seromuscular flap can be dissected off of the underlying mucosa from the outside.[196]

If the seromuscular enterocystoplasty is to be performed alone without autoaugmentation, the demucosalized flap is placed onto the bivalved bladder, as is routinely done for intestinocystoplasty. Postoperatively, some authors have suggested the need for diversion of urine from the bladder with externalized stents and distention of the augmented bladder with a silicone balloon for the first couple of weeks postoperatively to avoid flap contraction.[197]

If the seromuscular enterocystoplasty is to be combined with autoaugmentation, the flap is placed on top of the exposed mucosa following completion of the autoaugmentation, as described in the previous section. Adherence of the bladder mucosa to the raw surface of the seromuscular flap is felt to be critical to the long-term success of this operation. Several techniques have been suggested to facilitate this process. A small, flat Jackson–Pratt drain has been used to prevent the formation of a hematoma or seroma between the urothelium and the seromuscular flap that could prevent adherence between the two surfaces. Multiple mattress sutures can also be used to secure the flap to the native bladder urothelium. As with autoaugmentation, postoperative distension of the bladder with intermittent irrigation or constant distension of the bladder to 20–30 cmH_2O appears to be important for success. Carr et al.[194] have described the use of a Helmstein balloon in the bladder postoperatively to produce partial distension and compaction of the urothelium against the denuded muscle.

Results

Initial preliminary reports by Dewan and Gonzalez in both animal models and humans were encouraging.[188,189,198,199] In a series of 16 patients undergoing seromuscular colocystoplasty using sigmoid colon, bladder capacity was increased to almost 2.5 times the preoperative volume and

end filling pressures decreased by approximately 50%.[199] Dewan and Stefanek[198] reported on five patients undergoing seromuscular gastrocystoplasty. Four of the five patients had urodynamic evidence of improved bladder capacity and compliance during the first postoperative year. Despite these initial encouraging results, it is important to note that the follow-up in these early series was relatively short, and that approximately 25% of patients have eventually required a secondary operation due to either complications related to the seromuscular flap (contracture) or failure to adequately improve bladder capacity and/or compliance.

A subsequent report from Carr et al.[194] described 13 patients that underwent seromuscular gastrocystoplasty with variable success.[194] The mean follow-up was 50 months. Five patients had a good outcome and four had a fair outcome with regard to objective urodynamic and subjective clinical improvement. The remaining four patients had a poor result and required reaugmentation. Evaluation of preoperative urodynamic and radiographic data in these patients again demonstrated that it was not possible to predict preoperatively which patients would do well after seromuscular gastrocystoplasty.

More recent large series with long-term follow-up have been reported with more encouraging results. Lima et al.[197] reported on 129 patients that underwent seromuscular enterocystoplasty, of which 24 were done without concomitant autoaugmentation. Sigmoid was used in 104 cases, and ileum was used in the remaining 25. Median follow-up was 51 months. A 329% increase in bladder capacity was noted, and a sevenfold increase in bladder compliance. No significant mucus production was noted in any patient, and no cases of perforation were observed. Ten percent of patients did require reaugmentation. The authors attributed their improved success to several modifications in technique. This includes demucosalization of the seromuscular flap from the outside with use of an intraluminal Foley balloon during this important dissection and routine postoperative distention of the bladder and diversion of the urine for 2–3 weeks. Jednak et al.[200] have also reported favorable results in 32 patients. All were done in conjunction with autoaugmentation. Mean follow-up was 1.6 years. A near twofold increase in bladder capacity was noted with a 12.5% reaugmentation rate. A more recent report from the same group has also demonstrated the ability to combine seromuscular enterocystoplasty with placement of an artificial sphincter with no increase in the complication rate.

Recurrent or persistent intestinal mucosa has been found in several patients after seromuscular enterocystoplasty.[192,200] Whether this partial intestinal regrowth is progressive or clinically relevant remains to be determined. As mentioned above, it has been suggested and supported by animal studies that removal of the submucosa may prevent reepithelialization of the seromuscular flap with islands of native enteric mucosa.[192]

Ureterocystoplasty

The use of ureteral tissue for bladder augmentation was first described in 1992.[201,202] Since then, its use in children has become more popular.[203–205] For many reasons, native ureter is the best tissue available for augmentation cystoplasty. It is autologous, lined with urothelium, backed by muscle, distensible, and compliant. However, few patients in need of bladder augmentation have widely dilated ureters available for such use. Patients who are candidates for ureterocystoplasty should have either a nonfunctional renal unit that can be removed, making the ureter and renal pelvis available, or a functional renal unit that is associated with a massively dilated, tortuous, and elongated ureter.[203,206] The lower ureter can then be used for augmentation while kidney drainage is reestablished either by reimplantation of the straightened upper ureter into the bladder or by transureteroureterostomy.

One of the challenges that one faces in selecting the appropriate patient for ureterocystoplasty is determination of whether the ureter that is to be used is going to be adequate enough for successful augmentation. Recent clinical experience and long-term urodynamic follow-up suggests that the detubularized and reconstructed ureter following ureterocystoplasty remains compliant, but that the overall compliance, distensibility, and volume may not increase significantly compared with the dilated intact ureter in its preoperative state. Thus, postoperative urodynamic studies in a patient that has a refluxing ureter that was used for ureterocystoplasty may not show a significant increase in volume and compliance of the augmented bladder compared with preoperative studies (when the ureter was refluxing and intact).[207] However, if the ureter that is to be used is not refluxing, then improvement in urodynamics following ureterocystoplasty would be expected and may be directly related to the degree of ureteral dilatation that is present preoperatively. Given this, preoperative urodynamic studies can be very valuable in select patients in predicting success or failure following ureterocystoplasty, especially in the setting of refluxing ureter.

Ureterocystoplasty can also be appropriate in patients with end-stage renal failure on dialysis who are awaiting transplantation and are in need of augmentation owing to bladder dysfunction. As is the case with conventional intestinocystoplasty, the augmented bladder following ureterocystoplasty and subsequent transplantation has been shown to function adequately.[208]

Anatomy and Physiology

Preservation of the ureteral blood supply is paramount when performing ureterocystoplasty. The normal ureter receives its blood supply from branches of numerous vessels, including the aorta and renal, gonadal, and common iliac arteries (Figure 57.13). The upper ureter receives its blood supply medially, while the lower ureter receives it posterolaterally. There are extensive anastamosing plexuses in the adventitia of the ureter that are important to preserve if viability of the ureter is to be maintained. Careful attention to these vessels allows for long segments of ureter to be mobilized without vascular compromise. Ureteral urothelium is contiguous with the urothelium from the bladder and has similar physiologic characteristics. Peristalsis of the ureter depends on autonomic innervation and input from intrinsic pacemaker sites in the minor calyces of the renal collecting system.[209] Although the ureter is detubularized and its inherent innervation is

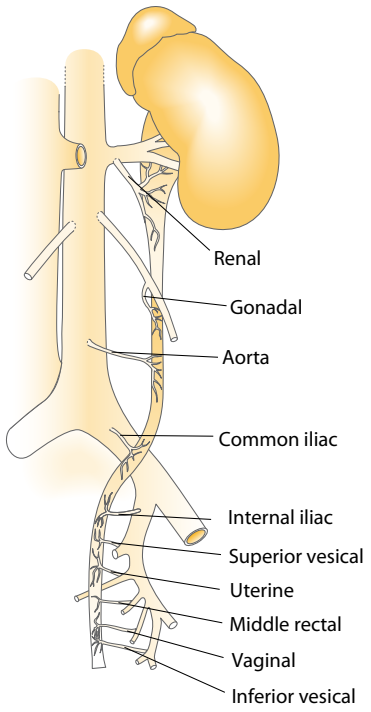

FIGURE 57.13 Arterial blood supply to the ureter. (Adapted from Lindner H. *Clinical Anatomy*, Norwalk, CT: Appleton and Lange, 1989. With permission.)

disrupted with ureterocystoplasty, it appears that the ureteral tissue still maintains some ability to contract.

Advantages and Disadvantages

There are several advantages in using the ureter for augmentation. As is the case with autoaugmentation, the major advantage of ureterocystoplasty is that the native urothelium is preserved, thereby avoiding the specific potential problems associated with the use of the bowel. Unlike some cases following autoaugmention, the full-thickness opened ureter does not tend to shrink with time, unless the vascular supply is compromised. In patients with end-stage renal disease, the procedure can be performed extraperitoneally, thus preserving the peritoneum for future peritoneal dialysis. Alternatively, it can also be performed with laparoscopic assistance for the nephrectomy and upper ureter mobilization.[210] When needed, concomitant procedures in the bladder may also be performed. It seems likely that the risk of tumor formation will be avoided, and perforation of the augmented bladder may be less probable. However, long-term follow-up will be needed to confirm these possibilities.[203] Finally, there is increased potential for spontaneous voiding postoperatively, especially in patients who are able to empty their bladders adequately preoperatively.

The main disadvantage of ureterocystoplasty is that it is only applicable in a minority of patients. More recently, the use of ureterocystoplasty has been expanded in an attempt to take advantage of this valuable tissue and make it available to more surgical candidates. Its use has been reported in patients with a duplex system in which either the upper or lower pole is nonfunctioning.[211] In patients with a duplex system and a dilated ureter in conjunction with a functioning renal segment, drainage of that segment can be accomplished with an ipsilateral pyeloureterostomy or a ureteropyelostomy with preservation of the distal portion of the ureter for augmentation. Ahmed et al.[212] also described the tandem use of bilateral megaureters for ureterocystoplasty.

Efforts are being made to produce dilated ureters in an attempt to make ureterocystoplasty available to more patients. Lailas et al.[213] have demonstrated in a rabbit model that a temporary cutaneous ureterostomy can be used to perform hydrostatic distension of the ureter with subsequent successful ureterocystoplasty. Others have reported that placement of a tissue expander in pig ureters adequately dilates the ureter.[214,215]

Surgical Technique

Patients undergoing ureterocystoplasty should have a full bowel preparation and sterilization preoperatively in case the ureter is not suitable for augmentation. The procedure can be performed either through a midline incision with a transperitoneal approach to the urinary tract or via two incisions, such as is used for nephroureterectomy.[216] The latter approach is extraperitoneal. This may be advantageous in patients with severe renal insufficiency who may subsequently require peritoneal dialysis. A nephrectomy is performed initially, preserving the renal pelvis. The upper portion of the ureter and renal pelvis are then mobilized (Figure 57.14). Efforts should

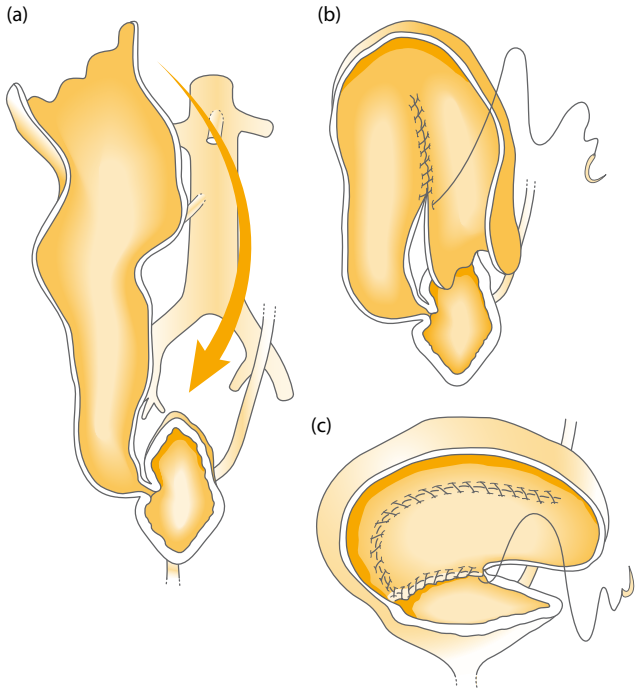

FIGURE 57.14 Ureterocystoplasty. A standard nephrectomy is performed with preservation of the renal pelvis. (a) The proximal ureter is mobilized with preservation of the medial blood supply. (b) The ureter is then detubularized with the incision for detubularization connecting with the off-center cystostomy. (c) The ureter is folded on itself and anastomosed to the opened bladder.

be made to preserve as much renal pelvis as possible since this increases the surface area of the augmentation. One should include any available periureteral tissue to protect the network of vessels within the ureteral adventitia. Although the blood supply from the lower ureter (which is derived posterolaterally) can maintain the viability of the upper ureter via this adventitial network, efforts should also be made to preserve collaterals from the gonadal vessels and the main renal vessels. These vessels supply the renal pelvis and upper ureter directly, and their preservation helps to ensure adequate vascular supply to the upper portion of the ureter. As Churchill et al.[217] have noted, preservation of the upper ureteral blood supply is most important when previous reconstructive surgery has compromised the collaterals involving the distal ureter.

Following mobilization of the renal pelvis and ureter, the ureter is detubularized and reconfigured to form a patch. The bladder is then opened. The bladder incision extends from the ipsilateral ureteral orifice to the contralateral ventral quadrant of the bladder. The incision is carried through the ipsilateral ureteral orifice so that it unroofs the intravesical ureter and meets the detubularization incision in the ureter. This allows the bladder to be opened sufficiently for ureterocystoplasty without much risk of an hourglass deformity. Alternatively, to preserve vascularity, the incision can stop short of the orifice, maintaining the normal configuration of the distal ureter for a few centimeters.[202] Once the bladder is adequately opened, the reconfigured ureteral segment is sutured to the defect in the bladder, creating a wide anastomosis. Prior to closure, a suprapubic tube is placed through the native bladder, and left indwelling for 2–3 weeks. Postoperative care is essentially the same as for routine enterocystoplasty except that daily irrigation for mucus is not required.

Results

Since its original description in 1992, widespread experience has been gained with ureterocystoplasty. Early reports demonstrating its efficacy led to increased enthusiasm for this technique and a desire to use the ureter instead of intestinal segments whenever adequate ureteral tissue is available. Churchill et al.[203] initially reported on 16 patients in which there was a 218% increase in bladder capacity, a 284% increase in pressure-specific bladder capacity, and a 227% increase in bladder compliance. In a follow-up to this study, Landau et al.[218] compared the urodynamic results between patients treated with ileocystoplasty and those with ureterocystoplasty. They reported no significant differences in the postoperative mean increase in bladder capacity and pressure-specific bladder volume. Both procedures resulted in excellent functional results. Hitchcock et al.[219] described similar excellent short-term results in eight patients.

Subsequent reports have also demonstrated that ureterocystoplasty can be an effective augmentation procedure but have further clarified which patients are most appropriate for the procedure and what amount of ureter is needed for success. Pascual et al.[220] described 22 patients in which only the distal ureter of a single ureter was utilized for augmentation. While increases in capacity and improvement in compliance were noted, only half of the patients reached the expected age capacity of the bladder, and the overall results were less successful than those of other reported previous series in which the entire ureter was utilized. In the largest series to date, Husmann et al.[207] reported on 64 patients from multiple institutions. In 40 of the patients, augmentation was performed with a complete single or double collecting system. In 9/40 patients, reflux was not present and postoperative success directly correlated with a preoperative ureteral diameter of greater than 1.5 cm. In the remaining 31 patients, reflux was present preoperatively. In these refluxing patients, if the system on preoperative urodynamics demonstrated only mild noncompliance (greater than 20 mL/cm water), then ureterocystoplasty improved compliance onefold and was adequate. However, if the system preoperatively demonstrated poor compliance, then ureterocystoplasty did not adequately improve capacity and compliance, resulting in 81% of patients having either undergone or being considered for reaugmentation.

Collectively, these results suggest that the ideal patient for ureterocystoplasty is one with a massively dilated ureter in which most or all of the ureter can be used for augmentation purposes. If reflux is present preoperatively, then preoperative urodynamics can be predictive of future success. If a poorly compliant system is present in the setting of a dilated refluxing ureter, then failure and the need for reaugmentation are likely. Novel techniques to make ureterocystoplasty more readily available for patients that do not have massive dilatation of the ureter are currently being investigated.

TISSUE-ENGINEERED BLADDER

The complications associated with using various portions of the gastrointestinal tract for genitourinary reconstruction in both adults and children who have been described in this chapter have stimulated the development of tissue engineering techniques for bladder reconstruction through bladder regeneration. Current research efforts are focused on the development of biodegradable materials that are well characterized with predictable behavior that can be used as alternatives to gastrointestinal segments for bladder reconstruction. Although attempts at bladder reconstruction via bladder regeneration are not new,[221] the major obstacle has been the unavailability of a biomaterial, either permanent or biodegradable, that will function as a suitable scaffold to allow the process of regeneration to occur either naturally or with the addition of cultured cells. The ideal graft material is one that would be replaced by the host tissue, provide a low-pressure reservoir, and serve as a scaffold for regeneration of the bladder wall with normal functional characteristics. If a suitable graft material were developed, the need for autogenous tissue and the associated complications of intestinal segments could be eliminated. Currently, two types of tissue engineering technology have been shown to induce bladder regeneration in preliminary studies. These are the “unseeded” and “seeded” technologies.

Unseeded Technology

The first technique currently being investigated for bladder regeneration is unseeded technology. This involves the use of tissue matrix grafts that are biodegradable, acellular, collagen based, autologous, or xenogenic.[222–224] This technology involves placement of the graft into the wall of the host bladder. The body then provides the needed environment for subsequent cell growth and tissue generation. This represents an unseeded bladder-regenerating process.

Historically, the major obstacle to unseeded tissue engineering technology has been the inability to develop an optimal biomaterial that will act as a suitable scaffold for the "natural" process of regeneration. Synthetic nonbiodegradable materials such as silicone, rubber, polytetrafluoroethylene, and polypropylene have been tried with unsuccessful results because of host–foreign body reactions.[225–229] As a consequence of these failures with nonbiodegradable materials, synthetic biodegradable materials were developed. It was anticipated that these grafts will allow the host bladder adequate time for regeneration but dissolve before the onset of foreign body reactions. These materials have been used experimentally and have shown less graft encrustation and fewer infectious complications than nonbiodegradable materials. However, graft shrinkage still limits the potential clinical utility of these materials.[230] Nonsynthetic biodegradable materials, such as placenta, amnion, and pericardium, have been investigated and have shown a clear ability to host bladder regeneration.[231–234] However, despite initial encouraging laboratory results, none of these materials have been found to be suitable for clinical use.

More recently, new types of biodegradable material have been developed that have shown tremendous potential for the induction of bladder regeneration with unseeded tissue engineering technology. These materials are acellular extracellular matrix (ECM) grafts that are derived from various organs. The graft is made acellular by a mechanical process that lyses the cells and/or by detergent and enzymatic extraction. These types of ECM grafts have been derived from full-thickness bladder and stomach and the submucosal layer of the small intestine.[222,235,236]

The most thoroughly studied collagen-based ECM graft for bladder augmentation and urinary reconstruction using unseeded technology is the small intestinal submucosa (SIS).[237] SIS is a xenogenic membrane derived from pig small intestine in which the mucosa is mechanically removed from the inner surface and the serosa and muscularis are mechanically removed from the outer surface. This results in a thin, translucent membrane (0.1 mm wall thickness) composed mainly of the submucosal layer of the intestinal wall. Production of SIS is reminiscent of the manufacture of sausage casing. This unique material has been shown to function well with rapid replacement by native tissues and evidence of tissue-specific regeneration.[238–240]

SIS has been shown to be nonimmunogenic, with more than 1000 cross-species transplants and direct challenge testing elucidating no response.[241–243] In addition, SIS is unique from other biomaterials that have been studied thus far in that it contains a combination of active intrinsic growth factors, cytokines, structural proteins, glycoproteins, and proteoglycans that may assist in cell migration, cell-to-cell interaction, and cell growth and differentiation during the regenerative process.[244–246]

SIS grafts have been shown to promote full-thickness bladder regeneration in both rat and canine animal models.[247] The regenerated bladder tissue is composed of all three layers of the normal bladder wall (urothelium, smooth muscle, and serosa). In addition, the regenerated segment is contractile, compliant, and functionally innervated. Urodynamic studies in a long-term canine augmentation model have demonstrated that the SIS augmented bladder maintains normal bladder capacity and compliance for at least 15 months postoperatively.[248] In vitro muscle strip studies on the regenerated portions of the bladders also demonstrate contractility and compliance that is similar to that of the normal bladder.[249] In these rat and canine studies, a partial cystectomy model was used for SIS augmentation in which $\geq$50% of the native bladder still remained as a bladder template. Subsequent work with a near-total cystectomy model in which a more severe defect is created ($\geq$90% of the bladder removed) resulted in less promising results. Severe fibrosis, adhesions, calcification, and graft contraction were noted. These discordant results in a near-total cystectomy model were likely secondary to poor neovascularization and resultant tissue ischemia in the central portion of the SIS graft. Therefore, the ability of unseeded SIS to induce functional augmentation of the bladder may in part be limited to the size of the graft and/or percentage of the native bladder that remains as a template for the support of neovascularization of the regenerating tissue.[294]

In all the animal studies utilizing SIS that have performed thus far, there has always been a variable degree of regeneration noted. This is likely due to the fact that SIS is biologic material that is derived from different segments of the small bowel, and that the intrinsic growth factors and structural makeup of the bowel may be variable depending on the bowel segment and animal that it is harvested from. This notion is supported by additional work by Kropp et al.[250] that has shown that bladder regeneration is more uniformly successful when using SIS that is harvested from the distal ileum from a 3-year-old sow as compared with the proximal jejunal segment from the same-age sow.[251] Additional work is now being done to develop improved processing techniques that will result in a more uniform type of SIS that will be more consistent in its regenerative capabilities.

Acellular ECM grafts to SIS have also been shown to induce bladder regeneration. Preliminary work by Sutherland et al.[224] and Piechota et al.[270] demonstrated that successful morphologic and functional regeneration of the rat urinary bladder can be accomplished with homologous bladder acellular matrix grafts (BAMGs). Reddy et al.[236] also reported on partial bladder substitution with porcine bladder acellular matrix allografts (BAMAs) in a porcine model. They demonstrated that the regenerated urothelium with BAMAs was multilayered and that there was also histologic evidence of organized smooth muscle regeneration and neoangiogenesis at 30 days.

The above experience with SIS and other similar ECM-derived biomaterials clearly demonstrates that bladder regeneration using unseeded tissue engineering technology is feasible. However, there are still several limitations that have prevented this technology from progressing to clinical implementation. Commercial manufacturing that

yields predictable biological activity has not yet consistently been achieved. In addition, there is increased central scarring with contraction in larger grafts that is likely in part due to insufficient neovascularization and resultant graft fibrosis. With greater understanding of the individual composition of the various biomaterials,[252,253] the cell-to-cell interactions, and the growth factors[224,254–256] that are involved in the bladder regenerative process that promote adequate ingrowth of native cells and neovascularization, the ability to produce a more uniform biodegradable graft may be realized. Thus, additional research is still needed to bring us closer to having an off-the-shelf, acellular, clinically available product for bladder augmentation.

Seeded Technology

The second type of tissue engineering technology, the seeded technique, involves the use of biodegradable materials that act as cell delivery vehicles for cultured cells from the patient. This technique has been applied to the urinary bladder. Initially, this process is begun by harvesting native bladder tissue for the establishment and expansion of primary cultures of both bladder smooth muscle and epithelial cells. Cilento et al.[257] demonstrated that it is possible to expand a bladder epithelial cell culture from a single biopsy specimen such that the cultured cells could cover a surface area of more than 400 m^2 within 8 weeks. Once the cells are grown, they are seeded on a biodegradable membrane in vitro and then transplanted back into the host for continuation of the regenerative process. Atala et al.[258] demonstrated the successful use of nonwoven polyglycolic acid (PGA) polymer sheets that allow the seeded growth of urothelial and smooth muscle cells. Further work demonstrated that these cell–polymer constructs could then be implanted into athymic mice, with the subsequent formation of organized layers of bladder epithelial and smooth muscle cells. Yoo et al.[259] and Oberpenning et al.[260] reported on the feasibility of dog bladder augmentation using allogenic bladder submucosa or PGA polymers seeded with urothelial and smooth muscle cells. Organized bladder histology was noted in the regenerated bladder tissue. More importantly, the regenerated bladder tissue was found to increase bladder capacity and was urodynamically compliant. Based on these encouraging results, more novel types of biodegradable scaffolds other than PGA polymers are now being evaluated both in vitro and in vivo for their potential use utilizing seeded technology.[261,262,292]

The demonstration that seeded technology can facilitate regeneration of functional bladder tissue in a large animal model provided the foundation for a landmark clinical trial that utilized autologous engineered bladder tissue as an alternative for conventional enterocystoplasty. Atala and colleagues performed augmentation cystoplasty on seven patients with spina bifida. PGA composite grafts seeded with autologous urothelial and smooth muscle cells were successfully implanted in these patients with additional utilization of an omental wrap around the seeded graft to aid in vascularization.[263] Although histological data at the 5-year follow-up displayed a trilayered architecture composed of urothelium, submucosa, and muscle, there was significant variability seen in the results with regard to the functional parameters of capacity, compliance, and leak point pressure. Only one of seven patients had an increase in bladder capacity and improvement in compliance similar to that which is routinely seen with conventional enterocystoplasty. This increase in bladder capacity took 5 years and was not observed in the first few years after augmentation. The reasons for this delayed response are not clear. In addition, patients were not able to spontaneously void and continued to require intermittent catheterization. This preliminary experience in humans with a neurogenic bladder clearly demonstrates that seeded technology can facilitate bladder regeneration to some degree. However, the results observed thus far do not compare favorably with conventional enterocystoplasty. Thus, additional research is needed to elucidate the reasons for the inferior results noted in this human trial compared with previous animal studies before it can be considered for clinical use.

Future direction

Although both unseeded and seeded technologies have been shown to be successful in animal models, the failure of these technologies to be successfully applied clinically demonstrates that there is much work to be done before bladder tissue engineering can be realized as a viable alternative to conventional bladder augmentation.[263] Three challenges that have been identified that currently limit our ability to be successful are (1) deficiencies in scaffold design, (2) use of an appropriate cell source for seeding, and (3) lack of adequate neovascularization of the regenerating graft. Current research is now being focused on these vital issues and is discussed next.

Scaffold Design

Biologic scaffolds have the advantage of their inherent content, in which intrinsic growth factors facilitate new tissue growth. However, as previously discussed, the inherent variability in these biologic materials is a hindrance. Synthetic materials are more consistent in content but lack biologic activity. Therefore, recent research efforts have focused on developing materials that are consistent in content yet still biologically active. Utilizing advancements in nanotechnology, synthetically derived and immunotolerant biomaterials are now being designed to provide the necessary structural and biological properties required to induce a seeded population of cells to successfully contribute to the dynamic process of bladder regeneration.[286] An example of this is the use of self-assembling peptide amphiphile (PA) systems. PAs are nanodesigned for self-assembly through the covalent attachment of hydrophobic (alkyl) and highly charged hydrophilic (peptidic) segments. The terminal end of each PA can include a biologically relevant epitope for signaling cells, binding other biomolecules, or yielding other functionality.[282] The PAs can then be designed to bind specific growth factors that can then be released locally in a time-dependent fashion to facilitate cell growth and differentiation. Harrington et al. have utilized this strategy to develop synthetic scaffolds coated with branched self-assembling PAs that can bind and release basic fibroblast growth factor (bFGF) and vascular endothelial growth factor (VEGF).[282,283] When these nanodesigned scaffolds were seeded with bladder cells, in vitro and in vivo studies

demonstrated the ability to modulate cell proliferation, cell adhesion, and matrix production.

Similar efforts have also been made to alter biodegradable scaffolds to alter structural content and enhance their regenerative properties with both unseeded and seeded technology. SIS and other ECM-based scaffolds have been coated with hyaluronic acid and/or poly(lactic-co-glycolic) acid polymers that can then impact cell adhesion, cell contraction, and permeability of the regenerating scaffold.[287] The latter could also positively impact the regenerative process in the bladder by limiting extravasation of urine and thereby reducing inflammation. Current efforts are now being directed at binding different bioactive nanoparticles in various manners to biodegradable scaffolds to better facilitate the regenerative process.[285,288,289] The ability to improve on current scaffold designs to enhance biologic response in a consistent fashion will be an integral component to enhance our ability to direct cell growth and activity during the regenerative process.

Cell Source

Despite the successful use of autologous bladder cells in seeded technology, there are significant concerns regarding the functional characteristics of the cells harvested from a dysfunctional or neurogenic bladder.[20,264,286] (Matoka and Cheng 2009). In vitro work has suggested that when bladder cells are harvested from a neuropathic bladder, they retain important functional differences, and that conversion to a normal phenotype when they are seeded on scaffolds may not occur.[249,278,280] These findings suggest that one of the plausible reasons that clinical trials with seeded technology failed to have consistent results is because the autologous *neuropathic* source of the cells did not have the capacity to facilitate regeneration of *normal* tissue. Therefore, emphasis has now been placed on exploring the possible use of both pluripotent and multipotent autologously derived stem cells that are capable of self-renewal and tissue-specific differentiation but will not illicit an unwanted immune response.[277] The potential use of stem cells in all disciplines of regenerative medicine has been heavily investigated. In the setting of bladder regeneration, the use of bone marrow–derived stem cells has been found to be particularly useful. Bone marrow–derived stromal cells have been shown to have the ability to differentiate into bone, fat, cartilage, muscle, and other lineages, as well as nonmesenchymal tissue cell types, such as endodermal and neural cells. Bone marrow stromal cells and mesenchymal stem cells (MSCs) derived from the bone marrow have both been successfully used as alternatives to autologous bladder cells for seeded technology.[291,293] These cells are easily harvested and highly proliferative, and undergo a relatively wide range of differentiation. When purified MSCs have been utilized with seeded technology for bladder augmentation in rodent models, bladder regeneration was noted that was indistinguishable from that obtained with autologous bladder cells.[279,292] This suggests that the MSCs have the capacity to differentiate into bladder smooth muscle. Recent work with seeded MSCs in a primate bladder augmentation model demonstrated that the seeded MSCs actively participate in the regenerative process, in addition to their role as a homing device for native cells.[290] Other sources of non–bone marrow–derived stem cells have also been shown to be plausible for use with seeded technology.[281,284] Clearly, the utilization of biocompatible scaffolds in combination with autologous stem cells for regenerative purposes in urology is an important advancement in the field of tissue engineering that may allow us to circumvent the use of abnormal cells from the host organ.

Neovascularization

Long-term survival of unseeded or seeded scaffolds depends on the development of adequate vascularization. A major hurdle that needs to be addressed with large grafts is the inability to provide adequate neovascularization to the regenerating tissue, which subsequently results in ischemia and tissue fibrosis.[285] A proposed strategy to overcome this problem is to create a scaffold or seeded graft for augmentation that already has a partially or fully intact autologous blood supply.[265–268] Alternatively, one can also create an angiogenic microenvironment in the regenerating tissue to facilitate improved vessel formation. This can be accomplished with the use of seeded vascular progenitor cells and/or vasculogenic growth factors. Sharma et al. has demonstrated that when both bFGF and VEGF are integrated into a synthetically derived scaffold, enhanced local angiogenesis can be observed.[289] In addition, it has been proposed that the use of MSCs in combination with CD34+/CD133+ endothelial progenitor cells (EPCs) may facilitate new vessel formation that further promotes improved neovascularization and muscle formation in the regenerated tissue.[269,290–292] These and other new strategies to facilitate adequate blood supply to the regenerating tissue may well be the most important issue that needs to be addressed if we are going to be successful in the clinical application of tissue engineering technology for bladder augmentation.

Further advancements in scaffold design, alternative cell sources for seeding, and measures to promote neovascularization will be areas of intense future research aimed at improving our current ability to provide large pieces of regenerated bladder tissue for augmentation purposes. However, before clinical application of this technology can be considered, additional work is still needed. At this point in time, conventional enterocystoplasty still represents the gold standard for augmentation of the neurogenic bladder. However, it is clear that bladder regeneration is possible using both unseeded and seeded tissue engineering technologies. Hopefully, further advances in current techniques will eventually revolutionize urologic reconstructive surgery to the point where tissue-engineered bladder will be offered as first-line therapy.

CHAPTER 58

Urinary Diversion

Peter D. Metcalfe and Richard C. Rink

INTRODUCTION

Efforts over the past generation have resulted in significant advances in the care of our most complex patients. Medical care has progressed to where renal insufficiency is rare and continence can be expected. Aggressive medical and surgical management often begins in childhood and is adapted to the clinical, individual, and social situation of the patient and family throughout their life. Therefore, while the majority of our patients and their families may desire complex reconstructions aimed at urinary continence, the need for simple and effective urinary diversion will always be required.

The best patient care will always demand judicious use of the full spectrum of urinary diversion, and this chapter acknowledges a broad array of diversion options. Some urologic scenarios still result in severe urinary obstruction in the premature neonate or critically ill, and effective, temporary diversion is required.[1,2] Furthermore, simple and effective diversion is still required for long-term care patients unwilling or unable to perform the necessary maintenance required of a continent urinary reservoir (CUR).[228] This chapter focuses on a multitude of temporary and permanent, historic and contemporary diversions, with an emphasis on surgical indications, techniques, and complications.

Temporary Urinary Diversion

Temporary Intubated Diversions

Urethral Catheter

The most frequently used urinary diversion is the Foley catheter. The most critical scenario occurs after the birth of a patient suspected to have posterior urethral valves (PUVs). Foley catheters (6 or 8 Fr) are readily available and usually easily inserted in the neonate. Sizing of the catheter is relatively accurate based on the patient's age (Table 58.1).[3]

Many current nursing policies recommend against the routine use of feeding tubes, due to their propensity to knot inside the bladder and result in traumatic extubation (Figure 58.1).[4,5]

Immediate catheterization of the newborn suspected of PUVs allows for stabilization of the patient until he or she is well enough to undergo VCUG and valve ablation. If the catheter is difficult to pass, a small lacrimal duct probe or manual guidance with a finger in the rectum may be helpful. Furthermore, it may be helpful to place a finger in the rectum to elevate and straighten the prostatic urethra during catheter placement. Occasionally, a bedside cystoscopy and placement of a council catheter over a guidewire are required, especially after a traumatic catheterization. After a difficult catheterization, it is appropriate to obtain an abdominal radiograph, after injecting a small amount of contrast through the catheter, or pelvic ultrasound, to ensure its proper position in the bladder.

Patients who suffer from chronic urinary retention, i.e., those with a spinal dysraphism, posterior valves, or other congenital anomalies, may benefit from intermittent catheterization, as opposed to the long-term use of an indwelling catheter. Clean intermittent catheterization (CIC) is an excellent option for children with chronic urinary retention and has proven to be safe in even the neonate.[6] However, the benefits in the short term need to be weighed against the difficulties with cooperation and the potential emotional trauma in the elementary school-aged patient.

Complications of urethral catheters in children are usually related to improper placement or prolonged use, and include urethral injury (Figure 58.1), urethritis or meatitis, urinary tract infection (UTI), urethral stricture, and bladder stones. Unfortunately, these are quite common, but they should be minimal with appropriate teaching and care and minimization of the use of urethral catheters.

Suprapubic Cystotomy

In rare circumstances, a urethral catheter is contraindicated or cannot be placed, and a suprapubic cystotomy tube can provide short- or long-term bladder drainage. A cystotomy is very useful in the infant or child with urethral trauma or following a reconstructive procedure for epispadias or complex hypospadias in the older child. Many excellent percutaneous kits are available to facilitate placement; however, in children this usually mandates a general anesthetic. A full bladder is an absolute prerequisite to percutaneous catheter placement and can be confirmed sonographically or cystoscopically. When attempting to place a suprapubic tube in the awake child, conscious sedation and infiltration of the skin and fascia with 1% lidocaine can be used to prevent anxiety and pain. It is helpful to establish the distance from the skin to the bladder lumen with a small needle to prevent injury to structures posterior to the bladder. The trocar is passed with gentle pressure until urine is obtained, and the catheter is passed 1–2 cm beyond the trocar. Alternatively, the percutaneous cystotomy tube and obturator needle are passed together into the bladder until urine is obtained,

TABLE 58.1 Approximate catheter size per patient age

Neonate	1500–2500 gm	6 Fr
0–6 months	3.5–7.5 kg	6 Fr
1 year	10 kg	6–8 Fr
2 year	12 kg	8 Fr
3 year	14 kg	8–10 Fr
5 year	18 kg	10 Fr
6 year	21 kg	10 Fr
8 year	27 kg	10–12 Fr
12 year	>27 kg	12–14 Fr

and then the catheter is advanced over the obturator. A recently described technique using the light from a flexible cystoscope to help localize the position of the bladder dome may allow percutaneous tube cystotomy in the more difficult cases.[7] In children with a history of prior reconstruction bladder surgery, it is often safest to use the site of a prior suprapubic tract that is fixed to the posterior abdominal fascia to place the suprapubic tube. The catheter is fixed to the skin with permanent suture. Suprapubic catheters tubes are intended for temporary bladder drainage, as long-term use has been associated with bladder wall thickening and contracture, UTI, bladder stones, and upper urinary tract dilation.[8,9]

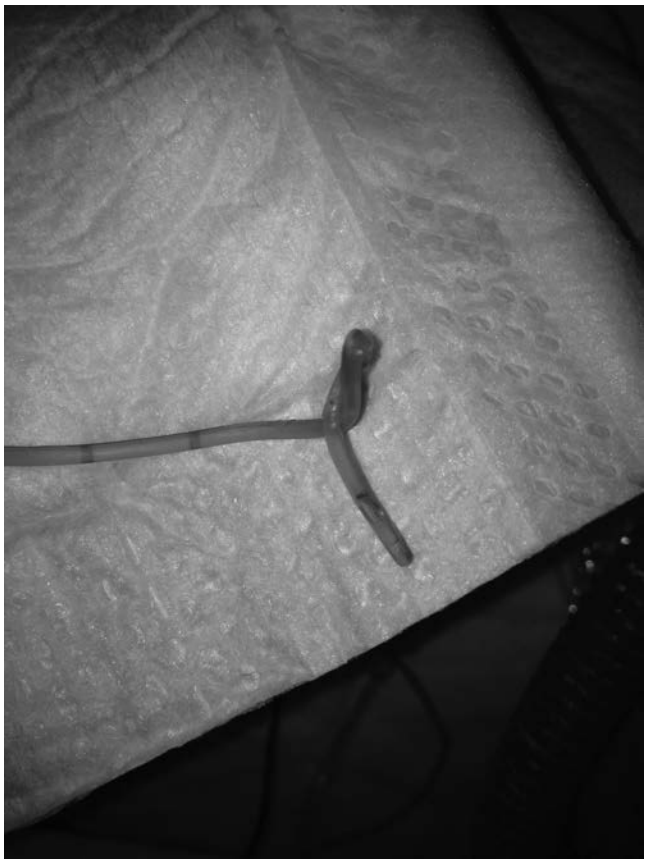

FIGURE 58.1 Photograph of 5 Fr feeding tube that had become knotted in the bladder of a neonate. Many nursing policies counsel against the use of feeding tubes as urinary catheters.

Open Cystotomy Tube

Because of the relative ease and safety of percutaneous cystotomy tube placement, open suprapubic tube placement is rarely used except in the context of a more extensive reconstructive procedure, or for placement of a large-bore drainage tube following urethral or bladder trauma. Another indication for the open technique is in a patient that has had prior extensive pelvic procedures that may have resulted in bowel adhesions to the anterior dome of the bladder.

With the patient in the supine position, the prevesical space is exposed using either a low transverse abdominal incision or a low vertical midline incision for those that may later undergo a transabdominal reconstructive procedure. After mobilizing the bladder dome, stay sutures are placed and a small cystotomy is made. The catheter is first brought through a small skin incision and then through the rectus fascia and muscle. After the tube has been placed in the bladder, it is pulled to the dome of the bladder and secured with a purse-string suture at the bladder. Bladder muscle adjacent to the tube is secured to the posterior fascial wall with absorbable suture, and the suprapubic tube is sutured to the skin.

Ureteral Stents

Ureteral stents are frequently used for temporary upper tract drainage following reconstruction, trauma, or stone surgery in children. There are two general options available, either an entirely internal stent or an external ureteral stent with one end brought out through the skin, urethra, or flank. External stents offer the benefits of not requiring an anesthetic for removal, being easily irrigated to prevent and treat internal obstruction, and having a miniscule risk of proximal migration. Problems that can be associated with internal JJ stents in children[10] include

- Obstruction
- Encrustation or stone formation
- Infection
- Proximal migration
- Stent fragmentation
- Discomfort or bladder spasms
- Requirement of anesthesia for removal of stent
- Hematuria

Internal JJ stents can be placed either at the time of open surgery, endoscopically, or by means of an antegrade approach through a percutaneous nephrostomy tract. Endoscopic placement of an internal stent may require fluoroscopy placement if the stent or "pusher" will not pass through the smaller size of the working port of pediatric cystoscopies. However, improvements are continuous, and most of our equipment can pass though the 5 Fr channels required for endoscopic correction of vesicoureteral reflux.

Percutaneous Nephrostomy Tubes

Improvements in the expertise and availability of pediatric interventional radiologists has led to percutaneous nephrostomy tube drainage almost completely replacing the need for open nephrostomy tube placement in children. Indications for nephrostomy tube drainage in

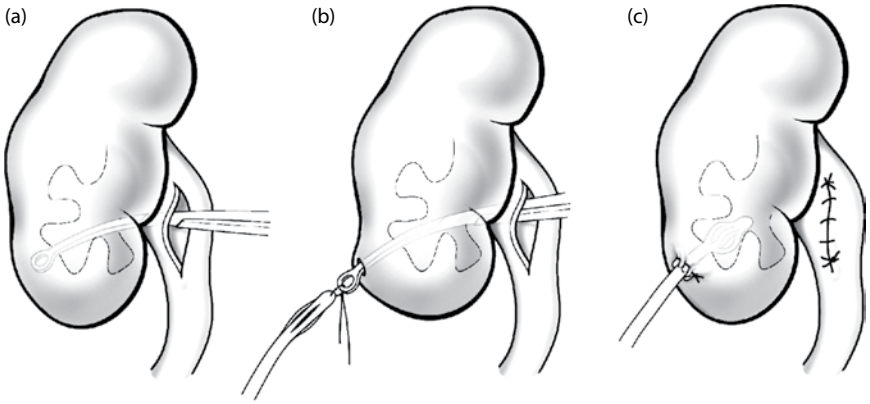

FIGURE 58.2 Technique for open nephrostomy. (a) Small Randall forceps or a right-angle clamp is passed through an inferior calyx via a small pyelotomy incision. (b) The renal capsule is incised with electrocautery, and the catheter is advanced into the calyx. The catheter is secured to the renal capsule with absorbable suture. (c) The pyelotomy is closed with either running or interrupted, absorbable suture.

children include obstruction, renal or ureteral calculi, pyonephrosis, and fungal bezoar, or for a diagnostic Whitaker study. Although general anesthesia will often be required in the young or uncooperative child, the procedure can frequently be performed with sedation only,[11] and has been performed with just local anesthesia in small neonates in the intensive care unit.[12] The technique most commonly used is the Seldinger technique. Under radiographic guidance, a small needle is placed into the renal pelvis, a guidewire is then passed into the renal pelvis, and the tract is dilated until a nephrostomy tube can be easily advanced. Several types of nephrostomy tubes are commercially available, most of which rely on a "pigtail" curl to maintain their position within the renal pelvis. It is critical that broad-spectrum intravenous antibiotics be initiated before tube placement, especially in the child with obstruction and infection, to prevent urosepsis. Complications directly related to the procedure are rare[13,14] and include

- Hemorrhage
- Urosepsis
- Arteriovenous fistula or pseudoaneurysm
- Urinary extravasation
- Pneumothorax
- Bowel injury
- Air embolism

Percutaneous nephrostomy tube placement and irrigation with antifungal agents has become the first-line therapy for neonates with obstructing fungal bezoars.[15–18] In addition to draining the obstruction and providing access for intermittent irrigation of the obstructed collecting system, the fungal ball can be fragmented with the guidewire at the time of tube placement, which will lead to more rapid clearance of the fungal debris.

Open Nephrostomy Tube

Open nephrostomy tube placement is rarely necessary, and only utilized when nephrostomy is technically not possible or carries an unacceptable risk. High-risk conditions include a low platelet count, a solitary kidney, an abnormal renal position following a complicated reconstruction of the renal pelvis, and exploration for renal trauma when significant injury to the ureter or pelvis has occurred. The kidney is exposed through a flank incision and mobilized until the renal pelvis is identified. Stay sutures are placed, and the renal pelvis is opened. A clamp is placed into an inferior calyx. A small nephrotomy is made, and the Malecot catheter is advanced into the renal pelvis as shown in Figure 58.2. The catheter is secured to the renal capsule with a purse-string chromic suture. The nephrostomy tube is brought out through a stab incision in the skin and secured. A small Penrose drain is left in the renal fossa. Some newer catheters come preassembled as either simple nephrostomy catheters or nephrostents, often with an attached trocar that can be advanced in a retrograde fashion out of the selected calyx.

Temporary Nonintubated Diversion

Cutaneous Vesicostomy

Cutaneous vesicostomy continues to command a prominent role in the armamentarium due to its simplicity, effectiveness, and low maintenance requirements.[19,20] Most commonly, it is used for patients with a neuropathic bladder or PUVs, in situations where CIC is unable to provide sufficient drainage to prevent hydronephrosis or infection. It must always be remembered that CIC places a significant burden on the family and caregivers, and therefore vesicostomy can be a tremendous relief to the burden of caring for a medically complex and demanding child. A properly functioning vesicostomy results in excellent bladder drainage, negligible bladder pressures, elimination of hydronephrosis due to bladder outlet obstruction, and decreased vesicoureteral reflux.[9,21–23]

The introduction of CIC in early infancy has limited the role of vesicostomy in some centers, and has provided equivalent long-term results.[24] One concern regarding temporary cutaneous vesicostomy is potential impairment in bladder function due to inadequate cycling of the detrusor during the period of diversion.[25] Jayanthi et al. reported on a large group of patients who underwent cutaneous vesicostomy and eventual bladder closure. They found no significant alteration in eventual bladder capacity or function.[26] These findings were also supported in a series of

patients with PUVs managed with either valve ablation or urinary tract diversion, with no evidence of bladder dysfunction based on urodynamics findings in those who had diversion with vesicostomy.[27]

Two basic techniques have been described for cutaneous vesicostomy in children. The procedure described by Lapides involves creation of extensive skin flaps to allow a tension-free anastomosis of the bladder to the skin, and a very wide stoma that is less prone to stenosis.[28] This procedure was initially intended as a semipermanent form of vesicostomy in the adult patient, where the bladder position is deeper in the bony pelvis. Because of the complexity of both creating and taking down the Lapides vesicostomy, there is limited application for the majority of pediatric patients. The more popular technique for vesicostomy in children was described by Blocksom and modified by Duckett, as outlined in Figure 58.3.[9,29] Key technical points are adequate mobilization of the bladder dome for a tension-free anastomosis to the fascia and skin, use of the dome of the bladder to create the stoma, and creating an adequate-caliber stoma (at least 22 Fr) that is flush with the skin.[9,30]

Common problems following vesicostomy are listed in Table 58.2. The majority of complications that lead to stomal revision are secondary to either technical errors of stomal placement inferior to the dome of the bladder, inadequate stomal diameter, or primary bladder pathology. The extremely thick-walled bladder is much more difficult to mobilize, and eversion of even a very wide segment of bladder may not allow an adequate-caliber stoma. A stoma located too cranially can result in the inability to contain the urine in a single diaper (Figure 58.4). This can be very frustrating for the caregiver, but can be managed with a horizontally placed pad or diaper within the normal one.

Bladder prolapse through the vesicostomy stoma is usually due to placement of the stoma too inferior, allowing the posterior bladder wall to evert through the stoma. Acute prolapse can usually be managed with manual decompression and bladder drainage with a catheter through the vesicostomy until the edema subsides. On rare occasions, the prolapsed bladder will incarcerate due to vesicular congestion. This requires emergency reduction under anesthesia. Revision of the vesicostomy by moving the stoma to a more superior position in the dome of the bladder will prevent recurrence.

Stomal stenosis will result in incomplete drainage of the bladder and often present with either UTI or hydronephrosis. Stenosis is thought to occur secondary to excess tension on the skin anastomosis or too small of a fascial opening, and is more frequent in patients with very thick-walled bladder or with prune belly syndrome.[9,30] Simple revision with creation of a wider-caliber stoma or use of a small V-shaped skin flap to disrupt the circumferential stomal scar tissue will usually correct the problem and prevent recurrence.

Cutaneous Ureterostomy

The indications and need for temporary and permanent urinary diversion with cutaneous ureterostomy or pyelostomy have been significantly reduced over the past several decades. Advances in percutaneous and endoscopic techniques have contributed to the trend away from cutaneous upper tract diversion. In addition, we have a better understanding of the pathophysiology and natural history of the dilated ureter in childhood. This has led to observation with radiographic surveillance instead of early surgical intervention in many circumstances.[31] However, despite the majority of asymptomatic, antenatally detected megaureters, the occasional patient will develop febrile UTIs, hypertension, or failure to thrive.[32]

For the ill neonate with an obstructed or refluxing megaureter, a temporary ureterostomy results in excellent urinary drainage, and rapid clinical improvement of the patient.[32,33] This allows for appropriate delay until the child is better able to tolerate a formal reconstruction, as outcomes from a tapered ureteric reimplant have been shown to be better once the child is greater than 1 year of age.[229] Over several months, there is a significant decrease in ureteric caliber, and therefore a simpler ureteric reimplantation. When there is a question of recoverable function, an interval of diversion may help one to decide between reconstruction and nephrectomy.[34]

A distal-end ureterostomy is useful in children with massively dilated ureters secondary to distal obstruction or vesicoureteral reflux that are not candidates for immediate reconstruction.[32,33] The surgical approach is usually through a low transverse muscle splitting incision that allows access to the retroperitoneum. The Pfannenstiel is a logical choice, as it may be required for future reconstruction. The ureter is carefully mobilized to the level of the bladder hiatus and transected, taking care to preserve the periadventitial and retroperitoneal blood supply. The ureteral stoma can be brought out either in the lateral margin of the incision or in the midline. Large-caliber (10 or 12 Fr) straight catheters are left for 3 days postoperatively to minimize the risk of obstruction from edema. A properly located stoma will be contained in the infant's diaper, and therefore is extremely easy to care for (Figure 58.5). A V-shaped skin flap can be used to prevent stomal stenosis, but this occurs infrequently with a dilated ureter.[35] Prophylactic antibiotics are often used postoperatively, but like the vesicostomy, colonization with bacteria is expected, but adequate drainage should mitigate the risk of a symptomatic infection.

In the case of a duplicated system, with an obstructed upper-pole moiety, the dilated ureter can be brought out in isolation, but great care is required to preserve the blood supply to the normal lower-pole ureter and to prevent its kinking.

The benefits of a more proximal ureteric diversion include the ability to perform renal biopsy for determining renal prognosis, the ability to accurately monitor the function of each kidney individually, and allowing a period of observation to decide on eventual reconstruction. Controversy still exists with respect to the benefit of a high ureterostomy in patients with PUVs who have persistent severe hydronephrosis and azotemia despite ablation of the valve or diversion with vesicostomy. Earlier studies suggested that proximal ureteral diversion would result in relief of functional obstruction at the ureterovesical junction and improve eventual glomerular filtration rate and somatic growth potential.[36,37] More recent studies, however, have challenged this concept, demonstrating no difference in eventual renal outcome between children who

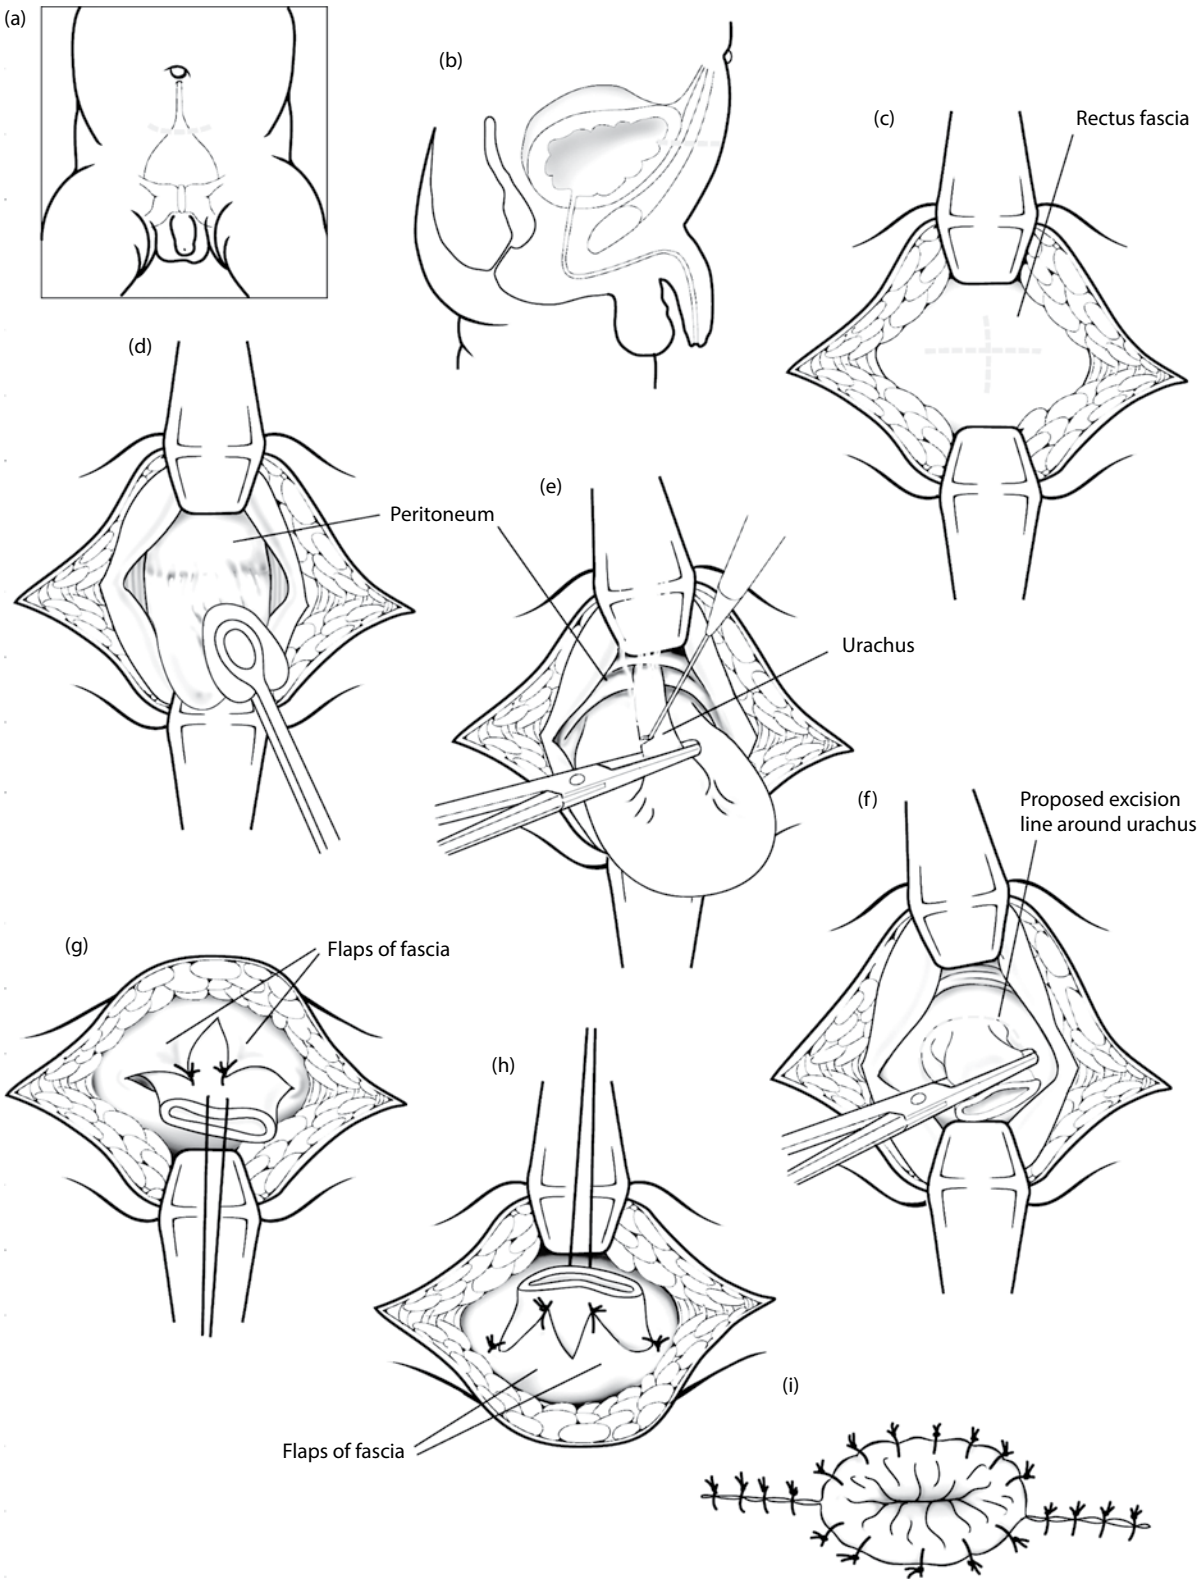

FIGURE 58.3 Technical points for Blocksom vesicostomy. (a, b) A small transverse skin incision is made midway between the pubis and umbilicus. (c) The rectus fascia is opened vertically and horizontally, and the muscle is retracted laterally. (d) Stay sutures are placed in the bladder, and the peritoneum is bluntly mobilized superiorly, exposing the bladder dome. (e) The urachus is identified and divided. The urachal segment is mobilized until it reaches the skin without tension. (f) The urachus is excised, ensuring an adequate-caliber opening into the bladder (22–24 Fr). (g) The detrusor is circumferentially secured to the rectus fascia. (h) The lateral edges of the fascia are closed, allowing easy passage of a 22–24 Fr sound. (i) The bladder mucosa and detrusor are secured to the skin, and the lateral skin edges are closed in layers.

TABLE 58.2 Complications of cutaneous vesicostomy

Complication	Frequency (%)

FIGURE 58.5 Photograph of an infant with bilateral ureterostomies performed in the neonatal period for left grade 5 reflux, right ureterovesical junction obstruction, sepsis, and renal insufficiency. The stomas are easily placed into the diaper, allowing for minimal maintenance, and the same incision is used for subsequent reimplant, minimizing scarring.

are managed with primary valve ablation and patients with an upper tract diversion.[38,39] Those who oppose routine proximal diversion think that the improved renal function following diversion is attributable to normal transitional nephrology that occurs with or without diversion.[39,40] In a study of 26 patients managed with bilateral high diversion for PUVs, Tietjen et al. reported renal dysplasia on biopsy in 85% and true ureterovesical junction obstruction based on Whitaker studies in only 4%.[40]

Potential problems of ureterostomy include ureteral kinking, stomal stenosis, the need for a more complex reconstructive procedure at a later date, impaired ureteral vasculature, and difficulty in covering the stoma with an appliance as the child grows.

The techniques for proximal diversion have not changed significantly for several decades. There is still debate over the preferred technique,[34] i.e., whether a pyelostomy, loop, or Y-ureterostomy should be utilized. The Y-ureterostomy, as described by Sober, allows for urine flow to the bladder, preserving some degree of bladder cycling.[41] This avoids the potential later problem of carrying out a complex lower tract reconstructive procedure in a small, defunctionalized bladder. Regardless of the technique used, adhering to three basic operative principles is critical for a successful outcome:[42] (1) during mobilization, the ureter should be manipulated to the least degree possible; (2) ureteral mobilization should be minimized to preserve maximal blood supply, yet be adequate to allow a tension-free skin anastomosis; and (3) kinking of the ureter or compression by the abdominal wall at the stomal site must be avoided.

Techniques for high ureterostomy are illustrated in Figure 58.6. All these procedures can be accomplished through a subcostal or flank incision, which allows mobilization of the ureter proximally to the renal pelvis and creation of a tension-free anastomosis to the skin. Loop ureterostomy is preferred by some surgeons because of the simplicity of the procedure. Closure of the ureterostomy and lower urinary reconstruction are often staged but can be performed simultaneously if there is careful attention to the periureteral vasculature.

Cutaneous Pyelostomy

Cutaneous pyelostomy has limited applications, but it can be an effective option for upper tract diversion. Best suited for patients with a dilated extrarenal pelvis that can easily reach the skin, the advantages of this procedure include

1. Minimal disturbance of ureteral blood supply during both formation and closure of the stoma
2. Direct urine drainage and avoidance of urinary stasis in the dilated distal ureter

The pelvis is easily accessed via a flank incision or a dorsal lumbotomy,[37] mobilized and exteriorized superior to the ureteropelvic junction, with great care to avoid angulation, obstruction, and stenosis (Figure 58.7).

Incontinent Urinary Diversions

With the advances made in medical prevention and an increased acceptance and desire for continent bladder reconstruction, the usage of permanent, noncontinent urinary diversion in children has significantly decreased. However, just as the vesicostomy provides for the simplest and most effective means of urinary drainage in the infant, its use in the older child and adolescent is hampered by high rates of stomal stenosis and desire to avoid diapers. An incontinent urinary diversion must always be considered in the complex patient who does not have the

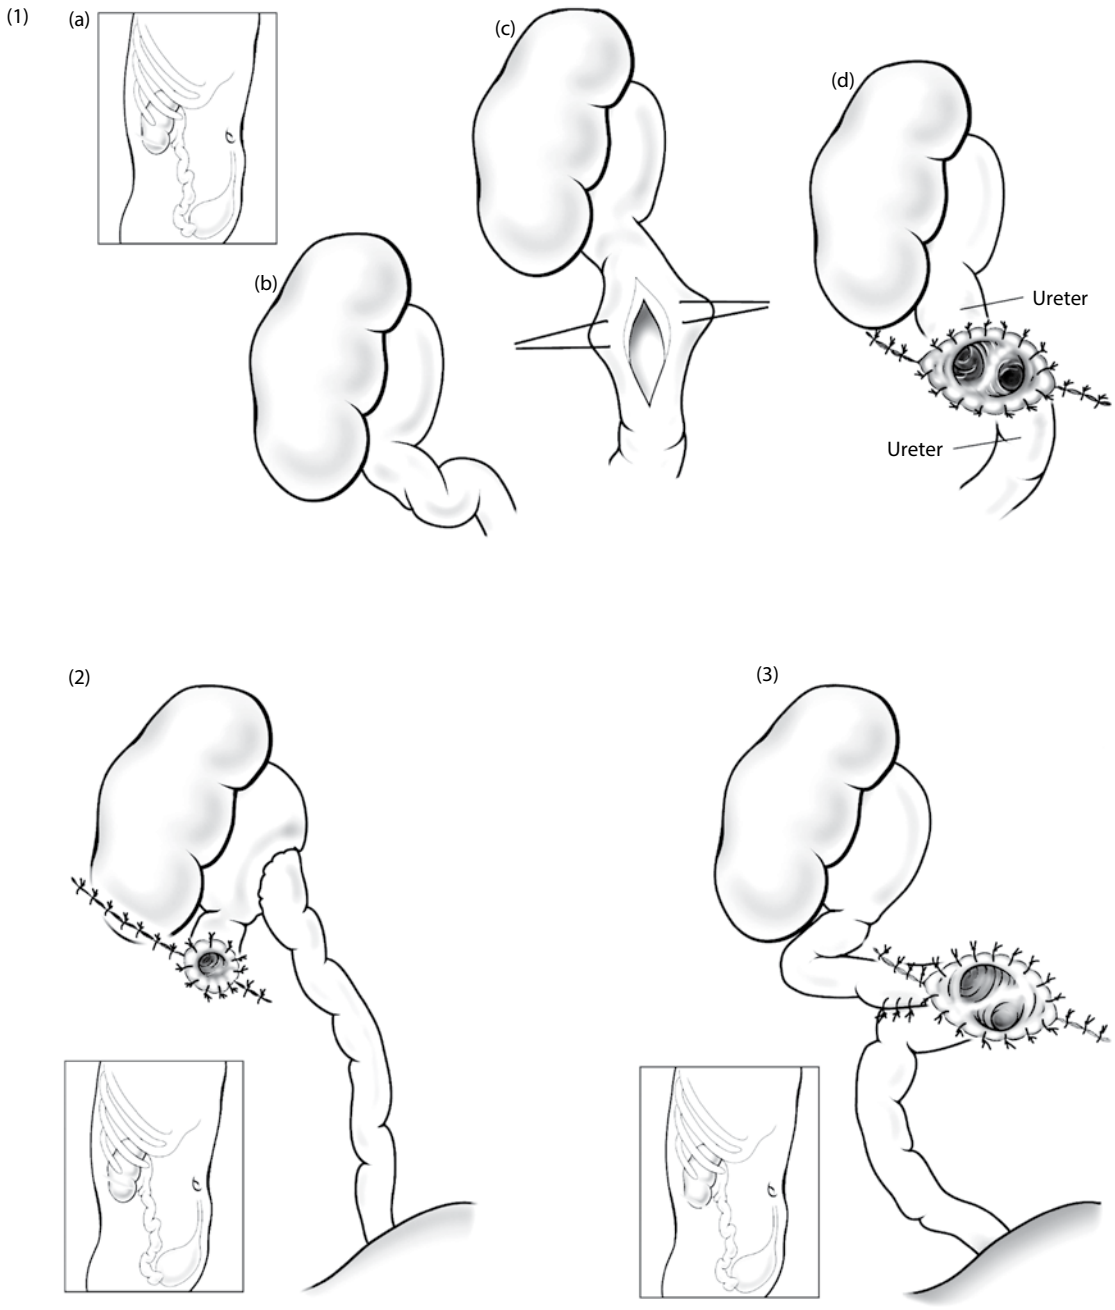

FIGURE 58.6 Various options for high cutaneous ureterostomy: (1) loop ureterostomy; (2) Sober ureterostomy; and (3) ring ureterostomy. Care is taken with each technique to preserve the medial blood supply and create a tensionfree skin anastomosis.

desire, resources, or physical or mental resources required for the significant effort that is mandated from a continent reconstruction.

These techniques can offer a simple, low-maintenance, and effective means of urinary drainage, although there are some long-term concerns about a higher degree of renal deterioration.[43–48] Patients with limited ability to care for themselves due to physical or mental disability and children with malignancies who have undergone extensive pelvic or abdominal radiation or who have limited life expectancy may be excellent candidates for an incontinent urinary diversion. As opposed to recommendations in the adult population,[49,50] renal failure in children is not an absolute indication for conduit diversion, as most children will be candidates for renal transplantation and will have a better eventual outcome with primary bladder reconstruction.[51,52]

Urinary Conduit

Any segment of small or large intestine can be used to create a urinary conduit; however, the ileum and colon are most frequently selected. Some surgeons prefer using colon conduits in children as the tenia facilitates a nonrefluxing anastomosis, which may ameliorate long-term renal deterioration.[44,47]

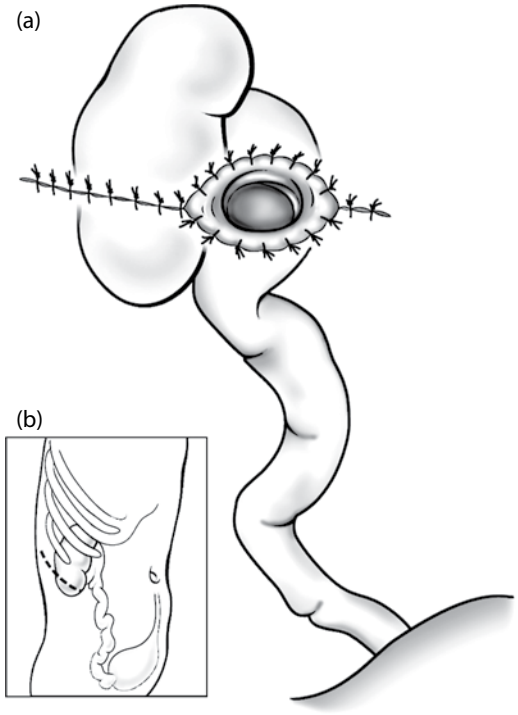

FIGURE 58.7 Cutaneous pyelostomy. (a) The renal pelvis is approached through a subcostal, posterior flank or dorsal lumbotomy incision. The kidney and dilated renal pelvis are mobilized until the renal pelvis can reach the skin without tension. (b) The renal pelvis is opened widely and secured to the skin with interrupted, absorbable sutures.

The ability to incorporate the colon segment into a continent reservoir at a later date without the need to revise the ureteral anastomosis is also advantageous.[53] Jejunal conduits carry an unacceptably high risk of severe metabolic problems and are not recommended. The primary electrolyte problem with incorporating jejunum into the urinary tract is hypochloremic, hyponatremic, and hyperkalemic metabolic acidosis.[53]

The important technical aspects of creating a conduit are similar whether using the ileum or colon. This starts with an appropriate mechanical and antibiotic bowel preparation, which may need to be altered based on specific patient needs in the pediatric population. Although several reports exist promoting intestinoplasty without a bowel preparation, we feel that the risk of ventriculoperitoneal (VP) shunt contamination warrants the extra caution. The standard pediatric bowel preparation involves admission to the hospital on the day before surgery for intravenous antibiotics to sterilize the urinary tract and whole gut lavage with a polyethylene glycol solution (GoLYTELY) via nasogastric tube until stools are clear. Another key aspect of the preoperative preparation is identifying an appropriate location for the stoma, which is most effectively done with the input of an enterostomal therapist with the child awake before surgery. Several locations should be identified that allow optimal fitting of the appliance with the patient in the sitting, standing, or supine position. This is most critical for the wheelchair-bound patient who may have significant abdominal girth.

TABLE 58.3 Complications of ileal and colon conduits

	Frequency (%)	
Early complications	Ileal	Colon
	Conduit	Conduit

Renal deterioration	18	15
Metabolic acidosis	16	5
Ureteroenteric stricture	8	9
Renal calculi	7	5

Source: McDougal WS. In Walsh P et al., eds., *Campbell's Urology*, Philadelphia: WB Saunders, 1998, 3121–61.

Although the incidence of postoperative complications may differ slightly for colon or ileal conduits, the types of associated problems are very similar and can be divided into early or late complications (Table 58.3). Both ureteroenteric and stomal complications are generally related to surgical technique, representing the most common problems leading to reoperation. The general principles of minimal handling of the ureter, maintaining maximal adventitial blood supply, minimizing mobilization, preventing angulation of the ureter, and securing a mucosa-to-mucosa watertight anastomosis with fine absorbable sutures will decrease the potential for postoperative problems. The use of ureteral stents has been shown to significantly decrease anastomotic leaks.[54] Suspected ureteral leaks should be promptly investigated and, if present, treated by a percutaneous nephrostomy tube drainage and antegrade stent placement.

Ureteral strictures can been seen early after surgery, or may take several years to form,[55] reinforcing the need for long-term periodic radiographic surveillance. Treatment of strictures at the ureteroenteric anastomosis can be initially attempted with endourologic techniques. Regardless of the technique used (balloon dilation alone vs. incision and dilation), approximately 50% will eventually require open revision.[55,56]

Stomal problems may vary from a minor nuisance (bleeding and dermatitis) to more life-threatening complications, such as stomal obstruction with UTI

- Bleeding
- Bowel necrosis
- Dermatitis
- Parastomal hernia
- Stomal prolapse
- Stomal stenosis
- Stomal retraction
- Loop obstruction (early or late)

Stomal complications rates are reported to occur in 15%–80%. Problems with local skin irritation can be minimized by creating an everted nipple or loop stoma, so

that the appliance can be fit snuggly to the adjacent skin. Stomal stenosis and parastomal hernia are the most common problems with conduit diversion that require surgical revision. The risk of these complications can be minimized by bringing the bowel through an adequately sized fascial defect without angulation, securing the conduit to the fascia in four quadrants, and creating a nipple stoma.[57] It was initially thought that colon conduits had a lower incidence of stomal stenosis than ileal conduits, but this has not been supported in more contemporary series.[58] Skin and peristomal complications are best dealt with by an enterostomal therapist, preferably with pediatric expertise.

If the bladder is left in situ, the lack of drainage and urine may result in pyocystis. Therefore, some authors recommend cystectomy if a conduit diversion is chosen for benign disease.

Tumor within a conduit has been reported using both ileal and colon segments.[59] Although the risk for malignancy is unknown, it should be significantly lower than for ureterosigmoidostomy where urine and stool are mixed.

Technique for Ileal Conduit

The abdomen is opened through a midline incision, and the ureters are identified and mobilized at the level of the iliac bifurcation. The left ureter is brought across the midline in a retroperitoneal tunnel, taking care to avoid angulation. A 10–15 cm segment of ileum is selected that has an adequate vascular arcade, and the mesentery to this segment is isolated. The mesentery of the distal end of the segment is mobilized off the bowel to allow this end to be brought up to the skin as the stoma. *The last 15 cm of distal ileum should be avoided, as this segment of ileum is important for iron and vitamin B_{12} absorption*. The bowel segment is harvested and bowel continuity is restored using either a side-to-side stapled or end-to-end hand-sewn anastomosis. The mesenteric defect is closed with permanent suture. The proximal end of the conduit is closed in two layers (after removing the staples if a stapling device was used to harvest the segment) and secured to the sacral promontory. Ureteroileal anastomoses are carried out using either the Bricker[60] or Wallace[61] technique (Figure 58.8a and b), the proximal end of the loop is brought out at the predetermined site for the stoma, and an everting nipple or loop stoma is created (Figure 58.9).

Technique for Colon Conduit

The colon conduit is constructed in a fashion similar to that for the ileal conduit, with the exception of the ureteral anastomosis, which is usually created in a nonrefluxing manner using the tenia (Leadbetter technique) (Figure 58.10). Alternatively, a submucosal tunnel may be created (Goodwin technique).[50] Injecting saline or dilute epinephrine under the mucosa will minimize bleeding and aid in the dissection. Because of the added risk of ureteral obstruction within the submucosal tunnel, stenting the ureteral anastomosis is recommended.

Most commonly, a sigmoid segment will be used to create the conduit (Figure 58.11), but in children with a history of pelvic radiation or inadequate ureteral length, the transverse colon should be used.

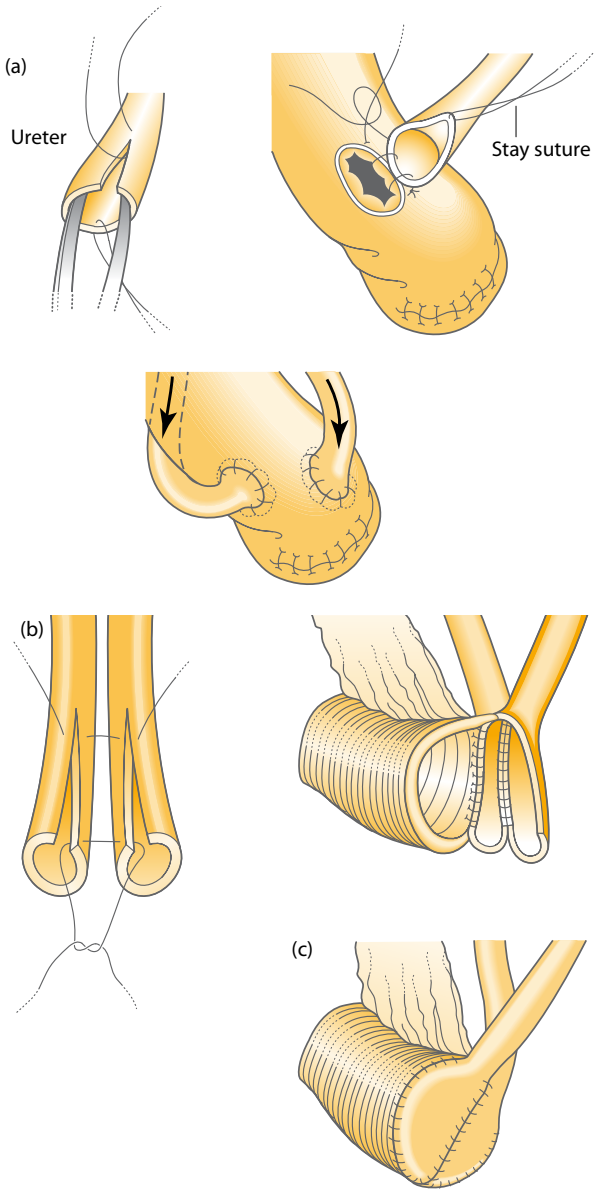

FIGURE 58.8 (a) The Bricker technique for ureterointestinal anastomosis. The ureter is spatulated, and following excision of a small ellipse of intestine, the anastomosis is secured with fine interrupted absorbable sutures. The external stent is placed across the anastomosis and brought out through the stoma. Both ureters are secured using an end-to-side anastomosis. (b) The Wallace procedure for ureteroileal anastomosis. The ureters are spatulated and joined at their medial borders using running or interrupted absorbable sutures. (c) The lateral edges of both ureters are then secured to the conduit in an end-toend anastomosis.

Ileocecal Conduit

By using the nonrefluxing properties of the ileocecal valve, the ileocecal conduit provides an alternative to the tunneled ureteral reimplantation used to achieve a nonrefluxing ureteral anastomosis with other colon conduits. The ileocecal conduit can later be incorporated into a ureterosigmoidostomy with reduced risk of cancer, as the ileocecal valve will prevent the direct contact of feces and urine at the site of the ureteral anastomosis. The greatest

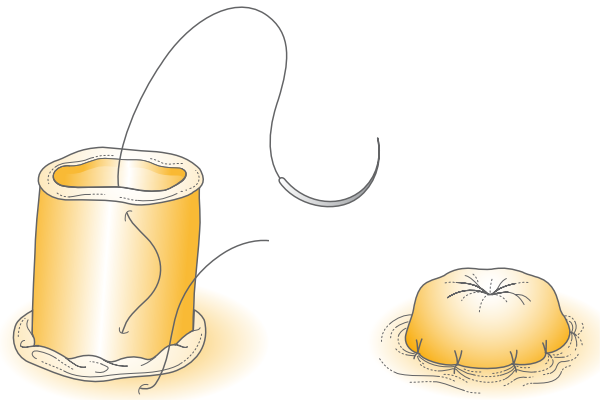

FIGURE 58.9 An everted stomal nipple is optimal for creating a snuggly fitting appliance. This is created by placing sutures between the skin/subcutaneous tissue, lateral bowel serosa, and distal edge of the stoma.

concern in using this segment for urinary diversion is the theoretical risk of diarrhea and fecal incontinence in the myelomeningocele patient who may depend on the intact ileocecal valve to prevent rapid transit of liquid stool into the colon. The technique involves isolating a portion of the right colon and distal ileum (Figure 58.11). The ileocecal valve is reinforced with permanent plication sutures that intussuscept the valve into the cecum.[62] The ureters are reimplanted into the proximal portion of the ileum using either the Bricker or Wallace technique.

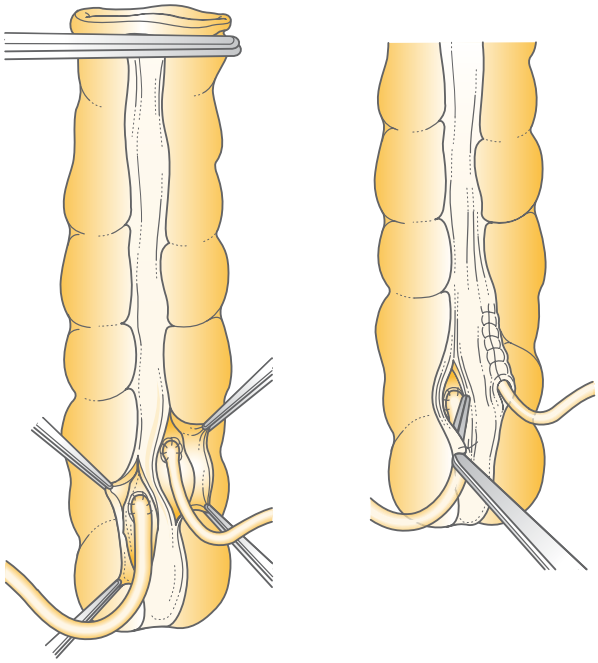

FIGURE 58.10 The non-refluxing ureterocolonic anastomosis described by Leadbetter. A submucosal tunnel is created by incising the tenia to create a submucosal trough, the ureter is anastomosed to the colonic mucosa, and the muscularis loosely closed over the ureter with absorbable suture.

Ileovesicostomy

Although animal studies and the first reports occurred more than 50 years ago, McGuire popularized the ileovesicostomy in patients with spinal cord injury.[2] The obvious advantages to the patient are a low-pressure reservoir and simple maintenance. By keeping the bladder in situ, the patient has minimal risk of pyocystis and avoids the potential complications of the cystestomy and ureterointestinal asatomosis. Long-term outcomes have been good, although revision surgery and infections are common.

Continent Urinary Diversion

The incredible progress in medical care of the complex pediatric patient has elevated expectations to beyond simple survival. Patients and families have promoted and increased interest in quality of life and integration into mainstream society. For the pediatric urologist, this has heralded the advent of continent urinary reconstruction, whereby a multitude of surgical techniques have evolved to provide the potential for urinary continence. Because the vast majority of our patients' pathophysiology arises from nonmalignant causes, their bladders may be left in situ, and the majority of reconstructions involve bladder augmentation. This is not addressed in this chapter, and the focus remains on urinary diversion.

A true CUR implies that a reservoir to store urine has been constructed entirely from the gastrointestinal tract, with no detrusor present, and is emptied by CIC, usually via the abdominal wall. Gilcrest and Merricks created the first modern-day reservoir by making a cecal bladder with continence based on the ileocecal valve, with the ileal "urethra" brought to the abdominal wall.[63] Gilcrest et al. reported good success with this, but others had difficulty in duplicating their results. One of the major impediments to widespread adoption was that intermittent catheterization was not well accepted.[64,65] Gilcrest continued to use this method and was able to achieve continence in 37 of 40 patients.[66,67]

The orthotopic *neobladder* is constructed from gastrointestinal segments attached directly to the native urethra, allowing the patient to spontaneously void. Neobladders are now commonplace in adults who require cystectomy for cancer, but are rarely used in the pediatric population. In children, the native bladder is often left in situ, and instead of replacement, it is augmented with a gastrointestinal segment. This is commonly referred to as a bladder augmentation, or an ileocystoplasty. This also requires drainage via CIC, through either the urethra or a catheterizable abdominal wall channel. For the purposes of this chapter, we do not consider orthotopic neobladders or enterocystoplasty, and focus on CURs.

Lapides's introduction of CIC in the 1970s was critical in the implementation of the reconstructive techniques we know today.[68] With acceptance of CIC, volitional voiding was no longer required, and therefore the reconstruction only needed to recapitulate the storage function of the bladder. In addition, accurate urodynamic evaluation in children allowed for improved renal outcomes and improved patient selection.[69] Reliable pediatric anesthesia

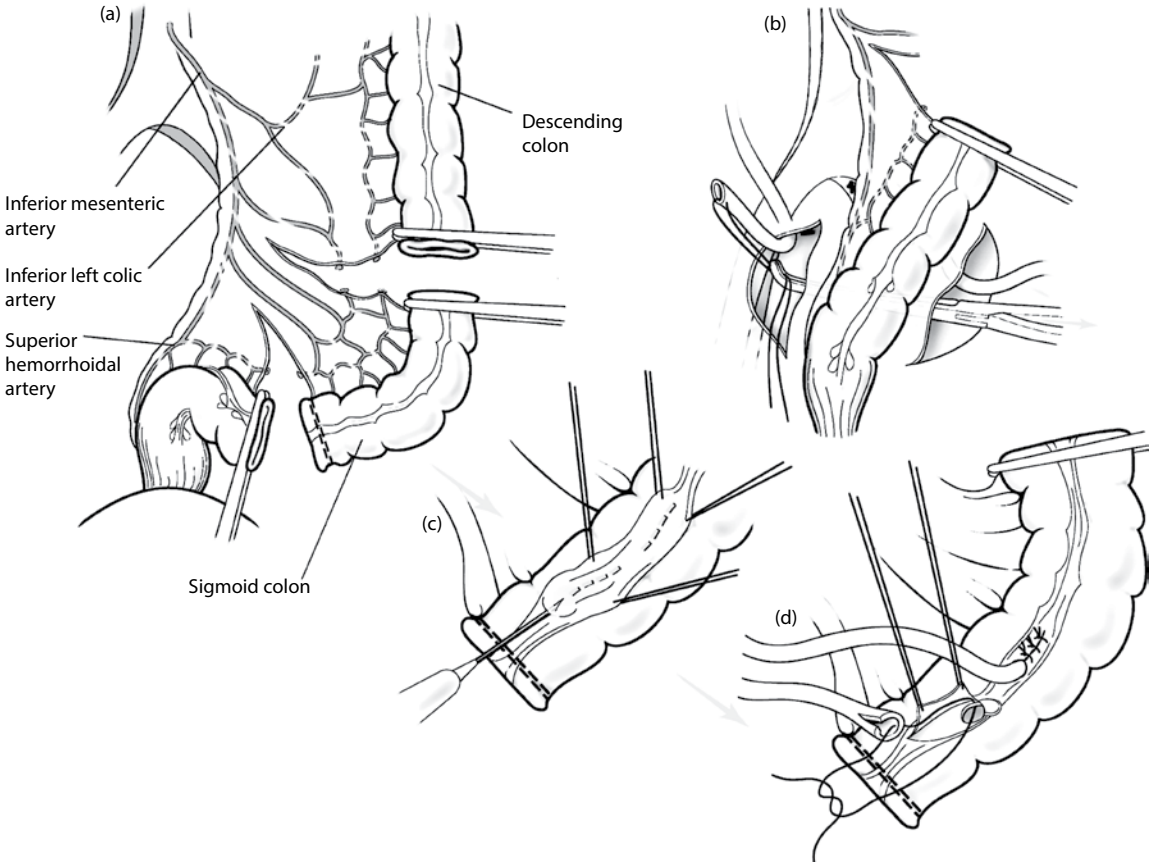

FIGURE 58.11 Surgical technique for creation of a sigmoid colon conduit. (a) A segment of colon is isolated, maintaining a wide mesenteric pedicle. (b) The ureters are mobilized through posterior incisions in the peritoneum and transected. The right ureter is brought across the midline in a retroperitoneal tunnel. (c) The tenia is incised to create a tunnel. (d) The ureters are anastomosed, as illustrated in Figure 58.10.

now permitted long reconstructive cases to be safely performed. Finally, Hendren's demonstration that the previously diverted urinary tract could be refunctionalized (undiversion) also spurred the decline of incontinent diversion in children.[70,71]

Kock's continent urinary ileal reservoir was the first widely used CUR, which was adapted from his continent ileostomy.[72] The Kock pouch was refined and further popularized by Skinner's team.[73–75] Over the past 25 years, there have been more than 40 variations of CURs described. Gastrointestinal CURs have been used in the adult population primarily as a means of diversion following cystectomy. In these adult patients, the urinary and gastrointestinal tracts are usually anatomically and neurologically normal, allowing the surgeon to use one of the many named procedures, such as the Kock pouch, Indiana pouch, or Mainz pouch. However, the majority of children undergoing true CURs, such as those with classic exstrophy or myelomeningocele, have significant anatomic and/or neurologic abnormalities. Some have a combination of both abnormalities, such as the cloacal exstrophy patient, who is more susceptible to short gut syndrome.[76] In these situations, creation of a standard named CUR may not be possible. These anatomic and neurologic abnormalities do not prevent continent urinary diversion in children, but they do require the surgeon to have a fertile imagination and depth of knowledge of all options available, as well as a good understanding of the concepts necessary to provide a reliable reservoir.

Patient Selection and Preoperative Evaluation

It is our belief that the urinary tract should remain intact whenever possible. In this regard, all efforts should be made to exhaust medical management prior to electing surgical options. Reconstruction is generally performed for one of two reasons: to protect the upper urinary tract or to achieve urinary continence. In the majority of children with lower urinary dysfunction, these two goals can be achieved with CIC and/or pharmacologic management. In our experience with the neuropathic population, approximately 70% can be managed nonsurgically. If this fails, then we would not hesitate to reconstruct the lower urinary tract, but this again usually involves reconstructing the native bladder by enterocystoplasty and bladder neck reconstruction rather than CUR.

The most common contemporary reason to construct a true CUR (without any native bladder being used) in a child, like in the adult population, is after a genitourinary malignancy. Although bladder-sparing protocols are being popularized, the severe doses of radiation and chemotherapy can leave the patient with an unusable or unsafe

bladder. Excellent long-term results have been reported in the pediatric population.[77,78]

For any continent reconstruction, the child must have adequate upper extremity function to catheterize reliably and the mental capacity to do so. The patient and/or family must be motivated and reliable. Both must understand that a lifelong commitment to CIC is required, and failure to catheterize reliably may result in urinary infection, stone formation, reservoir perforation, or renal deterioration, even in the face of a technically perfect operation.

Preoperatively, the overall renal function should be determined by measuring serum creatinine and electrolytes. It cannot be overstated that the very high doses of chemotherapy used in pediatric malignancies can be significantly nephrotoxic. Benson and Olsson suggest that no patient should undergo reservoir creation if creatinine clearance is <60 mL/min.[79] With the incorporation of ileum or colon into the urinary tract, chloride and ammonium are absorbed and sodium bicarbonate is excreted, which may result in a hyperchloremic metabolic acidosis (Figure 58.10). This was first noticed by Ferris and Odel in patients with ureterosigmoidostomy.[80] Children with normal renal function generally tolerate this well, but in those with renal insufficiency, a severe metabolic acidosis may occur.[80–82] Mitchell and Piser noted that the chloride level increased and bicarbonate level decreased in every patient following enterocystoplasty at their institution.[83] Rink et al. later reviewed 231 patients and found 16% to have a serum chloride level above the normal range.[84] Those patients with severe elevations all had colonic segments in their urinary tract. Others have reported similar findings following CURs.[85–89] These changes would be expected to be more severe in CURs where the entire storage surface area is enteric, rather than with augmentation of the native bladder. Nurse and Mundy demonstrated that following enterocystoplasty, the blood gas values may be abnormal even with normal serum chloride levels.[90] There has been concern regarding poor linear growth from the use of bony buffers in response to chronic acidosis.[90–94] Others have found no significant difference in growth or bone density.[95,96] Regardless, both groups would agree that if acidosis exists following CUR, bicarbonate therapy should be started.

Many children undergoing creation of a CUR have renal tubular dysfunction from primary urinary obstruction, resulting in a severe urine-concentrating defect. The end result may be the excretion of very large volumes of urine. Therefore, a 24-hour urine for volume should always be checked preoperatively. The reservoir must be made large enough to handle the patient's urine output adequately at low pressures to allow emptying no more frequently than every 4 hours. A technically perfect CUR would be inadequate if it required catheterization every 2 hours plus awakening at night to catheterize. Graphs and guidelines have been developed to predict the length of a bowel segment needed to achieve a certain volume.[97] However, these graphs may prove cumbersome and are not routinely used.[98] Even if renal and bowel function are normal, it is better to err on making the reservoir too large than too small. However, unlike the fibrotic or diseased bladder they are replacing, CURs have shown the ability to increase in capacity. Anticholinergics may also be used to decrease any residual contractility and improve compliance.

Liver function testing should also be carried out, as suggested by McDougal.[50] Hyperammonemia can occur in patients with large or small intestine incorporated into the urinary tract when hepatic dysfunction is present, as these segments absorb ammonium.

In all children, the urinary tract must be imaged preoperatively. A combination of ultrasonography and radionuclide scanning will adequately assess structure and function. Ureters, which have undergone prior reimplantation, may be hydronephrotic due to fibrosis and aperistalsis, as opposed to increased storage pressures. Therefore, even though the bladder is not being used, videourodynamics can be very helpful, especially after radiotherapy to the pelvis.

If the CUR is being performed after removal of the bladder or prostate after a malignancy, all efforts should be made to ensure that chemotherapy is finished and the patient declared free of residual disease.

Stomal location should also be determined before the operative procedure. All efforts should be made to place the stoma on the abdomen corresponding to the dominant hand of the patient. While this is less important for continent diversion than conduit diversion, it is still important to be certain the child will be able to pass the catheter easily. Skin folds and areas of abdominal wall scarring should be avoided. It is best if the patient can visualize the stoma. The stoma may be placed in an orthotopic location to allow catheterization of a normal urethral meatus, but in most patients, this is not warranted. In a study by Horowitz et al., patients who had the opportunity to catheterize either their native urethra or an abdominal wall stoma overwhelmingly preferred the latter.[99]

Finally, latex allergy precautions must be observed in all patients with spinal dysraphism.

Principles of Continent Urinary Diversion

The ideal reservoir (1) provides the high-capacity, low-pressure reservoir that the kidneys require to minimize pressure on the upper urinary tract, (2) avoids reservoir-ureteral reflux and ureteral obstruction, (3) allows for simple and effective emptying, (4) is continent, and (5) has minimal short- and long-term complications.

Creation of a Compliant Reservoir

Fashioning the ideal reservoir of the CUR will depend on the underlying diagnosis and the patient's anatomy. Virtually all gastrointestinal segments have been used to create CURs, and therefore it is important to know the pros and cons of the gastrointestinal segments available and the length and configuration of the bowel segment chosen. The promise of a tissue-engineered bladder substitute is extremely exciting, and although substantial progress has been made, the promise of human application will still require further innovation and time.

The native bowel is capable of significant peristalsis, and if left unmodified, very high reservoir pressures may be generated by the intestinal contractile activity. Multiple studies have demonstrated bowel segments capable of

pressures of 60–100 cmH_2O.[100–103] These high pressures can result in urinary leakage and upper urinary tract deterioration, and may even contribute to perforation.[104] Since McGuire et al.'s landmark paper, it is now well accepted that intravesical (intrareservoir) pressures must be maintained well below 40 cmH_2O. More recent data with laboratory research suggest that intravesical pressures far less than 40 cmH_2O may have a deleterious effect on the bladder.[105–107]

Therefore, regardless of the gastrointestinal segment used, it is imperative that the segment is detubularized and reconfigured into a sphere (Figure 58.12).[108,109] Detubularization will dampen the contractile activity of the segment, and thereby increases tissue compliance. However, the surgeon must understand that contractile activity is not totally abolished by detubularization. In fact, Lytton and Green found contractions up to 60–110 cmH_2O in patients reconstructed with detubularized right colon,[110] and Sidi et al. noted average peak pressures of 41 cmH_2O following cup-patch sigmoid cystoplasties.[111]

Although the ileum is often considered to have much lower peristaltic activity, detubularization is still required to minimize pressures in the ileum, as recorded pressures of 81 cmH_2O were seen in native, tubularized ileal reservoir versus 28 cmH_2O in the detubularized ileal reservoir. Clinically significant contractions (>40 cmH_2O at volumes <200 mL) were observed in 10% of the right colon and none of the ileal segments. Ileal segments were thought to be urodynamically superior, especially at large volumes.[112]

The reservoir must also have sufficient capacity to allow storage of at least 4 hours of urine production. This volume must consider the patients with high outputs secondary to renal tubular concentrating defects (i.e., PUVs). Reconfiguring the segment from its native cylinder to a sphere has the advantages of increasing the capacity from the same amount of tissue. Furthermore, from LaPlace's law ($t = Pr$, where t = wall tension, P = pressure, and r = radius), the larger the radius (r), the greater the wall tension (t), resulting in enlargement over time.

If upper tract deterioration or urinary leakage occurs, urodynamics must be repeated to ensure reservoir pressures are satisfactory. In the author's augmentation cystoplasty population, a second segment of bowel had to be added in 19 of 323 patients owing to persistently elevated pressure in the initial bowel segment.[113] Twelve of 87 undergoing colocystoplasty (13.8%), 4 of 30 undergoing gastrocystoplasty (13.3%), and only 2 of 145 ileocystoplasties (1.4%) required a secondary augmentation bowel segment.[113] The authors agree with Goldwasser and Webster that ileum is the least contractile intestinal segment, with cecum intermediate and sigmoid and stomach being the most contractile.[113,114]

Choice of Bowel Segment

While some of the metabolic and contractile properties of the gastrointestinal tract have been discussed above, there remain several advantages and disadvantages of each segment (Table 58.4). Several studies have reported on experience with the various gastrointestinal segments used in reconstructing the lower urinary tract.[53,98,104,115] The majority of data in children come from augmentation cystoplasty rather than complete reservoir construction.

Ileum, as noted previously, when reconfigured, will provide the most compliant, least contractile segment. Mucus production, while greater than with the stomach, is less than with the sigmoid or cecum and tends to decrease with time.[116] Hyperchloremic acidosis occurs with small and large bowel but seems to be less significant with the ileum.

Except in instances of short gut syndrome, as in cloacal exstrophy, there is generally an abundance of ileum available for reservoir construction and for the creation of catheterizable channels. If short ureters are present, a "tail" of ileum extending from the pouch can be used to bridge the gap. However, at times the mesentery is short, making an anastomosis to an orthotopic catheterization site difficult.

The ileum is responsible for vitamin B_{12} absorption, which occurs in the terminal portion. If possible, the distal 15 cm of ileum should be preserved. Resection of

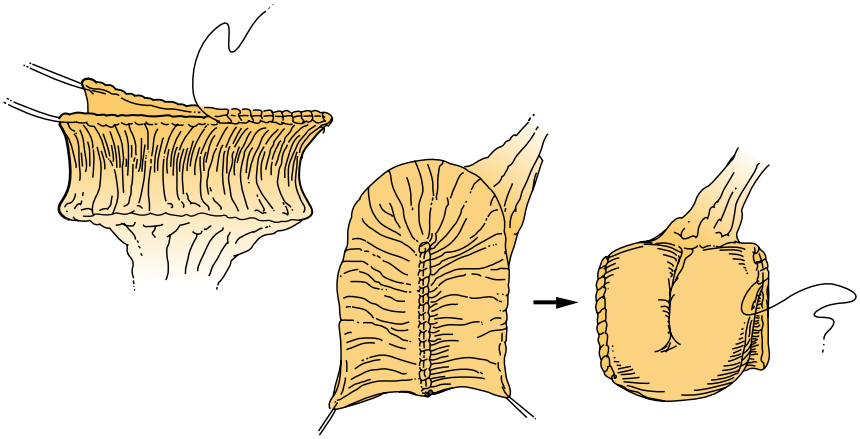

FIGURE 58.12 The bowel must be detubularized (upper left) into more of a flat plate and reconfigured into a sphere (bottom right) to minimize peristalsis and maximize the ratio of surface area to volume. (From Indiana University, Indianapolis, Indiana. With permission.)

TABLE 58.4 Advantages and disadvantages of each segment

Segment	Advantages	Disadvantages
Ileum	Most compliant	Diarrhea
	Less mucus	Vitamin B_{12} deficiency
		Short mesentery
		Hyperchloremic acidosis
		Poor muscle backing
Sigmoid	Readily mobilized	Unit contractions
	Easily implanted	Lower compliance
	Good muscle backing	Mucus
		Hyperchloremic acidosis
		Perforation risk
Ileocecal	Valve as antireflux or continence mechanism	Diarrhea
	Good-capacity reservoir	Not always available
	Constant blood supply	Contractile
Stomach	Useful as alternative to intestine for short gut or lower abdominal/pelvic radiation	Hypochloremic alkalosis
	Chloride pump	Rhythmic contractions
	Minimal mucus	Hematuria and dysuria
	Few infections	
	Ease of implantation	
	Good muscle backing	

long segments of ileum have resulted in B_{12} deficiency but may take several years to clinically manifest as a megaloblastic anemia and neuropathy, as B_{12} stores may last for years.[53,117,118] Akerlund et al. noted this problem in patients following Kock pouch construction.[119] Canning et al., however, did not find any patients with a B_{12} deficiency in 26 patients evaluated following bladder augmentation using ileum, but this group was followed for only 3 years.[120] A large cohort of bladder augmentations at Indiana University did not find any clinical manifestations of B_{12} deficiency, although levels in many were low, and the authors recommended supplementation.[121] The Mainz group also looked at vitamins A, B, B_2, B_6, D, and E and folic acid levels, as well as bone density, after their diversions, and all were within normal limits.[122] Vitamin B_{12} levels and bone density were normal in the 51 children but dropped significantly in adults. They recommend checking B_{12} levels after 4 years.[122]

Resection of large segments of ileum has also been found to result in diarrhea and to increase the risk of cholelithiasis.[118,123] Roth et al. reported the occurrence of chronic diarrhea in 11% of patients who had a CUR constructed from ileum.[124] Baker and Gearhart noted that if >100 cm of ileum is resected, steatorrhea and cholelithiasis can develop.[125]

The cecum and ileocecal segments have been the most widely used tissues for CUR construction. The ileocecal segment has a constant, reliable blood supply that allows easy mobilization and placement of the pouch in the pelvic inlet, when necessary. The large cecal size makes for an excellent reservoir, and the ileocecal valve can be used to augment either the continence or antireflux mechanisms. The appendix is also readily available for use as a continent catheterizable channel. This segment is used in several of the most popular reservoirs, i.e., the Indiana pouch, Florida pouch, Mainz pouch, and Penn pouch.

In patients with a spinal dysraphism, the ileocecal valve may be important in maintaining fecal continence. Roth et al. noted that 23% of patients having an ileocecal reservoir had chronic diarrhea.[124] Gonzalez and Cabral reported that a patient required replacement of the ileocecal valve to reverse or correct intractable diarrhea.[126] Furthermore, in cloacal exstrophy patients the colonic segment may have been absent or discarded at the time of previous surgery, and thus not available for use. Cecal incorporation into the urinary tract may lead to hyperchloremic metabolic acidosis, as well as significant mucus production.

The sigmoid colon was historically used a great deal in lower urinary tract reconstruction in children. It is often quite enlarged and redundant in the spinal dysraphism population, allowing it to reach easily any portion of the abdomen or pelvis. Its mucosa can be easily dissected to provide submucosal tunnels for antireflux or continence mechanisms. While it seemingly has a number of advantages, it has the disadvantages of significant contractile activity in spite of detubularization and reconfiguration.[113] It also has the greatest mucus production[116] and highest rates of bacteriuria,[127] and is most likely to result in significant hyperchloremic metabolic acidosis. In the authors' hands, when used to augment the bladder, it has resulted in the highest spontaneous bladder perforation rate.[104] However, this latter problem was not found in other series, where complete detubularization and reconfiguration was performed.[128,129]

The use of the stomach in lower urinary reconstruction in children was popularized with the initial report by Adams et al., which purported several unique advantages.[130] The stomach has excellent muscle backing, facilitating ureteral implantation or tunneled continence channels.[131] The stomach was also thought to be an ideal tissue for those who had undergone pelvic radiation, as it is generally outside the irradiated field. Bladder calculi, secondary to mucus production, have nearly been nonexistent with the use of the stomach.[132–134] Kaefer et al. found that only 2 of 70 patients developed stones with the use of stomach compared with 30 of 137 with stones following the use of other enteric segments. Perhaps most importantly, the stomach differs metabolically from the other intestinal segments.[135] Gastric mucosa has no absorptive properties, so the risk of metabolic acidosis is mitigated. Furthermore, it secretes hydrogen and chloride, which may be beneficial in those with renal insufficiency and subsequent preexisting acidosis.[135,136] Serum chloride has been noted to decrease and bicarbonate increase following the use of stomach in the urinary tract.[130,137] The net excretion of hydrogen chloride and acidification of the urine is also able to reduce bacteriuria.[84,115]

Unfortunately, the popularity of the stomach has diminished significantly due to the potential for a profound hypochloremic metabolic alkalosis, hematuria–dysuria syndrome (HDS), and a high risk of malignancy.[115,138–146] Although uncommon, the metabolic derrangment has resulted in death. HDS may occur in up to one-third of patients, and can be debilitating in those with incontinence, normal sensation, and oliguria.[144] If a reservoir is to be constructed from the stomach, the continence mechanism must be 100% reliable, as severe skin excoriation may occur with urinary leakage.[142,143,145] The stomach should be avoided if a period of anuria is anticipated, as the urine is necessary to buffer the gastric acid production, thus preventing irritation and perforation.[138] Pharmacologic therapy with H_2 blockers and hydrogen ion pump blockers may be helpful in reducing acid production.[146–148]

Another disadvantage of the stomach is its contractile activity. Rhythmic contractions are reported in all large series, occurring in up to 62% of patients.[131,140,149] This is partly due to the small wedge segment of stomach actually used. Larger, more rhomboid segments have improved the urodynamics, but contractility can remain a problem, necessitating a secondary augmentation.[113,150]

To mitigate these shortcomings, a composite reservoir can be created using a second, separate segment.[76,151–153] The hypochloremic alkalosis associated with the stomach is offset by the hyperchloremic acidosis associated with small and large bowel usage, creating a more "balanced" reservoir (Figure 58.12). Only a relatively small (8 × 4 cm) gastric segment is necessary to achieve neutrality. Lockhart et al. have demonstrated that larger segments may result in HDS. In 12 patients with long-term follow-up, 11 have normalized their mean serum $HCO_3$1evels. Serum pH levels have also been corrected, and only one patient has had persistent metabolic acidosis.[153] Using a more compliant segment likely will also offset the increased storage pressures. Gastroileal composite reservoirs seem to provide many advantages but take longer to construct, as a second anastomosis is necessary and there is potentially significant blood loss.

The mobilization of the greater curvature along the gastroepiploic artery is also very demanding technically, and results in quite a long transabdominal mesentery. This has been postulated to be the main reason that the author's augmentation series has the greatest risk of bowel obstruction when gastric segments are used.

Finally, the risk of malignant degeneration appears to be very high, as reported by Gozalbez's group (https://www.ncbi.nlm.nih.gov/pubmed/22425048) and others.[154–156] Therefore, the use of gastric segments has fallen out of favor with many, but the University of Cincinnati has shown good long-term outcomes with its composite reservoirs.[157]

Creation of an Antireflux Mechanism

A nonrefluxing ureteral anastomosis is felt to be important in the pediatric patient. While the necessity for this can be debated in the adult patient, concerns over the greater life expectancy and susceptibility of the developing kidney have driven this sentiment. The historic aspects and the various mechanisms were reviewed by Walker.[158] Reimplantation of ureters into gastrointestinal segments can be quite challenging, and although many techniques have been described, all have their basis in the original technique introduced by Coffey.[159] Antireflux mechanisms today are generally based on a mucosal tunneling technique or by the creation of nipples by intussusception.

Le Duc et al. described by an intralumenal tunneling technique, whereby a 3 cm mucosal sulcus is created.[160] The ureter is brought through the bowel wall, placed in this sulcus, and secured. The intestinal mucosal edges are sutured to the ureteral adventitia and, with time, with mucosa will cover the ureter to create a tunnel with muscle backing. Abol-Enein and Ghoneim described an ingenious technique using a serosal tunnel, which is easily constructed and appears to reliably prevent reflux (Figure 58.13).[161]

Nipple valves are generally constructed by intussuscepting ileum or using the ileocecal valve but have had more complications than tunneling techniques and are more difficult to construct. In the authors' experience, there has been nearly a 50% incidence of reflux noted on long-term follow-up in those in whom a reinforced intussuscepted ileocecal valve was used as the antireflux mechanism. A split-cuff nipple valve using ureter has been reported by several authors, and is very easily constructed and surprisingly reliable (Figure 58.14).[114,162,163] Stone and MacDermott noted mild reflux in only 1 of 35 ureters, all of which had at least a 2-year follow-up.[162] This is particularly useful in the dilated ureter, where tunneling techniques are more likely to lead to ureteral obstruction.

Regardless of the technique used, reported results are generally favorable. Walker noted that success rates are slightly worse than reimplanting into native bladder.[158] Most interesting is the report by Lockhart et al., where 165 of 201 ureters were anastomosed end to side with no effort made to prevent reflux.[164] Neither reflux nor obstruction occurred in 87%. Tunneled reimplants have successfully prevented reflux in greater than 95% of patients.

Creation of a Continence Mechanism

Due to the absence of the urethra, the CUR is entirely dependent on a continent catheterizable channel. The creation of the perfect reservoir with no reflux is of no value to the child who continually leaks urine onto the abdominal wall. Difficulty or the inability to catheterize the reservoir puts the child at risk for recurrent infections, renal deterioration, and reservoir perforation. As Benson and Olsson have observed, the integrity or failure of the continence mechanism determines the success or failure of the diversion.[165] Numerous techniques have been described to provide continence, but they all fall basically into one of the following categories: nipple valves, ileocecal valves, and flap valves (Mitrofanoff principle). The reservoir can be catheterized through a segment of ileum or appendix. Some techniques use a combination of these valve mechanisms. Examples of each type will be demonstrated. The interested reader should be aware of two excellent reviews of continence mechanisms by Sagalowsky[166] and Austin and Lockhart.[167]

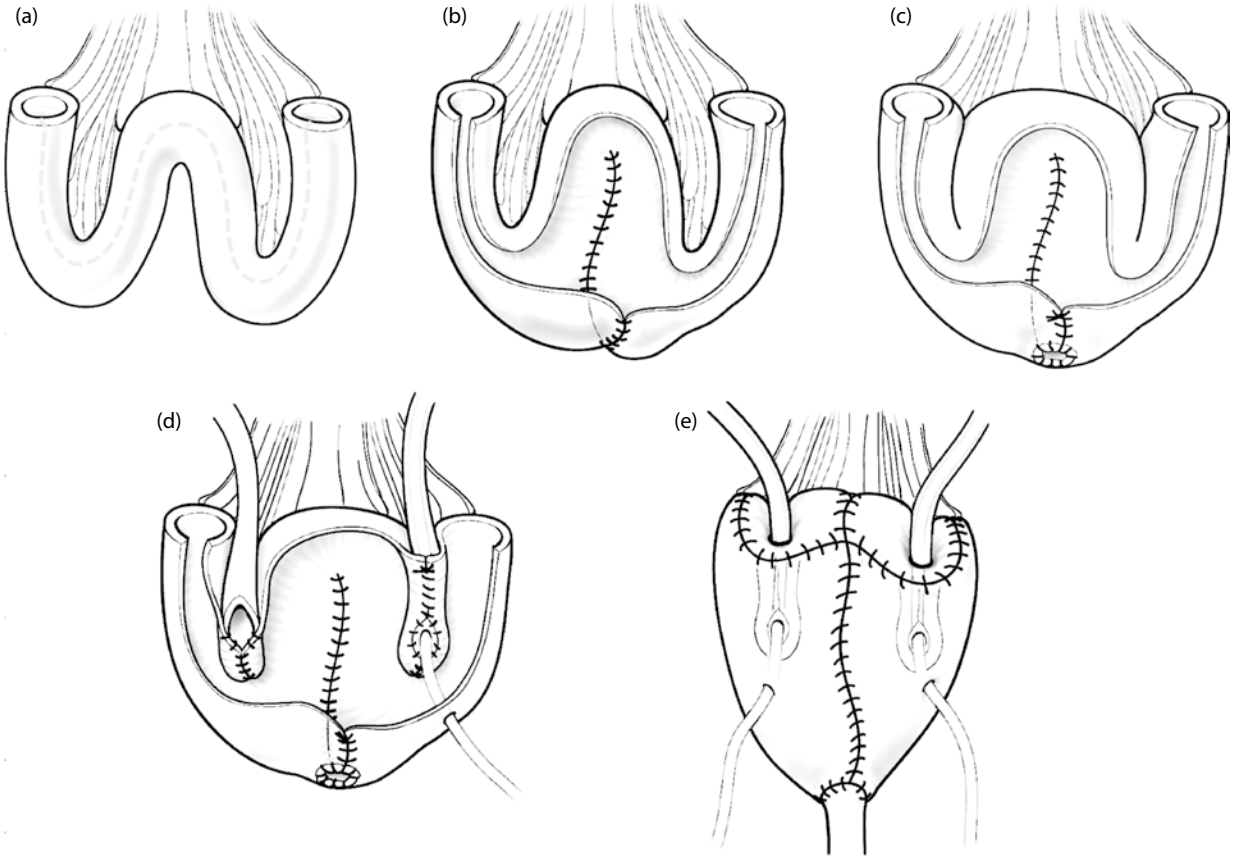

FIGURE 58.13 Abol-Enein and Ghoneium reimplant. (a and b) A W-shaped ileal segment is fashioned and the bowel is opened on the antimesenteric border. (c and d) Two serous lined troughs are created and the ureters are placed in the troughs with the ureteral meatus anastomosed to the intestinal mucosa. (e) The free bowel edges are closed over the ureter, creating a serosal lined tunnel. (Adapted from Abol-Enein H, Ghoneim MA. *J Urol* 1994;151(5):1193–7. With permission.)

Ileal Stomas

Nipple Valves

Nipple valves are generally created by intussuscepting an intestinal segment to create a sphincteric compression mechanism via the bowel, and are used in many of the most popular CURs. An ileal nipple is used in the Kock pouch (Figure 58.15) and the Mainz pouch (Figure 58.16). An ileocecal nipple is used in the pouch described by Mansson et al.[168]

When the nipple valve is within the lumen of the reservoir, the principle of equilibration pressures adds further to continence. Unfortunately, the intrareservoir pressure that compresses the nipple to provide continence also applies forces to evert, flatten, or destabilize the nipple (Figure 58.17). Because of the nipple's tendency to fail over time, many ingenious methods to stabilize the nipple have been reported. Hendren described dissecting the mesentery off the ileum to be intussuscepted and scarifying it to provide internal fixation.[169] The Kock pouch has been modified many times from its original application as a continent ileostomy.[170] The procedure reported in the first 12 patients involved the use of 60–70 cm of ileum for the reservoir.[72] The middle 40 cm was folded into a U shape after being opened on its antimesenteric border. In later patients, the nipple valves were constructed by intussuscepting the ileum into the reservoir. The nipples were stabilized by staples, and either Marlex mesh or fascia was positioned as a cylinder around the base of the nipples and secured to the reservoir. One nipple was used for continence and the other to prevent reflux. The Kock pouch has since been popularized by Skinner, who made further modifications.[73] There appears to be a steep learning curve, but in Skinner's hands, the results have been reported to be excellent, with excellent compliance and pouch capacities over 700 mL.[79,73] The large amount of ileum required (78 cm), the complexity of the procedure, and the requirement for two nipples with stapling and collar fixation have deterred its widespread use in children. Hanna and Bloiso achieved success in a small series in children, but modified the nipple to avoid the use of staples and Marlex.[78] Benson and Olsson noted that nipple failure occurs in approximately 15% in the best of hands, and no longer recommend its routine use.[165] The three most common complications are fistulae at the base of the nipple, nipple valve prolapse, and shortening of the nipple length.[79]

Ileocecal Valves

The ileocecal valve is commonly used as a continence mechanism; however, in its native form it is functionally adequate in only 25% of the population.[171,172] Rendelman et al. found that at 25 cmH_2O, the valve is competent in 75%, but only 7% at 50 cmH_2O pressure.[172] Reinforcement to achieve continence was described by Zinman and Libertino by wrapping the cecum around the ileum.[173] Intussusception of the ileocecal valve as a nipple to enhance its continence is the basis for the pouch described by Mansson et al. in 1990.[168] Hussman and Cain reported very good outcomes using a hemi-Indiana pouch.[174] The Mainz pouch (mixed augmentation with ileum and zecum) uses tunneled ureteral implants to prevent ureteral reflux and an unusual nipple valve for continence, with the reservoir created by combining the cecum and Ileum.

To improve results, many groups have described placating the ileocecal valve, and this has become widely accepted as a reliable continence mechanism. The Indiana pouch is based on a modification of Gilcrest and Merricks's cecoileal reservoir. It has undergone several modifications since the initial report in 1985.[175] In this procedure, the cecum is detubularized and used as the reservoir. Reflux prevention is obtained by tunneling the ureters into the tenia or by the Le Duc technique.[176] The continence mechanism is based on plication of the ileum to the level of the ileocecal valve. The native ileocecal valve is reinforced by Lembert sutures (Figure 58.19). A very similar technique has been used by Lockhart et al. in the Florida pouch.[177] The advantage of this procedure is its ease of construction, using techniques familiar to all urologists. Carroll and Presti[230] compared plicated versus stapled ileal segments and noted that mean contraction pressures were higher in the stapled group (63 ± 27 cmH_2O at 41 ± 21 cmH_2O). Mean reservoir volumes were 675 mL, with mean reservoir contractions being 24 cmH_2O and mean plicated ileal pressures 40 cmH_2O in the reservoir. As would be expected from these data, continence rates have been quite good. Rowland reviewed several series and noted that one of 17 patients (6%) required repair of the efferent limb for leakage.[178] Canning, however, reported that leakage occurs more readily with this mechanism than with nipples.[179] Ring and Hensle achieved a 95% continence rate in 29 chi1dren undergoing the Indiana pouch.[180] In Rowland's most recent report, 5 of the last 81 patients had incontinence secondary to high reservoir pressures;[181] however, the cecal reservoir with ileum may correct this.

Koff et al. reported a technique to provide hydraulic compression to the efferent ileal limb of the Indiana pouch.[182] A segment of ileum is used to wrap around the efferent limb and is anastomosed to the cecal pouch. While this would increase resistance further, it adds complexity to an otherwise easily performed procedure that already has a high continence rate. Koff's approach has not gained widespread use.

Appendiceal Stomas

Imprication

Many centers now take advantage of the in situ appendix, which can be imbricated into the cecum, as the continence mechanism (Figure 58.18). Stein et al. reported on 116 patients who catheterized via an imbricated appendix, where only 6.7% had early complications, 25% late complications, and all patients were continent.[183] Gerharz et al. compared the continence mechanisms and noted that 12% of the nipple valves required revision, compared with 17% of the appendiceal stomas. However, the majority of the appendiceal revisions were relatively simple cutaneous revisions for stomal stenosis, while the nipple valves were much more complex and required a laparotomy.[184] Therefore, the imbricated appendix is now their preferred catheterizable channel. If the appendix is not available, a Lampel tube of cecum can be used (Figure 58.19b).[185]

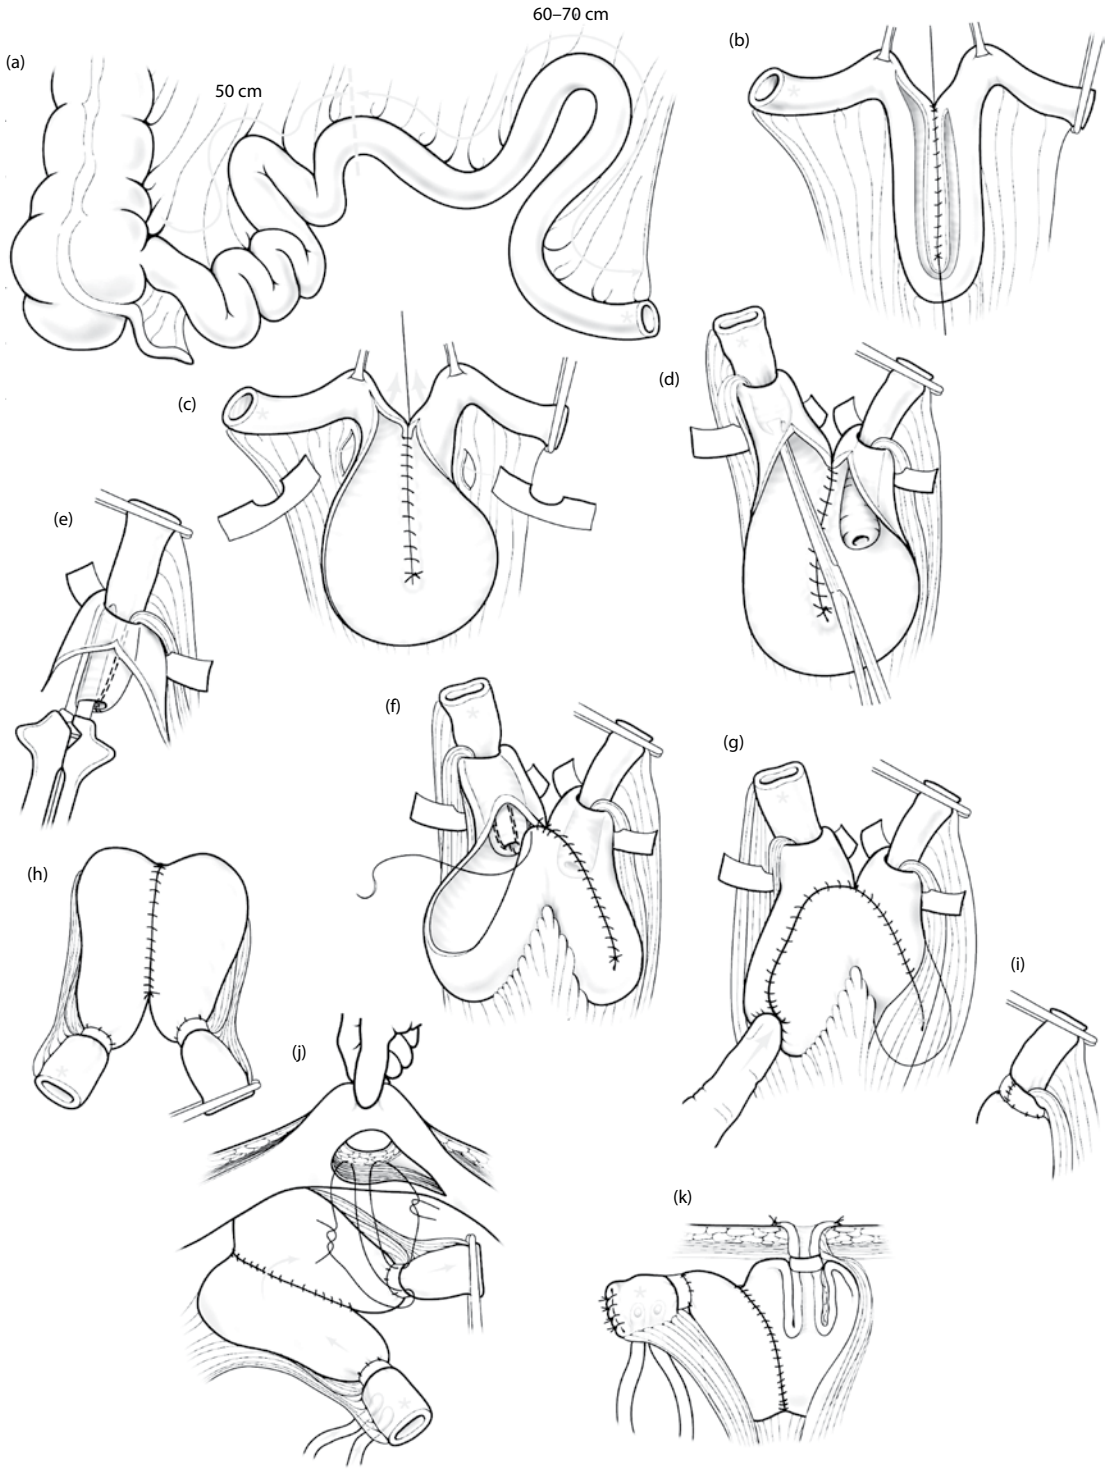

FIGURE 58.15 Kock pouch (continent ileal reservoir). (a) Bowel segment measuring 60–70 cm is isolated approximately 50 cm from the ileocecal valve and positioned as the letter U with the terminal end directed toward the head of the patient and the bottom of the U toward the left side of the patient (https://www.ncbi.nlm.nih.gov/pubmed/1502742). (b) The legs of the U are united at the antimesenteric border with continuous 3–0 polyglycolic acid sutures. (c) The intestine is divided adjacent to the suture line and the incision is continued for 3 cm on the afferent limb. The mucous membrane is sutured with continuous 3–0 polyglycolic acid sutures. Openings are made in the mesentery supplying the future base of the nipple valves. (d) Intussusception of the afferent and efferent segments into the future reservoir. (e) The nipple valves are secured with staples. (f) The reservoir is closed with two continuous inverting 3–0 polyglycolic acid sutures. (g–h) The reservoir is brought into its final position by pushing the corners of the reservoir downwards between mesenteric leaves. (i) A fascia of Marlex mesh encircles the base of the nipple valve, and the ends are approximated with three or four non-absorbable sutures. The reservoir wall is sutured to the cylinder with 3–0 polyglycolic acid sutures. (j) The cylinder at the efferent segment is attached to the opening and anterior rectus sheath with non-absorbable sutures. (k) The completed continent ileal reservoir.

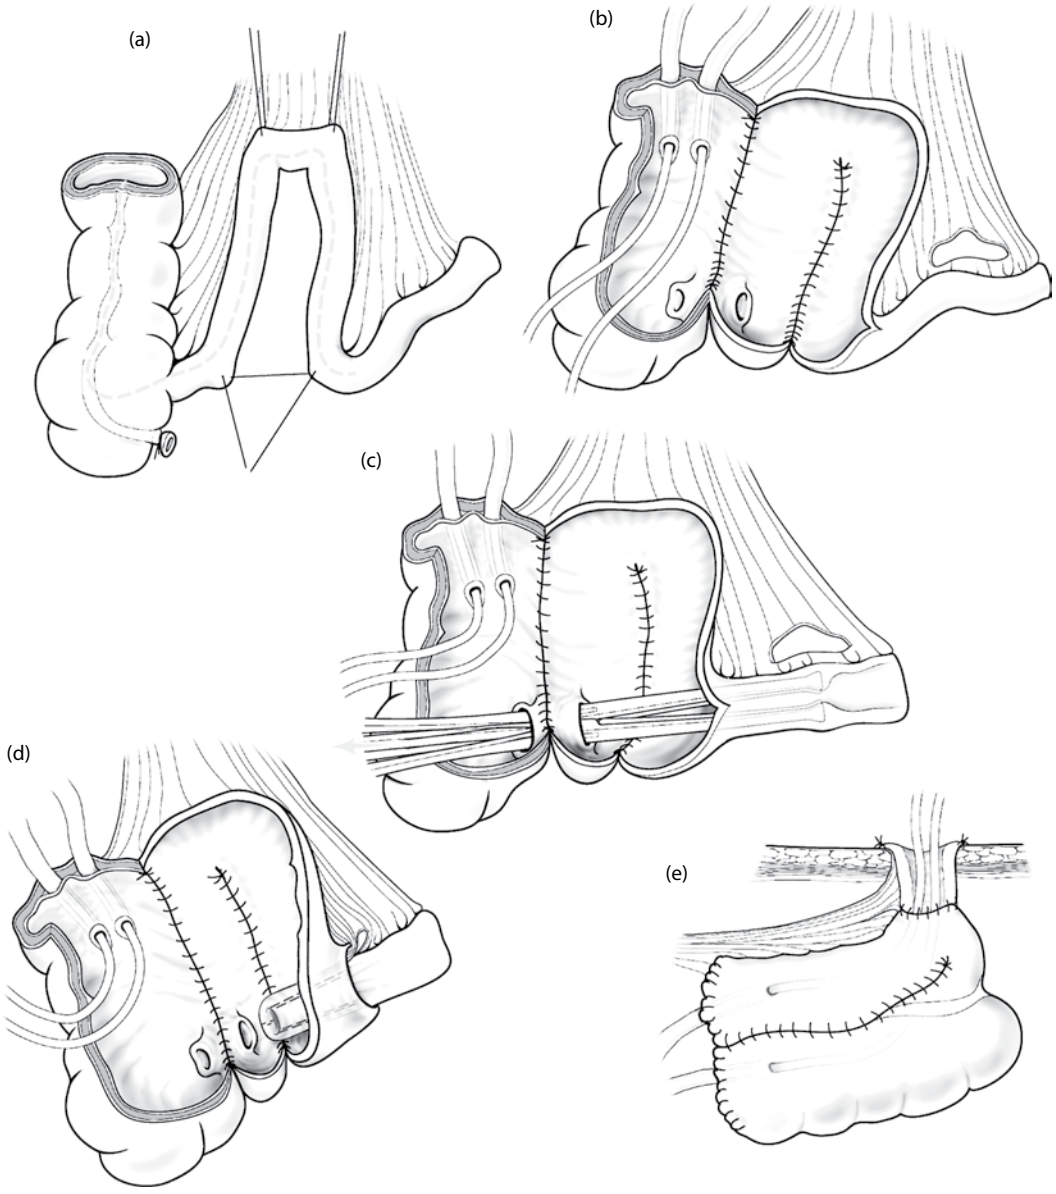

FIGURE 58.16 The Mainz pouch utilizes intussuscepted ileum pulled through the ileocecal valve (c) as the continence mechanism.

Reimplantation

Without question, the most commonly used continence mechanism in children is based on the flap valve principle, as introduced by Mitrofanoff (Figure 58.20).[186] He reported the use of the appendix to tunnel into the neuropathic bladder (similar to a ureteral reimplantation to prevent reflux) to provide a continent catheterizable stoma into the native bladder. The procedure was popularized by Duckett and Snyder,[187,188] who extended the use of this technique to create a continent ileocecal pouch, the Penn pouch (Figure 58.21).[189] Since these early reports, many authors from around the world have reported their experience using not only appendix but also ureter; tapered ileal, colonic, or gastric tubes; fallopian tubes; and vas deferens.[190–199] The continence mechanism is based on placing a supple tube in a submucosal tunnel with a 5:1 ratio of length-to-tube diameter. Firm muscle backing of the tube prevents reflux. It was initially thought that the tube itself must also be muscular, but bladder urothelium, colonic mucosa, and preputial skin alone have all been used successfully.[200–202]

This is a relative simple procedure using techniques familiar to pediatric urologists. It is also particularly useful in children who, as noted previously, often are not candidates for use of the ileocecal valve or long segments of ileum. Kaefer and Retik reviewed several series and found that continence rates ranged from 86% to 96%.[196] The most common complication reported is stomal stenosis. Khoury et al. noted stomal stenosis in 5%–57% of patients and described a technique of placing the stoma at the umbilicus.[203] The Mainz group concluded that the stomal stenosis is slightly higher when placed at the umbilicus. A high risk for stenosis has also been seen when using the appendix compared with tapered ileum; however, this

difference was not seen in the largest published series from Indiana University.[204,205,208] The Great Ormond Street group has reported a decrease in the incidence of stomal stenosis using a VQZ skin-flap technique.[206] Using the concealed umbilical stoma technique, the Pittsburgh group has seen a stomal revision rate of 7% at nearly 3 years' mean follow-up.[207] At a minimum, a skin flap should be placed into the spatulated tube. In the authors' last 100 patients in whom the Mitrofanoff principle has been applied, there is a 99% continence rate. Stomal stenosis has occurred in 12% (5/57 appendix, 1/22 ileum, and 6/21 bladder).[208] In the Boston experience, 5 of 50 patients leaked at the stomal level, 5 had stomal stenosis, and 1 had an appendiceal stricture.[196]

Since the introduction of the Malone antegrade colonic enema (MACE) procedure, which used the appendix brought to the skin for irrigation of the cecum to treat constipation, it has become necessary to find other tissue to form a catheterizable urinary stoma. The recent description of the Yang–Monti technique,[209,210] which uses only 2 cm of reconfigured ileum to form a

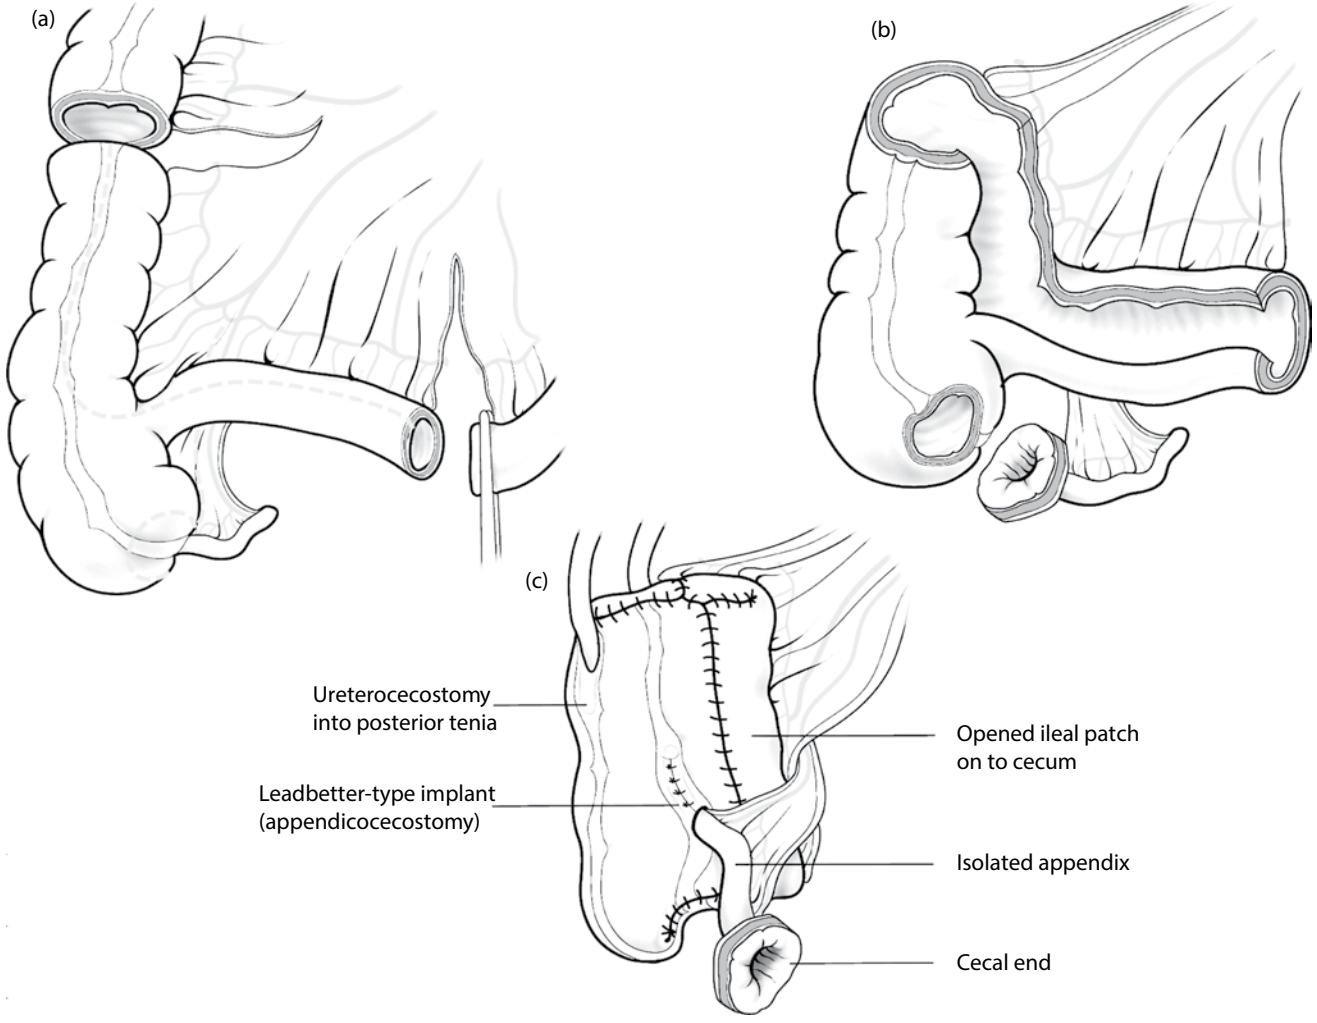

FIGURE 58.21 The Penn pouch. (a) The ileocecal segment is isolated and incised on its antimesenteric border; the ureters are implanted into the colonic segment. (b) The appendix is isolated in its mesentery. (c) The ileocecal segments are joined and the appendix is implanted into the cecum; the cecal end is brought to the skin as a catheterizable stoma.

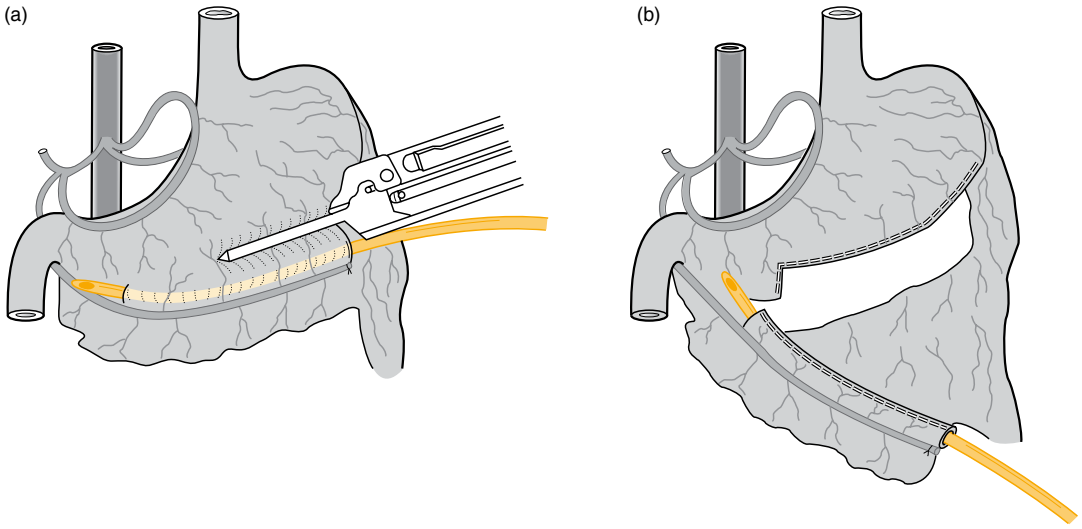

FIGURE 58.22 (a) An isolated gastric tube is harvested with a GIA-90 stapler over a 12 Fr catheter. (b) The mobilized isolated gastric tube is ready for placement into an augmented bladder or reservoir.

tube, has been a great advance and used successfully (Figure 58.23).[211] Tunneling of these tubes into colon or stomach is easily accomplished but is difficult in ileum. A seromuscular trough for implantation has been described,[194] and Plaire et al.[212] have described a serosal reimplant similar to the Abol-Enein and Ghoneim ureteral reimplant (Figure 58.14). It is now clear that the Mitrofanoff principle is a major advance and that virtually any supple tube placed in a tunnel that has adequate muscular backing will successfully provide continence (Figures 58.26 and 58.27).

Ureterosigmoidostomy

The only reservoir that provides a volitional continence mechanism, which also happens to be the first continent reservoir, is the ureterosigmoidostomy.[213] Since its introduction, more than 60 modifications have been proposed. Because of the problems with upper tract deterioration, occasional incontinence, acidosis, and the risk for adenocarcinoma, it has been largely abandoned. However, the opportunity to control continence without CIC continues to make it very attractive. It cannot be used in spinal dysraphism, as a neurologically intact anal sphincter is required. Therefore, in children it has been used almost exclusively in the exstrophy population when continence with CIC is not possible or continence cannot be achieved with bladder neck surgery. It has been suggested that oatmeal enemas be given preoperatively to check anal continence.[214]

Classically, ureterosigmoidostomy has been done by simply tunneling the ureters into the rectum. However, the risk of cancer at the anastomotic site and nighttime incontinence led surgeons to pursue other efforts to provide more of a reservoir effect and avoid direct contact of the ureters with the stool. Development of neoplasms seems to require urine to be in contact with stool and bowel mucosa.[215,216] Of 94 children with ureterosigmoidostomy followed at the Children's Hospital of Boston, 7 developed adenocarcinoma of the colon, 4 of whom died.[217] Rink and Retik

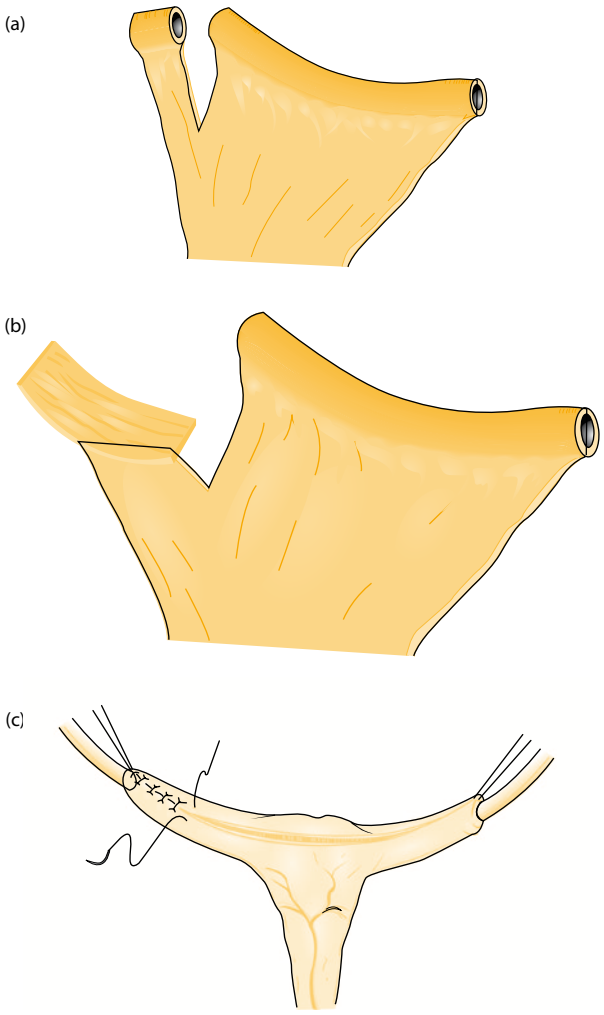

FIGURE 58.23 Yang–Monti. (a) A 2 cm segment of small bowel is isolated on its mesentery. (b) It is opened on its antimesenteric border. (c) The segment is retubularized by closing it in a longitudinal fashion (see also Figures 56.23 and 56.24).

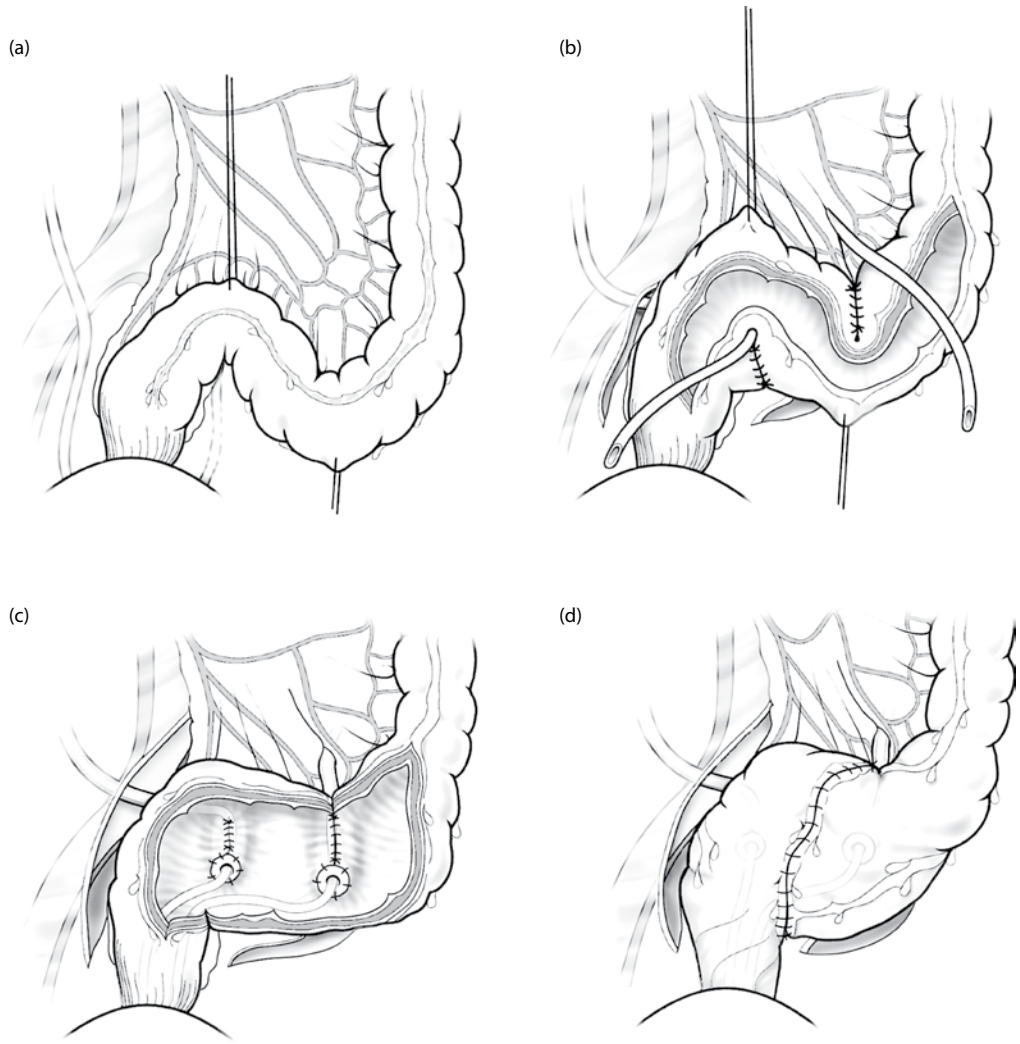

FIGURE 58.24 The Mainz pouch II (sigma rectum) has been presented as a means of reconstructing a low-pressure ureterosigmoidostomy. (From Djokić JH et al. *Acta Chir Iugosl* 2014;61(1):29–34. https://www.ncbi.nlm.nih.gov/pubmed/25782222.)

proposed that an ileocecal conduit be initially constructed and the conduit later anastomosed to the intact sigmoid by end-to-end colocolostomy.[218] Kock et al. described a "valved rectum" with the colon intussuscepted at the rectosigmoid junction to prevent reflux of rectal contents and an ileal patch anastomosed to the anterior rectal wall.[219] This allowed the rectal capacity to increase from 200 to 700 mL, with maximal pressures of only 24 cmH_2O and minimal metabolic disturbances.[219]

A hemi-Kock pouch anastomosed to the rectum has also been described,[219] but the complexity of creating the colonic nipple in these two procedures makes them less attractive. The sigma rectum (Mainz pouch II) has been proposed from the Mainz group as a means of lowering the very high pressures in the intact rectosigmoid colon without the need for nipples or augmentation (Figure 58.24).[220] Continence was achieved in 40 of 47 patients, with voiding five times per day, and extracolonic pressures remained low. The results in 34 patients of the Mainz II were reported by Gerharz et al.[221] All were continent during the day. One had nighttime soiling and creation of an ileal conduit due to recurrent septicemia. One ureteral obstruction led to a nephrectomy, and two had mild hyperchloremic acidosis. While lower pressures with the new procedures should reduce the risk for upper tract changes, the risk for adenocarcinoma still weighs heavily when contemplating any type of ureterocolonic diversion.

Postoperative Care

The complexity of the repair and the potential for complications demand diligent postoperative care in the immediate and long-term periods. In the early postoperative interval, externalized ureteral stents are required to divert the urine from the fresh ureteral-enteric and CUR anastomoses for at least 1 week. H_2 blockers are given temporarily if stomach is used. A large-bore (20–24 Fr) silastic suprapubic tube and a 12–14 Fr catheter in the channel ensure maximal drainage of the reservoir and will remain in situ for 3 weeks. The reservoirs are gently irrigated to remove mucus and prevent plugging of the catheters three times a day for the first 3 weeks, and then slowly decreased to daily, for the rest of the patient's life. A pouch-o-gram may be obtained before removal of the stents.

The patient and all primary caregivers are seen in the outpatient clinic 3–4 weeks from the date of surgery. The catheter is removed and the family is taught CIC through the channel. The indwelling reservoir drainage (suprapubic) tube is only removed after they have demonstrated that they can easily catheterize the stoma and empty the reservoir. Demonstration of complete emptying is mandatory to prevent long-term problems of infection, stone formation, incontinence, and perforation, and to maintain stable renal function. Antibiotics are given until all tubes are removed. The family is to catheterize every 2 hours for the first week, then every 3 hours, and then every 4 hours by the third week. They may then gradually increase the intervals overnight (daytime frequency remains at 4 hours), until it is possible to go the entire night without pain or leakage.

It should be reinforced with the caregivers that the sensation of the reservoir is associated with the gastrointestinal tract. This means that when the CUR is distended, and needs to be catheterized, the patient will not feel a "full bladder" but will often complain of a "full tummy." A distended reservoir will often protrude and be visibly distended.

If the patient or caregiver is unable to catheterize the reservoir, the patient must be seen and the situation addressed urgently. Cystoscopic assistance may be required to reinsert a catheter, or a suprapubic tube be inserted with ultrasound guidance.

The family must be aware that sudden or severe abdominal pain may result from a rupture of the CUR, and this is a life-threatening event. This can be very subtle in the neuropathic populations, as their sensation is impaired and presentation can be delayed.

Renal and pouch sonography, abdominal radiographs, and serum creatinine and electrolytes are all obtained 3 months postoperatively, repeated at 6-month intervals twice, and yearly thereafter. Vitamin B_{12} levels should be checked in the long term and somatic growth monitored. Endoscopic evaluation of the pouch should be carried out annually starting 5–10 years postoperatively.[222–224] Cytology has also been proposed to detect any malignant degeneration.[225] However, these strategies have not yet demonstrated any benefit in the early detection of malignancies.[225]

SUMMARY

Tremendous advances have been made in lower urinary tract reconstruction in children. The entire urinary tract can now be completely replaced, with continent bladders, nonrefluxing ureters, and transplanted kidneys. Incontinent cutaneous diversion is an extremely useful temporary measure of urinary drainage and is easily reversed once the child and family are prepared for continent diversion. However, several permanent options also exist for scenarios where the patient and caregivers are unwilling or unable to provide the care required for a continent diversion.

Although it may be ideal to maintain the native urinary tract intact, if this cannot be achieved, a CUR should be considered. The limits of reconstruction are based only on the surgeon's imagination and skills. As long as the principles of CUR construction outlined in this chapter are met, a successful surgical result can almost always be achieved. True success, however, will always require the cooperation of a well-motivated child and equally motivated parents.[226] Furthermore, the type of major reconstruction necessitates that the surgeon be surrounded by dedicated personnel who function as a team for the betterment of the health of these children.

CHAPTER 59

The Malone Antegrade Continence Enema (MACE)

Joseph M. Gleason, P. S. J. Malone, and Martin A. Koyle

INTRODUCTION

Congenital anomalies of the bowel and urinary tract frequently coexist, and constipation by itself may produce significant bladder dysfunction, leading to incontinence and urinary tract infection.[1] As a result, the pediatric urologist must be conversant with bowel problems and play an active role in their management. Both systems should always be assessed simultaneously, and with present surgical techniques, it is the urologist who is often best placed to treat both urinary and fecal incontinence synchronously.[2]

The first antegrade continence enema (ACE) or Malone (MACE) procedure was performed in 1989, in an attempt to treat the intractable fecal incontinence associated with spina bifida. Koyle et al. subsequently introduced the technique in North America in 1991.[3] Malone et al.[4] reported that 53% of young adults with spina bifida suffered from fecal incontinence, and similar results have been reported by Holschneider[5] in patients with anorectal anomalies, many of whom also had neuropathic bladder dysfunction.[6]

The MACE combined three well-recognized surgical principles that have been clearly described in many papers and the previous editions of this book, and will not be described in detail again here. The combination of these principles, applied to the colon, provided continent intermittent catheter access to the cecum or proximal colon for the administration of antegrade enemas while the patient sat on the toilet. This produced colonic emptying and fecal continence. The preliminary series was reported by Malone et al.,[7] and subsequently, numerous reports have been published so the procedure is now widely practiced around the world.[1,3,8–12] Many modifications have been introduced following the original description,[13] to both simplify the procedure and reduce the high complication rates initially reported.[8] This chapter reviews the techniques in current use, the medical management of constipation, patient selection and preparation, the enema regimens, and the most recent results.

MEDICAL MANAGEMENT

As is the case in any other surgical condition, careful thought and consideration must first be given to more conservative, nonoperative means of treating intractable disorders of defecation. A medical plan, consisting of dietary changes, oral laxatives, and retrograde enemas is often sufficient to manage patients with chronic constipation. In patients with intractable constipation, it is important to ascertain whether an enema program would be beneficial before definitive surgical therapy is instituted. Matsuno et al.[14] suggested in a recent study that fecal continence was comparable whether the enema is administered rectally or antegrade. However, procedural independence was significantly better in the group performing antegrade enemas.

The pediatric surgery group from Cincinnati Children's Hospital Medical Center has devised a bowel management protocol using retrograde enemas to treat patients with fecal incontinence due to either constipation or a tendency toward diarrhea.[15] Prior to beginning any maintenance enema protocol, the rectosigmoid should not be severely impacted. If it is, disimpaction should be performed with multiple daily enemas, oral laxatives, or even manually under anesthesia if needed in extreme circumstances. Once disimpacted, the program is initiated and lasts 1 week. It consists of seeing the patients daily, monitoring the amount of colonic stool with daily abdominal radiographs, and modifying the volume and content of the retrograde enemas to suit the individual needs of each patient. Normal saline is used as the solution, and additives of glycerin (5–30 mL), liquid soap (91–18 mL), or phosphate are added to the solution, in that order (from least to most irritating), when needed to obtain the desired effect. Fleet's phosphate was added for the most difficult patients. The dosage used is 30 mL (half of a pediatric Fleet's) for children <4 years old, 60 mL (full pediatric Fleet's) for children 4–10 years old, and 120 mL (adult Fleet's) for children >10 years of age. The volume of the enema must be tailored to effect, with constipated patients requiring 500–1000 mL on average. Management is considered successful when the underwear remains clean for 24 hours. A 98% (217/220) success rate was reported in their constipated patients. Accordingly, they have stressed the importance of attempting to achieve a successful nonoperative result before consideration of a MACE. Given this high success rate, their approach to intensive medical bowel control is warranted. The enema formulation itself, not the route of administration, should

be considered the key determining factor for a successful outcome.

PATIENT SELECTION AND PREPARATION

For those in whom more conservative measures fail, retrograde enema compliance becomes an issue, and in those who experience successful bowel management through rectal enemas, but desire or require a more convenient means of administration, surgical MACE creation should be discussed. The underlying diagnosis is important, as it influences the success rate. In the initial Southampton experience, patients with a neuropathic bowel and anorectal malformation had a success rate of 73% compared with 38% for patients with chronic idiopathic constipation.[16] Most subsequent worldwide experience similarly has shown that those whose primary bowel problem is constipation fare worse than those with other elimination problems. In part, this might be secondary to the spastic pelvic floor and sphincter, and/or the bowel motility issues themselves. These results have been mirrored by the wider experience in the United Kingdom, where a success rate of 91% was also reported for patients with Hirschsprung's disease.[17] Recent personal communications from pediatric surgery colleagues suggest that the results for patients with chronic constipation have improved. Kokoska et al.[18] reported significant improvement in 10 and continence in 6 of 11 children undergoing a MACE procedure for chronic constipation. The age at operation was also important. In Southampton, there was a 70% failure rate for patients under 5 years of age compared with 24% for those aged over 5 years, a highly significant difference.[16] This was independent of the underlying diagnosis, and it probably reflected the inability of a child under 5 years of age to sit on a toilet for up to 1 hour before emptying is complete. Christison-Lagay et al.[19] reported that age under 12 years was another predictor of success, and Gerharz et al.[20] showed high failure and complication rates when performed in adults. In that study, patient and caregiver motivation was vital in determining success. A lack of compliance to the washout regimen was a major contributory factor to failure in nine patients in our early experiences. Detailed preoperative counseling and continued postoperative support, ideally provided by a nurse practitioner, are essential to ensure adequate and continued motivation, without which the MACE is doomed to failure. It is an advantage to introduce the potential patient to a child and family with a functioning MACE prior to the surgical procedure.

In summary, the ideal patient for a MACE should be between the ages of 5 and 12, have a diagnosis of neuropathic bowel, have an anorectal malformation or Hirschsprung's disease, be well motivated with a dedicated family, and have tried and failed all conservative measures first.

OPERATIVE TECHNIQUES

An aggressive preoperative bowel preparation is essential to facilitate the initial postoperative enema. A cleanout from below is often necessary, especially in the patient where constipation is the primary problem. Appropriate prophylactic antibiotics are always administered perioperatively. A bowel prep is up to the judgment of the surgeon and is not mandatory. In most instances, since coincidental urinary tract reconstruction is performed, a lower midline or Pfannenstiel incision is selected, depending on the patient's body habitus, prior surgical scars, and preference. The open approach can be combined with preliminary laparoscopy, as this allows laparoscopic mobilization of the colon, and is especially useful when the right colon has become more adherent cranially in the abdomen, often to the liver. In such cases (often the spina bifida patient who has prior abdominal incisions and a ventriculoperitoneal shunt), a large incision is avoided. In the patient in whom a MACE only is indicated, a laparoscopic or percutaneous approach or an appendectomy incision can be employed.

In Malone's initial description of the technique, the appendix was transected from the cecum and then reimplanted in an antireflux manner into the teniae. This was based on the concept that creating a valve mechanism would result in no leakage of bowel contents via the cutaneous stoma. Few surgeons perform the MACE in this fashion any longer. Rather, the in situ appendix can be folded over with the cecal wall wrapped around it to produce the antireflux mechanism. This is an adaptation of the technique originally described for the Mainz pouch urinary reservoir.[12] This procedure is performed in slightly different ways depending on the surgeon. Koyle simply wraps the cecal wall around the folded appendix using permanent sutures, similar to the technique for a Nissen fundoplication. On the other hand, Malone continues to produce a submucosal tunnel along one of the tenia and inlays the appendix into this, finally closing the seromuscular layer over it with absorbable sutures (Figure 59.1). The authors recommend catching the serosa of the appendiceal wall with covering sutures in order to prevent it from pulling out of the tunnel. The mesentery of the appendix is fenestrated to prevent the wrap from compromising the blood supply to the appendix. Currently, both of these techniques are performing satisfactorily without significant long-term leakage. Once the antireflux mechanism has been constructed, the cecum or colon is sutured to the posterior aspect of the anterior abdominal wall to ensure that the conduit is not lying free in the peritoneal cavity, as this can lead to kinking and difficulties with catheterization.

It has been reported that it is not necessary to construct an antireflux mechanism, and some surgeons simply pull the appendix out to an abdominal stomal site. This may be done using a laparoscopic approach.[21] We have attempted not using an antireflux mechanism on a number of occasions, and in some cases, the stoma was incontinent of flatus and/or stool, but in the majority, the stoma was continent. Other groups have retrospectively compared laparoscopic ACE (LACE) with and without cecoplication, and have found no increase in stomal incontinence.[22,23] Lawal et al.[24] challenged the previous thinking that an antireflux mechanism could be omitted laparoscopically due to technical difficulty, and showed that cecal plication is feasible with a laparoscopic-assisted approach, and virtually eliminates the risk of stomal incontinence. We continue to recommend that an antireflux mechanism be constructed.

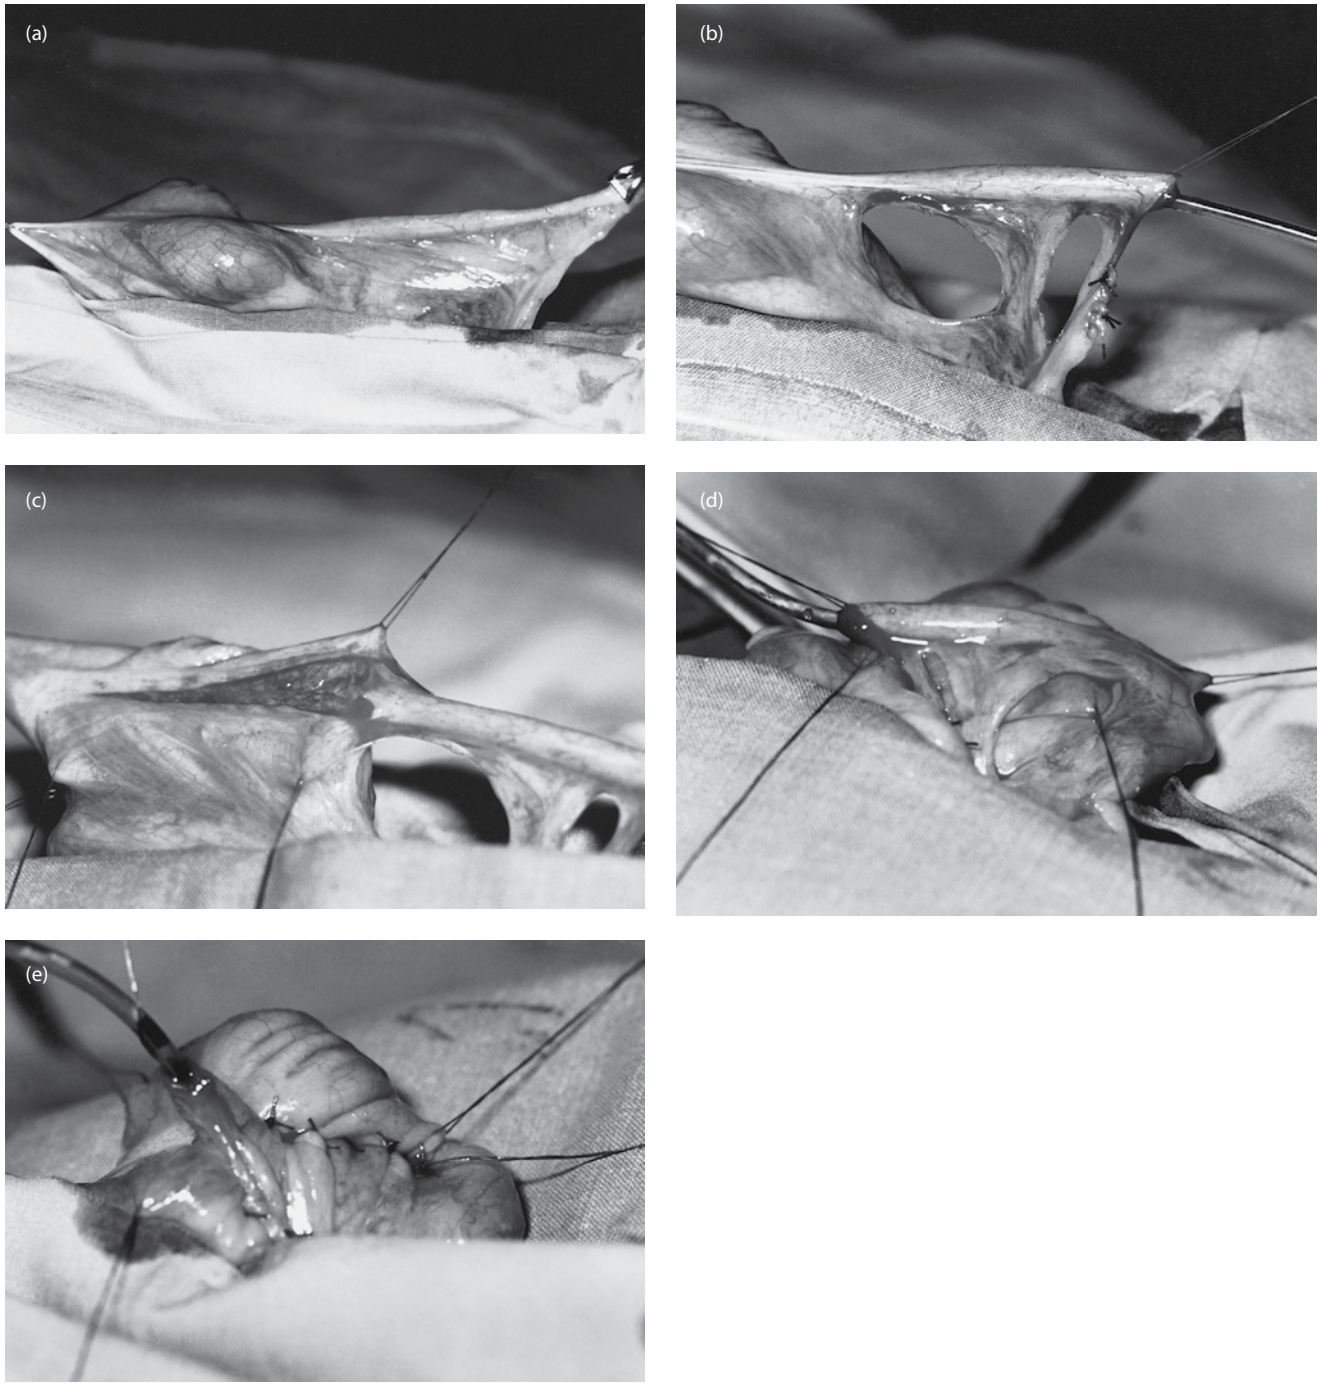

FIGURE 59.1 In situ formation of the MACE. (a) In situ appendix attached to the cecum. (b) Fenestrated appendix mesentery. (c) Submucosal tunnel along one of the tenia. (d) Appendix folded into the tunnel. (e) Completed tunnel (note the short length of the appendix).

The technique needs to be modified if simultaneous MACE and appendicovesicostomy procedures are being performed. If the appendix is long enough and the vascular anatomy is suitable, it is possible to split the appendix, and we have done this successfully. If the appendix is not suitable to split or is absent, another technique must be instituted. The tubularized cecal or colonic flap[25] was previously not recommended because of the unacceptably high complication rates associated with this technique.[3] More recently, it has been suggested that a colon flap or cecal extension of an unacceptably short appendix can be done with relative ease, good results, and improved complication rates.[26] There are two additional alternatives to the appendix worthy of serious consideration. The first is the Monti procedure.[27] This is an ingenious technique where a segment of ileum is harvested on its pedicle and transversely detubularized on its antimesenteric border. The rectangular patch is tubularized along its longitudinal

axis to create a catheterizable conduit of approximately 7 cm in length. The internal valvulae conniventes run in the longitudinal direction of the conduit, thus facilitating easy catheterization. Both ends of the conduit are free of mesentery, and this makes the creation of the antireflux mechanism easy. When a Monti conduit is used, the Mitrofanoff flap valve principle is followed and a submucosal tunnel is created along one of the tenia, which is wrapped around the conduit. This is similar to the original description of the MACE.[13] If the patient is obese, it is possible to use two segments of ileum or colon and produce a 14 cm conduit ("the full Monti"), which is long enough for virtually all patients. This is the procedure of choice when the appendix is not available.[28]

The other technique worthy of consideration is the use of a cecostomy tube and cecal button. Shandling et al.[29] initially described a technique for the percutaneous placement of a cecal tube that could be changed at a later date to a low-profile cecal button (similar to a gastrostomy button), which is then used to administer the enema. A number of patients in our series manage their MACEs using a button, with results no different than those using an appendiceal MACE (Figure 59.2). The indications for the button were

- Sloughing of cecal tubes formed when the appendix was absent
- Refusal by children or caretakers to catheterize their stomas, and thus the buttons are being used semipermanently in these cases
- Patients who developed stomal stenosis on at least one occasion and the families have preferred the nonoperative button option to that of repair under anesthesia

Our greatest worry has been erosion or skin problems as the abdominal wall girth increases with age; hence, a close follow-up is mandatory. The tubes are unsightly, and occasionally leakage around the tube will occur that leads to embarrassment. In a survey of 300 MACE procedures performed in the United Kingdom, 19 cecal buttons were used, and they worked well in most cases.[17] Chait et al.[30] placed buttons percutaneously under local anesthesia with good results, and follow-up data of a 7-year experience showed successful placement in all 163 procedures, with outcomes similar to those of other approaches.[31] The same procedure has been performed laparoscopically during concomitant appendicovesicostomy in three patients without any differences noted.[32] It is our subjective impression that in the long term, many of the patients with stomal appliances develop skin problems and leakage and, as a result, or because of pure image issues, request formal conversion to a bowel-based MACE.

One of the problems encountered in some patients with the MACE, particularly those with constipation, is the time it takes for the washout to work. This has led to failure and abandonment of the procedure in a number of patients.[9] In an attempt to overcome this problem, some surgeons have placed a Monti-MACE conduit in the left colon to reduce the length of bowel that has to be washed through, and thus the time taken. Preliminary results with this approach are very encouraging and show similar results with equivalent complication rates compared to traditional MACE.[33–37] In addition, a recent literature review showed that left-sided conduits had less enema fluid requirements, shorter transit time, and fewer complications when compared with right-sided conduits, with comparable outcomes.[38] A left MACE should always be considered in patients with severe associated constipation. More recently, a new development embracing the principles of minimally invasive surgery and the left-sided MACE has occurred. Following bowel preparation, a colonoscopy is performed. With the scope in the distal descending colon, a colostomy tube is inserted as one would insert a percutaneous endoscopic gastrostomy (PEG), the percutaneous endoscopic colostomy (PEC), with washouts being able to commence the next day. We have used the percutaneous tubes as "training wheels," especially in constipated patients. In such cases, when it is uncertain where the enema should be administered, an initial tube is placed in the right colon. If the flushes are successful clinically, then the patient and family may wish for no further surgery or desire conversion to a formal MACE. If the results, however, are inadequate, a second tube can be inserted into the left colon or sigmoid. If results are better than on the right, a left-sided MACE is then offered.[39]

There are therefore a number of different approaches to the MACE in 2014. If the patient requires a synchronous bladder reconstruction, a formal conduit is constructed using the in situ appendix in the cecum, or a left-sided Monti-MACE if constipation is a severe problem. If the MACE is all that is required, a LACE would be the procedure of choice for cecal placement, or a PEC if the patient is constipated and a left-sided placement is needed. Now, it is also easy to perform simultaneous MACE and Mitrofanoff urinary diversion, offering patients the chance of complete continence for the first time.[2,40,41]

By adopting these newer techniques, complications such as incontinence of the conduit or difficulties catheterizing it are rare. However, another potential complication is conduit perforation and intraperitoneal instillation of the enema. DeFoor et al. retrospectively reported a 3.7% risk of perforation in 187 patients between 1989 and 2002. Seven patients presented with abdominal pain and/or traumatic catheterization, two requiring laparotomy for peritonitis. The remaining patients were managed with endoscopic placement of a catheter for a 6-week period.[42]

The remaining aspect of the operative technique is the construction and placement of the stoma. The most common complication of the MACE in our earlier series was stomal stenosis. Curry et al.[16] reported an incidence of 55%. Nineteen and twenty-two percent of the patients in our initial series required surgical revision. In an attempt to reduce this stenosis rate, patients were advised to intubate the stoma twice a day, and this seemed to be reduce the problems with stenosis. The initial description of the MACE advocated a cutaneous V-flap, but we changed to using modifications of the Ransley VQZ-flap when the MACE was positioned in a location other than the umbilicus to try to reduce the incidence of stenosis still further. This has been shown to significantly reduce stomal problems in the Mitrofanoff,[43] as well as the MACE procedures.[44] This method uses two separate skin flaps and can be constructed on the abdominal wall or in the umbilicus (Figure 59.3). The conduit is left intubated for a period

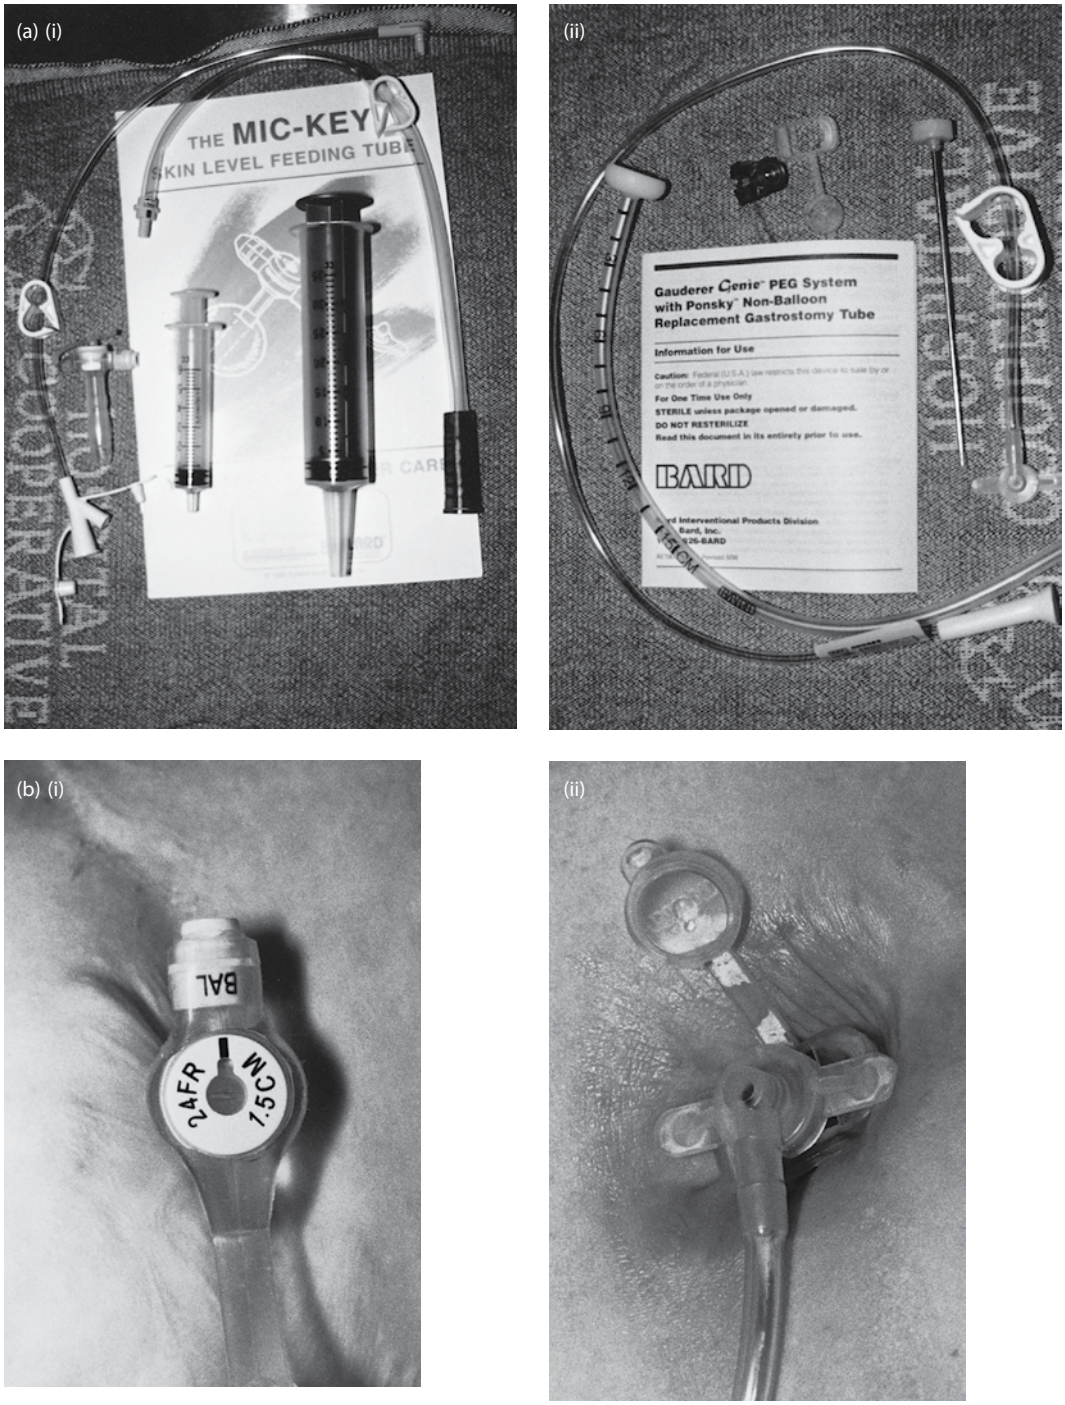

FIGURE 59.2 (a) (i) Mic-Key (Ballard Corporation). (ii) Genie (Bard) button kits. (b) (i) Mic-Key button in right lower quadrant MACE stoma. (ii) Genie in umbilical stoma.

of 2–4 weeks postoperatively before intermittent catheterization is begun. McAndrew and Malone[45] reviewed their experience of all continent catheterizable conduits. They found no difference in the complication rates between the Mitrofanoff or MACE procedures. Ninety-seven percent of the conduits were continent, and the stomal stenosis rate was 31%. There was no difference relating to the type of conduit or the site of the stoma. Stomal stenosis occurred in 41% of V-flap stomas and 25% of modified VQZ-flap stomas, and although this did not reach statistical significance, there was certainly a trend in favor of this stoma. Barqawi et al.[46] reported very similar results, with a continence rate of 98% and a stomal stenosis rate of 18%. More recently, Landau et al.[44] demonstrated superiority of the VQZ-flap when compared with umbilical stomas or tubularized skin flaps, with no stomal complications reported.

In summary, these data suggest that the ideal MACE should use the in situ appendix or the Monti conduit with

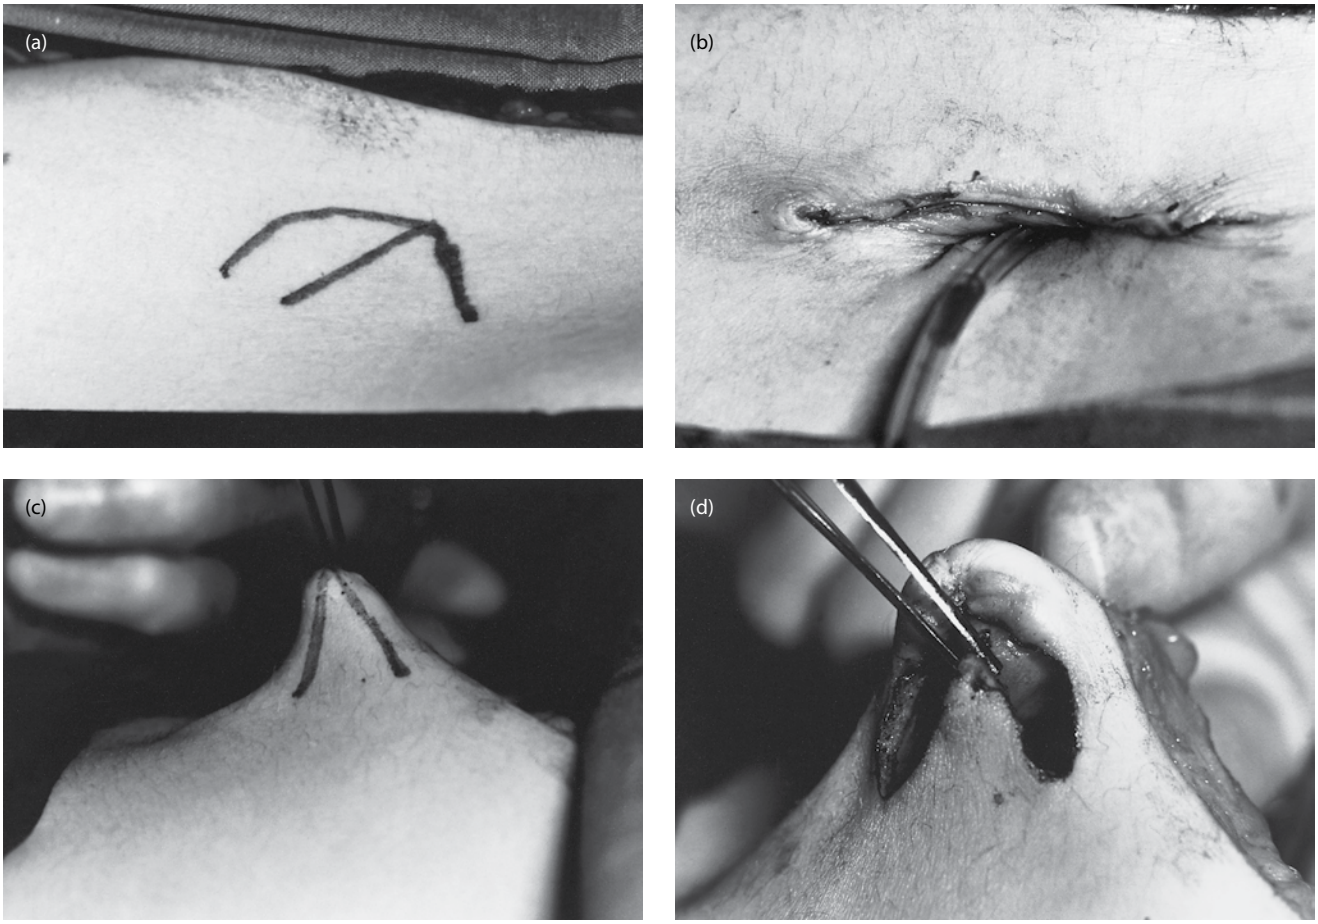

FIGURE 59.3 VQZ right lower quadrant (VQZ) and V-flap umbilical stomas. (a) Multiflap VQZ abdominal stoma. (b) Complete VQZ stoma in the right lower quadrant. (c) Everted umbilicus for the V-flap. (d) Mobilized V-flap. Note that this produces a second anterior flap.

an antireflux mechanism. A two-flap cutaneous stoma should be used and placed either on the abdominal wall or in the umbilicus.

ENEMA REGIMEN

The first enema is given via the indwelling catheter when bowel activity returns, usually around the third to fifth postoperative day. In those patients whose primary problem is constipation, it may be necessary to clean out the bowel from above and below initially, until an effective MACE regimen has been achieved. The time of day that the enema is administered is patient dependent, and most families prefer to give the enema during the early evening hours, just after dinner. This time is chosen to allow a sufficient interval to achieve the desired result before bedtime.

Many enema regimens are used in the different centers performing the MACE, and patients frequently modify them to suit their own particular needs. One of the most important points is to advise patients not to expect immediate success. Each individual regimen usually takes up to 1 month to figure out, and is established by trial and error. In our series,[16] many children did not achieve a steady state or a successful MACE for periods of up to 6 months. It is necessary to counsel patients about this preoperatively, as early disappointment can lead to complete failure. Many patients experience a degree of rectal leakage within the first few hours of the washout, but this is rarely a major problem. While the washout regimen is being established, it is vital to maintain regular contact with the nurse specialist. Initially, daily washouts are recommended, but once the patients are comfortable with the procedure, they may attempt to decrease the frequency to alternate days. Once a steady state has been achieved, there is no benefit from interfering with the regimen. In our series, the mean time taken to perform the washout was 39 minutes (range 20–60 minutes) and 34 minutes (11–68 minutes), respectively. It is essential that patients and caregivers be aware of the time commitment that is required and be prepared to devote this time to bowel care, because if they do not, the MACE will fail. Because patients have to sit on the toilet for a long time, one of the complications encountered is pressure sores on the buttocks. It is possible to obtain padded toilet seat covers, and their use is recommended, particularly for the neuropathic patient with reduced or absent sensation.

The enema given differs from center to center, with most centers in the United Kingdom favoring the use of a stimulant, while those in the United States use mainly saline or tap water. In the United Kingdom, the common

regimen uses a phosphate enema (Fletchers, Pharmax, United Kingdom). Initially, 50 mL of enema solution is made up to 100 mL with tap water (this has replaced the saline initially used), and this is rapidly instilled, followed by approximately 500 mL of water. Depending on the response, adjustments are made to the strength and volume of the phosphate, up to a maximum of 100 mL of undiluted phosphate enema. Although a few patients achieve successful results with the phosphate alone, the majority require the additional water lavage. Care must be taken when using phosphate, and the dose will need to be adjusted, depending on the age of the child. If the enema does not produce a result, a second one should not be given, as phosphate toxicity may occur if it is retained, and this is a potentially life-threatening complication.[47] Three patients in our early series had experienced phosphate toxicity. Schreiber and Stone reported a case of fatal hypernatremia in a child whose irrigant was tap water with table salt used as an additive, occurring 5 months postoperatively.[48] Yerkes et al. showed safety in using hypotonic tap water as the solution for the washouts without finding water intoxication in any patient. They studied 71 patients, and did not demonstrate any significant hyponatremia or hypochloremia.[49]

If the enema does not produce an immediate result, patients should be advised to wait 1 hour and then perform a further water lavage. If that is unsuccessful, they should be admitted to a hospital for a retrograde enema and observation. However, care must be taken irrespective of the agent used, as there are anecdotal reports of deaths occurring when too much salt was added to tap water. In the United States, tap or salt water is instituted at 50 mL/day and increased by doubling the volume every 3 days until reliable evacuation occurs. If there is no success after reaching 500–600 mL, alternatives are sought, including mineral oil, GoLYTELY or Fleet's enema through the MACE, or altering the frequency of the enema.

Several difficulties have been experienced during establishment of the MACE. The most common problem has been pain during the enema, which occurred in 58% of patients in our early UK series.[16] In the majority of patients, the pain subsided during the first 3 months, but it persisted and was a major contributory cause to the failure of the MACE in three patients. Strategies for the reduction of pain include lowering the concentration of the phosphate, reducing the rate of the infusion, using an antispasmodic prior to the enema, or changing the enema agent to a licorice root solution, which produces less peristalsis than the phosphate. Three inches (7.5 cm) of licorice root or 5 mL of commercially available licorice granules are microwaved with 100 mL of saline until the mixture boils. It is allowed to cool to room temperature and then is diluted with a further 200 mL of saline prior to administration. It is also possible to vary the concentration of the licorice, depending on the response and whether the patient experiences pain. Many patients in the United Kingdom are now successfully using this regimen, and it does seem to produce much less pain. It is also possible to use many of the other laxatives, such as bisacodyl or docusate sodium, by instilling them directly into the colon via the MACE. In North America, where balanced fluids are primarily used, pain has been less of a problem. Usually, reducing the volume of infusate or the route of administration alleviates the problem.

Despite regular washouts, some patients get constipated, and this produces pain and washout failure. Under these circumstances, a Fletchers' arachis oil retention enema (Pharmax) instilled 12 hours before the washout was recommended, but because of possible peanut allergy, this has now been replaced by mineral oil. In the United Kingdom, saline enemas by themselves have been tried, but this seems to lengthen the time taken to achieve a successful washout, and the authors continue to recommend a stimulant such as phosphate or licorice.

One of the problems encountered with the MACE is the time taken for the enema to pass and achieve a result, more than 1 hour in some cases. In our series,[16] the most common cause of failure was the inability to pass the enema, which occurred in 9/12 (75%) cases that failed. Also, if passage time has been greater than 45 minutes, compliance, and hence success, was also reduced. The constipated, as opposed to the incontinent, group clearly comprises the majority of these patients. It is in these patients that the left-sided MACE is to be recommended, preferably commencing with a trial of the PEC tube, as described above.[35,36]

Liloku et al.[36] described six patients with a left Monti-MACE, with a washout time of 10–30 minutes, with five being clean. Churchill et al.[37] reported 18 patients with a left-sided MACE with a mean washout time of 18 ± 12 minutes and an 83% continence rate.

In summary, many different enema regimens exist, but they are all established in the individual patient by a process of trial and error and may take up to 6 months to stabilize. The frequency of the enema should not be less than alternate days, and patients should be prepared to spend up to 1 hour on each enema.

RESULTS

The results of the MACE have been classified as follows:[16]

- *Full success*: Totally clean or minor rectal leakage on the night of the washout
- *Partial success*: Clean but significant rectal leakage, occasional major leak, still wearing protection, but perceived by the parent or child to be an improvement
- *Failure*: Regular soiling or constipation persisted, no perceived improvement, and the procedure was abandoned, usually to a colostomy

Curry et al.[16] reported on 31 patients with a mean follow-up of more than 3 years. The MACE failed in 12/31 (39%) patients, and this included 5 of the 8 patients treated for chronic idiopathic constipation and 1 patient with Hirschsprung's disease. When patients with neuropathic bowel and anorectal malformation were analyzed separately, partial and full success rates were 75% and 70%, respectively. Curry and Malone[17] reported on a survey of MACEs performed by members of the British Association of Paediatric Surgeons (BAPS), in which 300 cases were identified and the success rates were dependent on the original diagnosis (Table 59.1).

TABLE 59.1 MACE: Success and failure based on original diagnosis

Diagnosis	Full success (%)	Partial (%)	Failure (%)
Spina bifida	63	21	26
Anorectal	72	17	11
Hirschsprung's	82	9	9
Constipation	52	10	38
Other	44	25	31

The overall success rate, including full and partial success, for this large national series was 79%. It is also interesting to note that complication rates were lower than those in earlier historical series. In particular, the stomal stenosis rate was down to 30%.

Shankar et al.[50] assessed the results of 40 patients who had a MACE more objectively by using a quality of life improvement (QOLI) score. A score of 5 denoted a perfect result, and the mean score for all patients was 3.5. They found the score to be significantly lower in wheelchair-dependent patients with spinal dysraphism (2.5) when compared with all other mobile patients.[4] Aksnes et al.[51] reported important improvements in self-esteem and psychosocial function in 20 patients with myelomeningocele 6 months after a MACE procedure. More recently, Ok and Kurzrock[52] utilized the validated fecal incontinence and constipation quality of life (FICQOL) questionnaire to obtain objective data on patients with spina bifida. They showed a decrease in the number of accidents per week (0.3 vs. 3.9), a decrease in the number of patients needing oral laxatives (6% vs. 44%), and reduced anxiety and family worry, allowing for a greater ability to leave the home without worrying about the child having leakage of stool. Also, Hoekstra et al.[53] demonstrated a satisfaction rate of 86% using a nonvalidated questionnaire, and 73% of their respondents would recommend the procedure to others with intractable defecation disorders. By using these objective measurements, the MACE has been shown to be successful.

Finally, it is valuable to assess those patients undergoing synchronous bladder reconstruction and MACE procedures. Wedderburn et al.[2] reported fecal and urinary continence in 76% of 46 patients undergoing synchronous procedures, but the rate of revision surgery was high. Kajbafzadeh and Chuback[54] reported similarly good results for synchronous surgery, with all 40 of their patients being clean and dry, and an overall 7.5% complication rate. Casale et al.[41] also reported excellent fecal and urinary continence rates in their cohort of 158 patients undergoing total continence reconstruction (both bowel and bladder), and showed no statistically significant difference in the continence or complication rates when compared with those undergoing staged reconstruction.

CONCLUSIONS

Despite the relatively high complication rates, the MACE offers in excess of 80% of patients with neuropathic bowel and anorectal malformation a chance to be clean. When successful, it transforms patients' lives, and it does not interfere with the final option of a colostomy, should that become necessary. No patient should undergo lower urinary tract reconstruction without a complete bowel assessment, and if necessary, a simultaneous MACE should be carried out. A simultaneous procedure does not jeopardize the success of either individual component, and double continence rates range from 76% to 100%. The reconstructive urologist is the best person to manage the bowel, as the operative techniques involved are those routinely employed in lower urinary tract reconstruction. Furthermore, the infrastructure should be in place for meticulous follow-up. This combined approach has been shown to enhance the quality of life for these sometimes complex patients.

CHAPTER 60

Minimally Invasive Approaches to Lower Urinary Tract Reconstruction

Glenn Cannon, Steven G. Docimo, and Christina Kim

INTRODUCTION

In the past 35 years, minimally invasive surgery in pediatric urology has evolved from simple diagnostic procedures to a method for performing complex reconstructive surgery. The goals of laparoscopy and robotic surgery are to maintain the principles of open procedures while minimizing morbidity for the patient. This chapter discusses the indications, techniques, and outcomes for minimally invasive lower urinary tract reconstruction.

PRINCIPLES OF BLADDER RECONSTRUCTION

Pediatric lower tract reconstruction is commonly indicated for patients with neurogenic or nonneurogenic voiding dysfunction associated with high pressures, low volume, or inadequate outlet resistance. In order to protect the upper tracts from damage, and to enhance or enable urinary continence, surgery is sometimes necessary to enlarge the bladder and lower the filling pressures. In addition, surgery is sometimes necessary to enhance outlet resistance and provide for methods of emptying.

Bladder enlargement may be achieved with or without the use of bowel segments. If a bowel segment is needed, it is detubularized and reconfigured to minimize internal contractions and maximize volume.[1,2] When the circular muscle fibers are divided in a longitudinal fashion, the source for the strongest generation of contractions is stopped.[3] Theoretically, detubularization doubles the volume of the original segment. Although studies have shown the detubularized segments ultimately retain some internal contractions, detubularization is the best method available to decrease its frequency and strength.[4]

Emptying the bladder regularly will reduce the risk of infections and protect renal function. Emptying may be through voiding or may require intermittent catheterization. Catheterization may be achieved through the native urethra or a constructed continent stoma.[5] If bladder outlet resistance is low, this can be treated with bladder neck reconstruction, insertion of an artificial sphincter, placement of a periurethral sling, or bladder neck closure—and intermittent catheterization allows a tight reconstruction without regard to the ability to void spontaneously.

Benefits of Laparoscopic Reconstruction

By creating a continent system, bladder reconstruction allows the patient more independence and better quality of life. Traditionally, the most common way to access the appendix, small bowel, stomach, and colon, as well as other pelvic organs, was by making a long midline incision.[6,7] Laparoscopic reconstruction or assistance allows the same access and manipulation through 5 mm ports with or without a lower midline or Pfannenstiel incision.

The number of visible scars has been shown to inversely correlate with pediatric patients' level of happiness and satisfaction.[8] In addition, scars associated with reconstructive surgery have been associated with lower self-esteem and poor body image.[9] It is reasonable to consider that these associations and outcomes are even greater in the pediatric and adolescent populations. Not only surgical scars, but also the appearance of stomas can have an impact. The development of a concealed umbilical stoma is a major step toward improving body image,[10] as well as decreasing the likelihood of stomal stenosis.[11]

Laparoscopy is associated with decreased morbidity and improved cosmesis. The outcomes in pediatrics have mirrored the outcomes in adults. The use of laparoscopy has been associated with lower narcotic requirements, shorter hospital stays, and quicker return to normal activities. In addition, and perhaps more important to long-term health, it has been shown that fewer adhesions develop after laparoscopic surgery than after open surgery.[12–14]

Most minimally invasive bladder reconstruction falls into one of three categories: laparoscopic, laparoscopic assisted, or robotic assisted. This chapter reviews the principles, techniques, and outcomes of these surgeries.

Indications and Contraindications

As previously noted, the primary indications for bladder reconstruction in children are to improve bladder filling pressures, improve urinary continence, and reduce the incidence of urinary tract infections. Candidates usually have reduced bladder capacity, poor bladder compliance, uninhibited

detrusor contractions, and/or inadequate bladder neck resistance. Options for bladder expansion include autoaugmentation, ureterocystoplasty, and enterocystoplasty.

As with open reconstruction, some contraindications for laparoscopic bladder reconstruction include uncorrected coagulopathy, poor patient compliance, or the inability to perform clean intermittent catheterization. Relative contraindications for laparoscopic bladder reconstruction are short gut syndrome, severe inflammatory disease of the bowel or bladder (e.g., inflammatory bowel disease and bacterial cystitis), multiple prior open abdominal procedures, and prior radiation therapy with significant intra-abdominal adhesions.

Neither a history of previous abdominal surgery nor the use of peritoneal dialysis is a contraindication for laparoscopic bladder reconstruction. In addition, it is safe to perform laparoscopic surgery in patients with an existing ventriculoperitoneal shunt.[15,16]

PREOPERATIVE EVALUATION

Preoperative evaluation is similar to screening for open bladder reconstruction. All patients undergo complete urodynamic evaluation to assess bladder capacity, bladder compliance, and Valsalva leak point pressure. In addition, patients undergo a voiding cystourethrogram to assess for vesicoureteral reflux. In children with hydronephrosis, concominant ureteropelvic or ureterovesical junction obstruction must also be ruled out. Existing renal function is assessed with a serum creatinine and possibly a nuclear renal scan.

Patients must be prepared to perform clean intermittent catheterization. This may be done through a new catheterizable stoma, a newly reconstructed bladder neck, or the native urethra. It is not uncommon to require that the patient and family comply with a preoperative routine of regular catheterizations, which may be a few weeks or even a few months.

Other considerations include the possible need for bowel continence mechanisms. If an antegrade continence enema (ACE) is needed, it should ideally be accomplished at the same time.[17]

Laparoscopic Bladder Autoaugmentation

The concept of bladder autoaugmentation was first described in 1989 as an alternate method to increase capacity.[18] Since then, laparoscopic bladder autoaugmentation (LBAA) has been described through a transperitoneal and retroperitoneal approach.

The first transperitoneal laparoscopic bladder augmentation in a child was described in 1993.[19]

In 1998, a case series in seven children was reported by Braren and Bishop.

A 5 mm trocar was placed at the umbilicus. Two 5 mm working ports were placed in the left and right lower quadrants. Using direct visualization, both ports were placed lateral to the inferior epigastric vessels (Figure 60.1).

An elliptical incision was used to wedge out a segment of detrusor muscle while leaving the mucosa intact

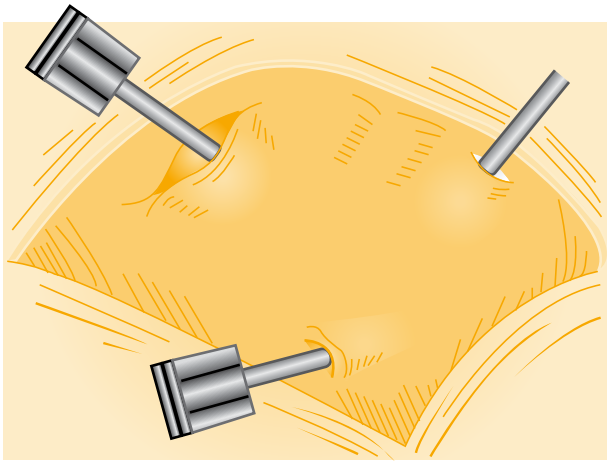

FIGURE 60.1 Three 5 mm trocars are placed. A camera port is located at the umbilicus. Two working ports are placed in the lower quadrants, lateral to the inferior epigastric vessels. (From Ehrlich RM, Gershman A. *Urology* 1993;42:175–8; Braren V, Bishop MR. *Urol Clin North Am* 1998;25:533–40. Reproduced with permission.)

(Figure 60.2). The bladder was filled with normal saline to assess the size of the created diverticulum and to assess for any leakage.

Operative time ranged from 55 to 93 minutes. The majority of patients were sent home the same day of the procedure.

Patients were followed between 10 months and 4 years. Bladder capacity increased from 55% to 95% of the original volume. Six patients achieved complete dryness.[20]

Extraperitoneal LBAA

Only one case of a preperitoneal LBAA has been reported. This was done in a 26-year-old female.

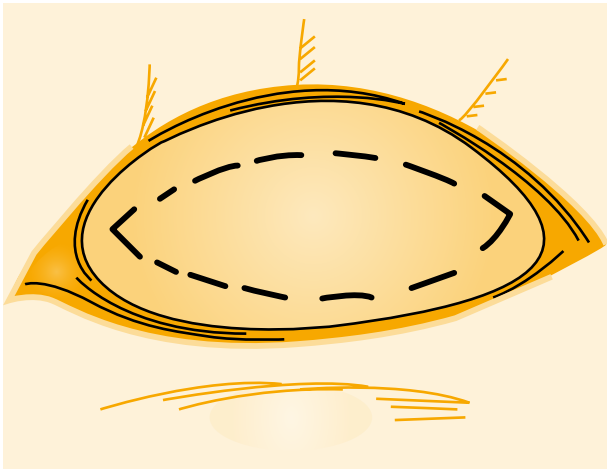

FIGURE 60.2 The detrusor muscle is divided in an elliptical fashion, leaving the underlying mucosa intact. (From Ehrlich RM, Gershman A. *Urology* 1993;42:175–8; Braren V, Bishop MR. *Urol Clin North Am* 1998;25:533–40. Reproduced with permission.)

The operation lasted 6.5 hours and had an estimated blood loss of 75 cc. The patient was discharged on postoperative day 2 with both catheters and ureteral stents in place. One catheter was left in place for 1 month before no leakage was confirmed on cystogram. Initially, the patient required intermittent self-catheterization and later voided by the Valsalva technique every 3 hours. At the 9-week and 6-month follow-ups, the patient was dry in the day and night.[21]

Laser LBAA

Poppas et al. then described a technique used in two pediatric patients. Both patients underwent a mechanical bowel preparation in preparation for a possible open enterocystoplasty if any difficulty with laparoscopy was encountered. Using an open technique, a 10 mm laparoscopic port was placed in an infraumbilical incision. Working ports (5 mm) were placed in the upper quadrants (one in the right and two in the left). A KTP 532 nm laser was used through a 600-micron fiber. This was done through a 5 mm port. The laser was used to incise the peritoneum overlying the bladder. The detrusor muscle was then mobilized bluntly, and the mucosa was easily visualized secondary to instilled methylene blue.

Each procedure lasted approximately 90 minutes. Initial results were favorable with no leakage and decreased detrusor peak pressure. However, at 4-month follow-up, there was urinary leakage between catheterizations and detrusor pressures greater than 40 cm H_2O. Ultimately, both patients underwent enterocystoplasty. At the time of that procedure, there was a thickened covering over the area of autoaugmentation. Pathology revealed mucosa with chronic inflammation but no muscular tissue.[22]

Although autoaugmentation is an ideal procedure for adaptation to a minimally invasive approach, the authors have no experience with the technique because long-term results have, in general, not been favorable. Nonetheless, this technique can be considered when the main goal is either improved compliance or decreased uninhibited contractions in a patient who already has adequate volume.

LAPAROSCOPIC ENTEROCYSTOPLASTY

Enterocystoplasty remains a commonly used technique for increasing bladder capacity. Classically, this is performed through an open laparotomy. First described in a canine model in 1888, it was then demonstrated in a clinical report in 1898.[23] As time has progressed, modifications have been made to improve operative technique and postoperative outcomes.

The first laparoscopic enterocystoplasty in an adult or child was a gastrocystoplasty that took place in 1994.[10] Three 12 mm ports were used. The camera port was placed through a supraumbilical incision. Two working ports were placed near the level of the umbilicus in the anterior axillary line. This access allowed manipulation within the pelvis, as well as the upper abdomen (Figure 60.3).

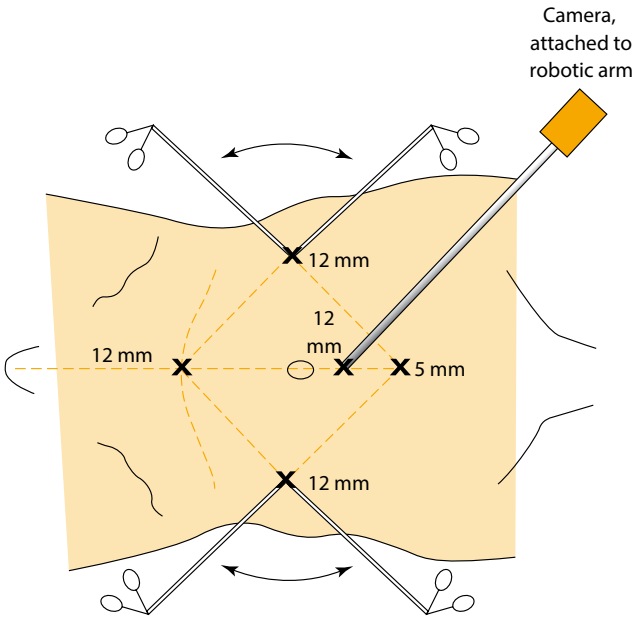

FIGURE 60.3 A camera is placed through the umbilicus. Two working ports are placed along the anterior axillary line. Positioning the working ports near the height of the umbilicus allows access into the upper abdomen and low into the pelvis. (From Docimo SG et al. *J Urol* 1995;154:1513–5; Meng MV et al. *J Urol* 2002;167:1386. Reproduced with permission.)

The dissection began by separating the bladder from the anterior abdominal wall. This dissection was taken caudally to the level of the urethra. Next, the greater omentum was separated and the right epiploic vessels were divided from the greater curvature. This division was performed using small clips close to the wall of the stomach.

A fourth 12 mm port was placed in the midepigastrium close to the pubic tubercle. A series of firings of an Endo-GIA stapler was used to resect a segment of the stomach (Figure 60.4). Stomach (20 cm) was isolated for the augmentation. This segment accounted for approximately one-third of the surface area of the stomach. The staple line of the stomach was oversewn with a 3-0 Vicryl suture in a running fashion. The bladder was then opened to the level of the urethra. The isolated gastric segment was sewn to the open bladder after the staple line had been removed. This started posteriorly and then moved anteriorly. Similar to the gastric segment, the anastomosis of the augmentation was completed with a 3-0 Vicryl suture in a running fashion. To assist in the anastomosis, an Endo-Stitch autosuturing device (Auto Suture Company, Norwalk, Connecticut) was used.

Due to incompetent bladder resistance, a modified Gittes bladder neck suspension was also performed. At the end of the procedure, a suprapubic catheter and an extravesical suction drain were placed. Operative time was close to 11 hours with no intraoperative complications.

Postoperatively, the patient was tolerating regular food on postoperative day 4. An external drain was required for 13 days until a urine leak sealed over. Because of social concerns, the patient was not discharged until the

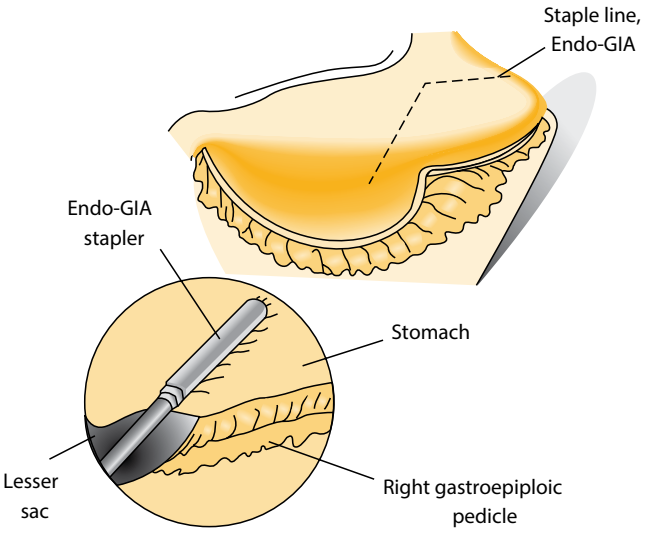

FIGURE 60.4 The gastric segment is isolated using multiple firing of an Endo-GIA stapler. (From Docimo SG et al. *J Urol* 1995;154:1513–5; Meng MV et al. *J Urol* 2002;167:1386. Reproduced with permission.)

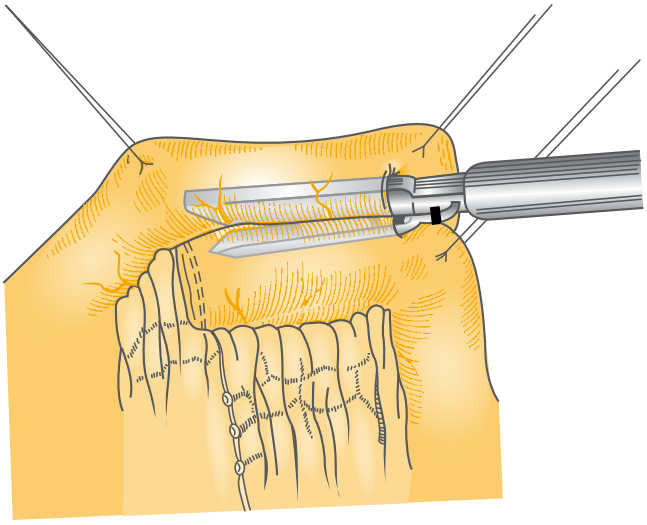

FIGURE 60.5 A gastrointestinal stapler can be used to divide the bowel segment. In addition, it may be used to perform the enteroenterostomy. (From Elliott SP et al. *Urology* 2002;59: 939–43; Hedican SP et al. *J Urol* 1999;161:267–70. Reproduced with permission.)

drain was removed. However, at the time of discharge the patient resumed normal activities.

The early outcomes from this case report were favorable. The bladder capacity doubled from 150 to 315 cc. The patient was dry on intermittent catheterization every 4 hours.[10]

Laparoscopic Ileal Augmentation

There are limited reports of ileal enterocystoplasty using a completely laparoscopic approach. Meng et al. described this technique in a 31-year-old paraplegic female. Five laparoscopic ports were used in a transperitoneal fashion. A gastrointestinal anastomotic stapler was used to divide the ileal segment and restore bowel continuity (Figure 60.5). The mesentery was incised using ultrasonic coagulating shears (Ethicon, Cincinnati, Ohio). Electrocautery was used to remove the stapled ends of the isolated segment and to open the segment on its antimesenteric side. Running 3-0 polyglactin sutures were used to configure the bowel into a U shape and to suture it to the opened bladder. At the end of the anastomosis, the bladder was irrigated and noted to have a watertight closure.

The operative time was 9 hours, and there were no intraoperative complications. Estimated blood loss was 100 mL. Postoperatively, the patient had a urethral catheter and an external Blake drain. On postoperative day 3, the patient resumed oral intake and had the Blake drain removed. Initial results showed an increase in bladder capacity from 85 to 400 mL. The bowel was returned to the peritoneum and ports replaced to reestablish a pneumoperitoneum.[24]

Although cases have been reported, the published outcomes are limited. A patient who had undergone the same procedure had follow-up at 8 months and had a bladder capacity of 550 mL and was continent in between catheterizations. But again, long-term outcomes data are limited.[25]

Small case series have been reported of laparoscopic enterocystoplasty using a combination of intracorporeal and extracorporeal techniques. The bowel segment used included ileum, sigmoid colon, and proximal colon.[26,27]

TECHNIQUE

A transperitoneal approach was used with four laparoscopic ports: a 12 mm port at the umbilicus, two working ports (5 or 12 mm) at the lateral edge of the rectus muscle at the level of the umbilicus, and a 5 mm port at the left anterior superior iliac spine (Figure 60.6). If sigmoid colon is used, an additional 10 mm port may be placed medial to the right anterior superior iliac spine.

The isolated bowel segment had to reach the bladder neck without tension and have a definitive arterial arcade in its mesentery. A laparoscopic camera is used to highlight the vasculature within the mesentery. Laparoscopic bowel clamps (5 mm) are placed accordingly. The umbilical port was widened 2 cm both circumferentially and inferiorly in the midline. The chosen segment was delivered outside of the abdomen. A total of 15–20 cm of bowel is needed. Using standard open methods, the segment was divided and the mesentery was closed (Figure 60.7). The bowel continuity was restored, keeping the isolated segment inferior to the mesentery of the remaining bowel. To minimize edema, the bowel segment was placed back into the peritoneum before continuing further manipulation.

The isolated bowel segment was divided on its antimesenteric side and irrigated with saline. Small bowel and sigmoid were refashioned in a U shape using 2-0 Vicryl in a side-to-side fashion (Figure 60.8). If a catheterizable stoma is created, the terminal ileum is narrowed over a 16 Fr red rubber catheter using a gastrointestinal stapler (GIA stapler, U.S. Surgical Corporation, Norwalk, Connecticut). This red rubber catheter was secured to the terminal end

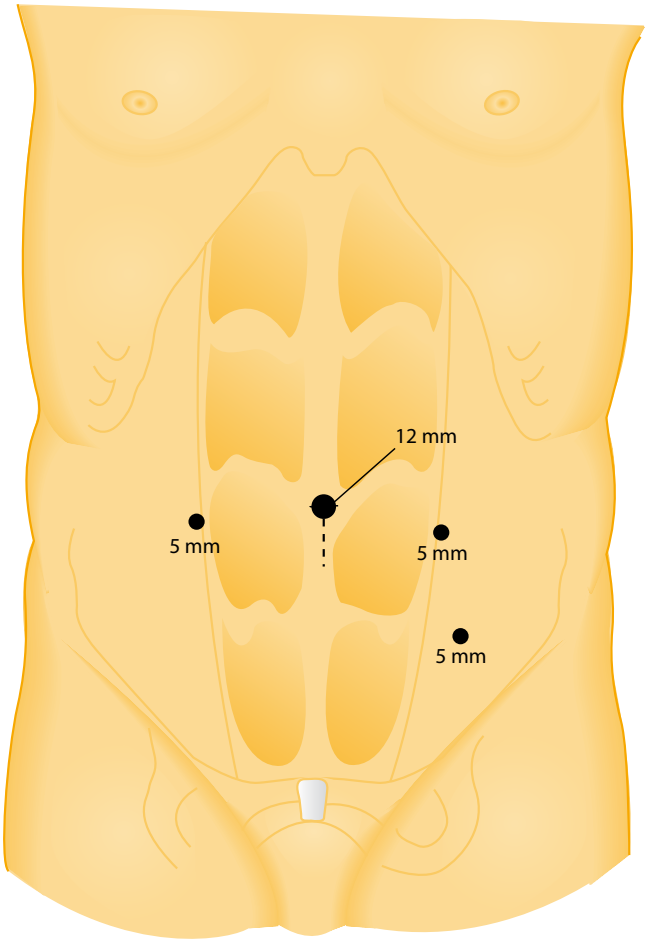

FIGURE 60.6 Laparoscopic enterocystoplasty port placement: a 12 mm port at the umbilicus, a 5 mm port next to the anterior superior iliac spine, and two 5 mm ports on the lateral edge of the rectus muscle at the level of the umbilicus. (From Gill IS et al. *Urology* 2000;55:178–81; Hedican SP et al. *J Urol* 1999;161:267–70. Reproduced with permission.)

of the ileum, which assisted in intracorporeal manipulation and delivery to the umbilicus. The bowel was returned to the peritoneum and ports replaced to reestablish a pneumoperitoneum.

To facilitate the enterovesical anastomosis, the bladder was filled with saline and the patient placed in the Trendelenberg position. The peritoneum was incised from the medial border of the left medial umbilical ligament to the right medial umbilical ligament. A large cystotomy was created by making a curvilinear incision that allowed maximal disruption of the detrusor muscle (Figure 60.9). The anatomosis to the bladder started posteriorly because starting at the anterior can inhibit visualization for the remaining anastomosis. A 5 mm laparoscopic needle driver was used to perform freehand intracorporeal suturing and knot tying. An assistant followed with a 5 mm grasper. An Endo-Stitch was used to facilitate this step (Figure 60.9).

If a catheterizable stoma is required, the right colon and terminal ileum are utilized. These segments can be isolated after incising the peritoneum laterally and then mobilizing the segments through an extending umbilical incision. In order to manipulate the laparoscopic equipment in the

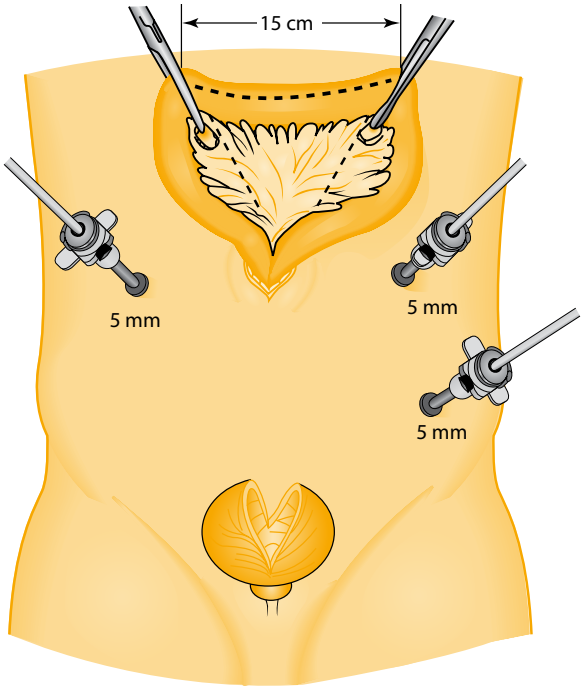

FIGURE 60.7 The umbilical incision is extended 2 cm circumferentially and inferiorly. Through this incision, the isolated bowel segment is delivered for resection and reanastomosis. (From Gill IS et al. *Urology* 2000;55:178–81; Hedican SP et al. *J Urol* 1999;161:267–70. Reproduced with permission.)

lower ports, it is important that the patient is positioned in low lithotomy.[26]

RESULTS

In the series by Gill et al., all patients had two Jackson–Pratt (JP) drains left in place. These were placed through the preexisting port sites. Operating time ranged from 5.3 to 8 hours. Intracorporeal suturing took between 1.7 and 2.1

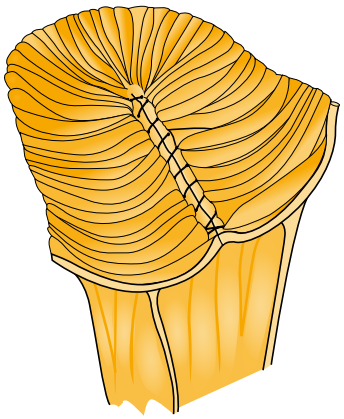

FIGURE 60.8 The bowel segment is refashioned in a U shape before performing the anastomosis. (From Rackley RR, Abdelmalak JB. *Urol Clin North Am* 2001;28:663–70; Gill IS et al. *Urology* 2000;55:178–81. Reproduced with permission.)

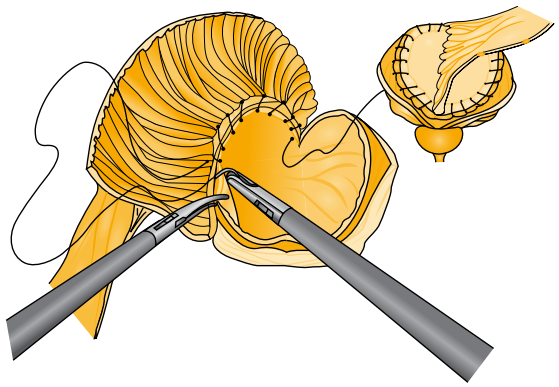

FIGURE 60.9 The enterovesical anastomosis is performed using a laparoscopic needle driver. Starting posteriorly, a continuous, full-thickness suture is used. (From Gill IS et al. *Urology* 2000;55:178–81; Hedican SP et al. *J Urol* 1999;161:267–70. Reproduced with permission.)

hours. Patients were discharged between postoperative days 2 and 5. A urethral catheter was left in place for 1 month and removed after a cystogram confirmed no leakage.[27]

The series by Rackley and Abdelmalak had an average operative time of 7 hours. The average time for laparoscopic suturing was 2.4 hours. The average blood loss was 175 mL. The majority of patients resumed oral intake 24 hours postoperatively. The average date of discharge was 5.7 days. The only complication noted was a rectus sheath hematoma secondary to port placement. This was recognized and corrected laparoscopically.[26]

Laparoscopic-Assisted Bladder Reconstruction

The most easily available and performed technique in minimally invasive reconstruction is the laparoscopic-assisted approach. The biggest concerns with a purely laparoscopic approach are the technical challenges of bowel manipulation, irrigation, and anastomosis. This can be intricate and time-consuming. In addition to time, reconstructive urologists are concerned about the technical ability to match the outcomes of open procedures. The goal of laparoscopic-assisted surgery is to combine the morbidity and cosmetic benefits of laparoscopy with the technical precision of open reconstruction.[28]

By using laparoscopy, the required bowel segments can be isolated and mobilized quickly with small access ports. Once the bowel segment is freed, the ureter or stomach harvested, and the omentum mobilized, the more precise aspects of the surgery can be performed through a small lower abdominal incision. If a bladder augmentation is planned without any bladder neck reconstruction, ureteral reimplantation, or continent stoma, this can often be done simply with a lower abdominal incision, and no laparoscopy is required.

The biggest benefit of laparoscopy is the ability to quickly mobilize the necessary bowel segments without the upper aspect of a large abdominal incision. Many of the pediatric patients requiring bladder reconstruction have an underlying neurologic disorder, such as myelomeningocele. These patients often have an abnormally rotated cecum and appendix with position in the right upper quadrant.[29] Although challenging to reach through a lower abdominal incision, the high cecum can easily be reached with laparoscopy. Patients with spina bifida may have severe lordosis, which can inhibit the mobilization of the cecum.[30] In addition, laparoscopy can easily allow lysis of adhesions that may have developed because of prior surgeries or long-term ventriculoperitoneal shunts. The presence of a shunt is not a contraindication to laparoscopic surgery.[16]

Once the needed segments are harvested, a lower midline or Pfannensteil incision is used to mobilize the bladder and bladder neck and to assemble the anastomosis. The lower abdominal incision may incorporate one of the lower abdominal ports as well (Figure 60.10).

The technique allows dissection similar to that of the open technique, with smaller incisions and lower morbidity.[10,31]

Using laparoscopic assistance to create an appendicovesicostomy was first described in 1993.[31] Since that time, there have been other reports of successful laparoscopic bladder reconstruction with creation of continent stomas.[28,30,32,33] The only large reported series is from Docimo and colleagues.[32]

TECHNIQUE

Preoperatively, the patient undergoes a mechanical and antibiotic bowel preparation if considered indicated.[34,35] Intraoperatively, the patient is positioned supine. If a concominant nephrectomy or ureterocystoplasty is

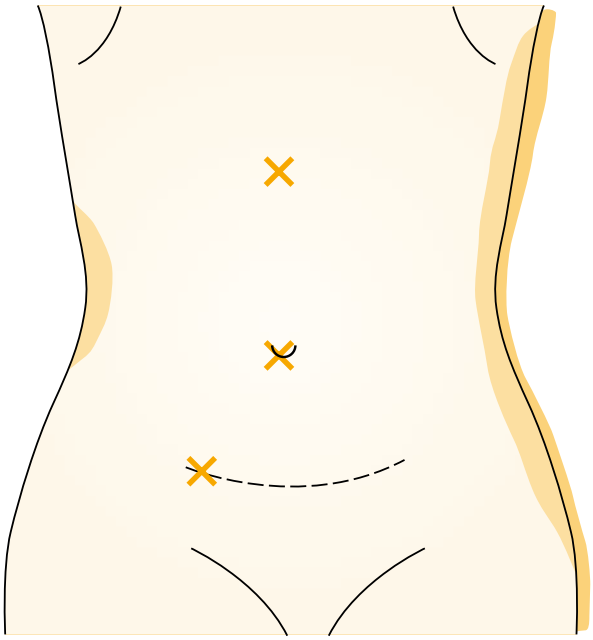

FIGURE 60.10 After harvesting the necessary bowel segments, the lower working port can be incorporated into a Pfannenstiel incision. (From Hedican SP et al. *J Urol* 1999;161:267–70; Brown SF. *J Iowa Med Soc* 1975;65:101–4. Reproduced with permission.)

anticipated, the patient may be positioned in a modified flank position. The patient is padded with foam and gel pads to protect any pressure points. In addition, the patient is secured to the table to allow repositioning with steep Trendelenberg and lateral rotation as needed.

Intravenous antibiotics are given to cover gram-positive and gram-negative bacteria. After induction of general anesthesia, a nasogastric tube is placed. If possible, an epidural catheter is also placed.

The first step is obtaining peritoneal access. If a concealed umbilical stoma is anticipated, a U-shaped flap is created on the lower umbilicus.[11] For the purposes of achieving a straight stoma, the fascia inferior to the umbilicus is opened and the peritoneum entered under direct vision. A radially dilating trocar sleeve is inserted into the peritoneum, and dilated using the trocar insert. This should be 10 or 12 mm in size to allow easy passage of the stomal segment without creating too large a defect, which would risk parastomal herniation.

Placement of the working ports depends on the type of repair planned and the bowel segments needed. Most commonly, two working ports are used. A 3 or 5 mm epigastric port is placed between the umbilicus and the xyphoid. An additional port in the lower abdomen can be of variable size because it will be incorporated into the abdominal incision (Figure 60.11). If an additional stoma is created (i.e., ACE), another U-shaped incision is made in the right lower quadrant and a 10 mm port placed at this site.

Laparoscopy is for bowel manipulation, lysis of adhesions, performing nephrectomies, harvesting ureter, and harvesting omentum.

If appendix is needed, the right colon is mobilized until the appendix can reach the lower abdominal incision. Through the open incision, the appendix can be divided from the cecum. An alternative is to isolate and divide the appendix using an Endo-GIA stapler. If this approach is chosen, care must be taken to avoid disruption of the mesoappendix (Figure 60.12). If laparoscopic examination reveals an appendix in the deep pelvis, easily accessed through a Pfannensteil incision, further laparoscopic dissection is not necessary.

FIGURE 60.11 After incorporating the lower port into a Pfannenstiel incision, the visible scars are minimized. Here the umbilical port site was used for the continent stoma, and the lower port healed within the Pfannenstiel scar. (From Chung SY et al. *J Urol* 2004;171:372–5; Strand WR et al. *Urology* 1997;49:272–5. Reproduced with permission.)

FIGURE 60.12 The majority of bowel manipulation can be done through a lower midline or Pfannenstiel incision. (From Chung SY et al. *J Urol* 2004;171:372–5; Strand WR et al. *Urology* 1997;49:272–5. Reproduced with permission.)

After the laparoscopic portion of the procedure is completed, a 4–5 cm Pfannensteil incision is made. This can incorporate the lower working port. To minimize bowel manipulation, the peritoneum is left intact and any bladder work is completed first. This may include bladder neck division or reconstruction, ureteral reimplantation, and cystolitholapaxy. The next step is opening the bladder, implanting the continent stomal segment, and creating the anastomosis to the augment. All stomas are matured to the skin, and any redundancy is addressed to allow easy catheterization. The bladder stoma is spatulated dorsally and then secured to the U-shaped flap. This helps conceal the stoma and reduce the chance of stenosis. The entry site of the stoma to the bladder is secured to the anterior abdominal wall to decrease the likelihood of eventual tortuosity and difficulty with catheterization.

Postoperatively, most patients are left with a nasogastric tube, a suprapubic tube, and a 10 Fr stomal catheter. Drains are rarely used. The stomal catheter is secured to the skin with the balloon deflated to avoid excess tension on the continence mechanism.

RESULTS

Laparoscopic-assisted bladder reconstruction allows patients to resume a normal diet faster and leave the hospital earlier. These outcomes exist without an increase in operative time or perioperative complications.[28,36]

In 2004, a series of 31 patients with a mean age of 14 years was reported. Twenty-nine of 31 patients had at least one stoma created. Ten patients had both a Mitrofanoff and an ACE stoma created. Nineteen patients had

additional procedures performed (e.g., fascial sling, bladder neck reconstruction, revision of epispadias, ureteral reimplantation, and revision of orchidopexy).

The mean hospital stay was 6 days. The mean follow-up was 32 months. Of all stomas, 94.9% were continent of either urine or stool and easy to catheterize. Improved compliance and capacity were maintained at last follow-up. There were no late bowel obstructions or other sequelae of problematic adhesion formation. Stomal stenosis occurred in 5.1%, and 7.7% required stomal revision secondary to incontinence or difficulty with catheterization. Minor procedures were required in 25.6% of stomas.

Complications occurred in five patients. This included the ileus, a partial small bowel obstruction, a delayed bladder perforation, deep vein thrombosis, and a wound infection.[32]

Robotic-Assisted Lower Tract Reconstruction

Robotic surgery offers several technical advantages over traditional laparoscopic surgery, such as a three-dimensional stable visual field, tremor reduction, and elimination of the fulcrum effect. However, the greatest advantage of robotic technology in reconstructive surgery is the ability to perform wristed intracorporeal suturing. Multiple studies have demonstrated faster speed, greater precision, improved dexterity, and a shorter learning curve of robotic suturing over conventional laparoscopic suturing.[37–41] In recent years, these advantages have been increasingly applied to laparoscopic lower urinary tract reconstruction in children.

Robotic Appendicovesicostomy

In 2004, Pedraza et al. reported the first case of a robotic-assisted laparoscopic appendicovesicostomy in a 7-year-old boy with posterior urethral valves, incomplete bladder emptying, and recurrent urinary tract infections.[42] The procedure took 6 hours, and the authors felt that the greatest advantage of the robotic approach was the ease in creation of the appendicovesical anastomosis. In 2007, Storm et al. reported three cases of robotic-assisted appendicovesicostomy in three patients aged 9, 17, and 45 years, with a follow-up range of 1–8 months.[43] Their mean operative time was 301 minutes. The next two cases of robotic appendicovesicostomy were not reported until 2008, both in combination with ACE procedures employing a split-appendix technique.[44,45]

In 2009, Nguyen et al. published the largest series to date of 10 cases of robotic-assisted laparoscopic appendicovesicostomy with a median follow-up of 14.2 months.[46] The original diagnoses of the patients included posterior urethral valves, spina bifida, spinal cord injury, and nonneurogenic neurogenic bladder. The mean operative time was 323 minutes but ranged from 181 to 507 minutes. One open conversion occurred secondary to inadequate appendiceal length. The stomal incontinence rate was a 20% complication rate. The overall complication rate was 50%, which included stomal incontinence, postoperative pulmonary distress (in a case that took 7 hours, 22 minutes), the need for open conversion, urine leakage, and pyonephrosis. The median length of stay was 5 days.

In this series, the authors did emphasize the significant learning curve associated with this procedure, as operative times decreased with greater experience. They reported that hitching the bladder to the anterior abdominal wall (prior to the appendicovesical anastomosis), adequate cecal mobilization, and measurement of the appendix to ensure adequate length were all useful maneuvers to reduce operative time.

Robotic Bladder Neck Sling Placement and Bladder Neck Reconstruction

Inadequate bladder outlet resistance is a common cause of urinary incontinence in children born with myelomeningocele. Until recently, bladder neck procedures in these children, such as sling placement or bladder neck reconstruction, have not been performed in a laparoscopic fashion secondary to technical limitations. However, the technical advantages of a robotic approach have allowed these complicated procedures to be accomplished laparoscopically.

Although published experiences are limited, Bagrodia and Gargollo reported four cases of patients with myelomeningocele managed with robotic-assisted laparoscopic bladder neck sling placement, Leadbetter–Mitchell bladder neck reconstruction, and appendicovesicostomy.[47] One was converted to an open approach secondary to adhesions related to a ventriculoperitoneal shunt. Although the length of follow was not specifically listed, urinary continence was reported as 100%. The mean operative time of 7 hours, 45 minutes certainly reflects the technical complexity of the procedure, but this report serves as proof of principle that bladder neck sling placement and bladder neck reconstruction can be successfully performed in a robotic-assisted laparoscopic fashion.

Robotic Bladder Augmentation

Literature regarding complete intracorporeal laparoscopic bladder augmentation is limited. In 2008, Gundeti et al. reported the first case of a complete intracorporeal robotic-assisted laparoscopic augmentation ileocystoplasty and appendicovesicostomy in a 10-year-old girl with myelomeningocele.[48] They utilized a nonreconfigured 20 cm ileal patch and performed the ileoileal anastomosis in a hand-sewn fashion. The procedure took 10 hours. At 6 weeks' follow-up, the authors reported complete continence.

In 2010, Gundeti et al. reported a series of five patients with myelomeningocele and incontinence who underwent robotic-assisted laparoscopic bladder augmentation with ileum.[49] Four of the five patients also underwent appendicovesicostomy creation. A sixth patient required open conversion secondary to intraoperative adhesions and difficulty achieving pneumoperitoneum. The mean operative time was 8.4 hours (range 6–11 hours). Similar to their initial case report, the bowel patch was not reconfigured. Postoperative complications included deep venous

thrombosis in one patient, knee parasthesia and wound infection in one patient, and paralytic ileus in one patient. Three of four patients who underwent appendicovesicostomy required stomal revision. Although continence was reported as 100%, postoperative bladder capacity ranged from 150 to 450 mL, with two patients having a maximal daytime bladder capacity of 200 mL. Although this series demonstrates the feasibility of the technically challenging procedure, whether there are specific benefits and an acceptable postoperative bladder capacity remains controversial.

CONCLUSIONS

Minimally invasive bladder reconstruction has become our standard approach. The outcomes match or exceed those of open operations, with recovery and cosmetic benefits. Long-term benefits of decreased intra-abdominal adhesions will be hard to measure, but may be the most important reason to continue to pursue these techniques. The ability of reconstructive surgeons to achieve consistent results depends on the precision of reconstructive techniques. Robotic-assisted approaches to lower urinary tract reconstruction are becoming more widespread and should be considered the state of the art. One thing that is certain: In this era, there is no need for a large abdominal incision in the majority of children who require bladder reconstruction.

CHAPTER
61

Genitourinary Rhabdomyosarcoma and Other Bladder Tumors

Paul A. Merguerian, Lisa Cartwright, and Antoine E. Khoury

INTRODUCTION

Accounting for 4.5% of all childhood cancers, rhabdomyosarcoma (RMS) is the most common soft tissue sarcoma in children under the age of 15 and has an incidence of 4.5 cases per million children (0–19 years old) per year in the United States between 1975 and 2005.[1,2] After neuroblastoma and Wilms' tumor, it is the third most common childhood extracranial solid tumor, and accounts for 60%[3] of all childhood sarcomas and 10%–15% of all solid pediatric tumors. Approximately 26% of these tumors arise from the genitourinary (GU) tract (10% from bladder or prostate) and another 16% from pelvic or retroperitoneal sites (paratesticular region, perineum, vulva, vagina, and uterus).[4–7] Since its discovery by Weber in 1854, extensive studies of the clinical and pathologic features of RMS have resulted in the development of uniform diagnostic criteria and prognostically relevant staging systems.[8]

A member of the group of small, round blue cell tumors (including neuroblastoma, lymphoma, and the primitive neuroectodermal tumors), RMS is a sarcoma demonstrating evidence of skeletal muscle differentiation. The fact that it can occur outside sites where skeletal muscle is found suggests that it is a tumor of primitive mesenchymal skeletal muscle differentiation.[9]

Histopathological variants of RMS (embryonal, botryoid, and alveolar) pursue different biologic courses. Embryonal RMS (eRMS) tends to occur in the head and neck and GU system, and the majority of patients survive beyond 5 years. In contrast, with few patients surviving beyond 5 years, alveolar RMS (aRMS) often presents with tumors in the extremities and early metastasis.[10]

The cure rate for patients with RMS improved significantly in the latter part of the last century from an estimated 25% in 1970 to 70% in 1995.[9,126,127] This improvement is credited to the use of increasingly effective multimodal, risk-adapted therapy; refinement in tumor grouping; better diagnostic imaging; and better supportive care, which have been developed through multiple international collaboratives, including the International Rhabdomyosarcoma Study Group (IRSG) trials IRS I–IV, which have transitioned to the Soft Tissue Sarcoma Committee of the Children's Oncology Group (COG), the Cooperative Soft Tissue Sarcoma Group (CWS), and the European Soft Tissue Sarcoma Study Group. Emerging information on the numerical and structural abnormalities of tumor cell chromosomes and the development of probes to identify molecular genetic lesions has improved diagnostic methods and afforded new insights into tumor pathogenesis, allowing for improved risk stratification and paving the way for advances in risk-based therapy.

EPIDEMIOLOGY

Nearly three-quarters of GU RMS cases are diagnosed before the age of 5 years, with a 3.3:1 male predominance. RMS has two large peaks of incidence: the first, accounting for more than half of the cases, occurs in the first decade and is mainly eRMS or botryoid RMS (bRMS); the second occurs during adolescence and is more frequently aRMS.[11,12]

Associated Syndromes

RMS may be associated with congenital anomalies, most commonly affecting the GU system, but also the central nervous system. Interestingly, patients with RMS are noted to have fewer musculoskeletal anomalies.[3]

Occurring in 0.5% of patients enrolled in IRS IV, neurofibromatosis is the most common syndrome in which RMS has been described. Among the five RMS patients with neurofibromatosis, three relapsed, and two of whom died of progressive disease. Because of the progressive nature of RMS in patients with neurofibromatosis, it is recommended that they be treated with intensive contemporary therapy protocols.[13]

Costello syndrome (HRAS mutation) is associated with an increased risk of solid tumors, the most common of which is RMS. Gripp et al. recommended a screening protocol of abdominal or pelvic ultrasound every 3–6 months up to 8–10 years for RMS and neuroblastoma in patients with Costello syndrome.[14]

Other congenital syndromes in which RMS has been reported include multiple endocrine neoplasia 2A, Gorlin's basal cell nevus, Rubenstein–Taybi, trisomy 21, Beckwith–Wiedemann (BWS), Li–Fraumeni, Noonan, Roberts,

Dubowitz, Nijmegen breakage, multiple lentigines, and constitutional mismatch repair deficiency syndromes.[15,16] While Wilms' tumor is the most common malignancy associated with BWS, in the first 7 years of life, RMS, adrenocortical carcinoma, and hepatoblastoma may also be seen.

Li–Fraumeni syndrome is associated with a known p53 mutation with autosomal dominant transmission. These patients are predisposed to multiple tumors, which often retain a normal p53 allele, suggesting that an alternate additional tumorgenic mechanism is involved in p53 inactivation. Malkin et al. evaluated two patients with multiple tumors in the presence of Li–Fraumeni syndrome who had a heterozygous germline p53 mutation. Tumors that they developed that maintained p53 heterozygosity were noted on immunostaining to contain the DNA tumor virus SV40. The authors postulate that p53 inactivation by viral proteins may contribute to tumor formation in these genetically susceptible patients.[17–19]

Environment

Environmental factors associated with RMS include ionizing radiation and alkylating agents. The increased risk of secondary malignancies in those patients with neurofibromatosis and Li–Fraumeni syndromes after treatment with alkylating agents and radiotherapy (RT) for RMS draws a link between the likely dual causation of malignancy by genetics and the environment. It is therefore particularly desirable to limit the use of alkylating agents and RT in these populations.[3]

GENETICS

Somatically acquired genetic changes underlie all forms of cancer, and the chromosomes of RMS contain both numerical and structural abnormalities.[20–22] Advances in the molecular and cellular biology of RMS have further elucidated the pathogenesis of this tumor and will aid in its diagnosis, staging, management, and risk stratification.

RMS appears to develop from a derangement in the final steps of myogenic differentiation. Genes of the *MyoD* family are crucial in the early differentiation of skeletal muscle precursors.[23,24] These genes express DNA binding proteins that facilitate the production of myogenic proteins, such as desmin, creatine kinase, and myosin. *MyoD* expression is higher in RMS cells. Activation of p38 MAP kinase, which is required for muscle differentiation, is absent in RMS cells.[25] Failing to differentiate completely, RMS cells continue to produce forms of actin seen only transiently in normal-developing skeletal muscle.[26] *MyoD1*, a myogenic regulatory protein, maps on chromosome 11p15.4 and is expressed during skeletal muscle development. Myogenin is a myogenic regulatory protein whose expression determines differentiation of primitive mesenchymal cells into skeletal muscle. It is regulated by pathways involving p38, calcium–calmodulin-dependent protein kinase (CaMK) or calcineurin, and its expression may be downregulated with terminal differentiation. The activation of myogenin by CaMK and calcineurin pathways fails in RMS cell lines.[27]

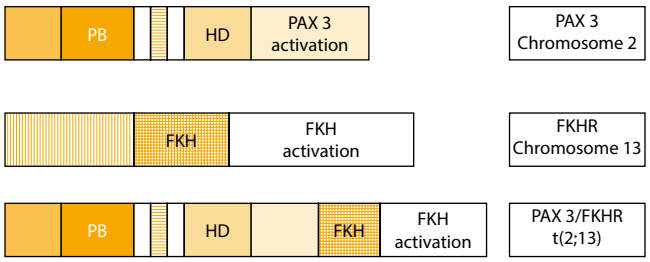

FIGURE 61.1 Structure of PAX3 on chromosome 2, the FKHR on chromosome 13, and the fusion product PAX-FKHR of the t(2;13) in aRMS. PB, paired box; HD, homeodomain; FKH, forkhead.

aRMS may be distinguished from eRMS and other tumors on the basis of genetic abnormalities. Cytogenetic analysis of aRMS revealed a chromosome 2;13 translocation unique to this tumor in 70%–80% of cases (Figure 61.1).[28–32] 1;13 translocations have also been identified.[30,33,34] These fusions result in expression of chimeric transcription factor PAX3-FKHR t(2;13)(q35;q14), or the less frequent PAX7-FKHR t(1;13)(p36;q14).

The presumed function of PAX3 is that of transcriptional regulation strictly during embryogenesis, important in the development of mesenchymal precursors.[35] A full-length cDNA of the wild-type chromosome 13 gene was cloned and found to be a novel widely expressed member of the forkhead transcription factor family.[36,37] A conserved DNA binding motif termed the "forkhead" domain characterizes this family. Based on homology to this family, the chromosome 13 gene was named FKHR for "forkhead in rhabdomyosarcoma."[36] These combined findings indicate that t(2;13) results in a chimeric transcript composed of 5′ PAX3 and 3′ FKHR exons (Figure 61.1). In the PAX3-FKHR fusion, the PAX3 gene within band 2q35 is fused with the FKHR gene within band 13q14. Both of the PAX3 DNA binding regions (the paired box and the homeodomain) are retained in the fusion gene, whereas the carboxyl-terminal sequences are replaced by the bisected forkhead DNA binding sequences of FKHR.[8,38] In PAX7-FKHR fusions, a chromosome 1 locus encoding PAX7,[37] another member of the paired box family, is rearranged and fused to FKHR in the t(1;13) conscript consisting of 5′ PAX7 and 3′ FKHR regions, which is very similar structurally to the 5′ PAX3-3′ FKHR transcript formed by the t(2;13) translocation.[39,40]

Assays of expression during embryogenesis demonstrate that PAX3 and PAX7 are expressed with specific temporal and spatial patterns in early skeletal muscle progenitors, the presumed origin of aRMS.[41,42] PAX3-FKHR and PAX7-FKHR fusion proteins affect the cellular activities of growth, myogenic differentiation, and apoptosis, and enhance cellular proliferation and invasion.[31,32,43,44] PAX3-FKHR results in genetic overexpression, while PAX7-FKHR is associated with gene amplification.[1]

PAX3-FKHR is capable of inducing myogenin and MyoD. It is also associated with upregulation of *Six1*, *Slug*, and *Igfbp5*, which are all genes associated with muscle development and noted to be upregulated in aRMS.[45] Insulin-like growth factor (IGF1) has an important role in muscle development and in the etiology of aRMS.

PAX3-FKHR has been shown to transactivate the IGF1 receptor gene (IGF1R) promoter in sarcoma cell lines with a higher potency than PAX3.[46]

Sorensen et al. determined the PAX3/PAX7-FKHR fusion status in 171 patients enrolled in IRS IV, identifying PAX3-FKHR and PAX7-FKHR fusions in 55% and 22% of the 78 patients with alveolar histology, respectively, and none with other than aRMS. Fusion status was a prognosticator for metastatic but not local disease, with an estimated 4-year overall survival (OS) of 75% with PAX7-FKHR versus 8% with PAX3-FKHR. Failure, death, and bone marrow involvement were all significantly increased on multivariate analysis in patients with metastatic disease harboring PAX3-FKHR compared with PAX7-FKHR.[47] This corroborated results by Anderson et al., who had previously evaluated 91 RMS tumors. Thirty-seven patients had PAX3-FKHR, 8 had PAX7-FKHR, and 46 had neither. The authors found a statistically significant association between PAX3-FKHR and higher-stage disease and its absence and lower-stage disease ($p = 0.06$ when grouping stages 1 and 2 and stages 3 and 4). PAX7-FKHR transcript numbers were too small to reach statistical significance, but stage results were similar to those of the fusion-negative group. PAX3-FKHR occurred in statistically significantly older children than the other two groups, and translocation status was not associated with disease site. Among 66 patients with nonmetastatic disease, OS and event-free survival (EFS) were significantly worse in the PAX3-FKHR group.[48] Collins et al. found that compared with PAX7-FKHR, PAX3-FKHR RMS demonstrated greater cell cycle dysregulation related to both increased cell proliferation and apoptosis and concluded that this contributes to the poorer prognosis in the PAX3-FKHR group.[49] Stegmaier et al. evaluated PAX-FKHR fusion status for the CWS from 1996 to 2004 and confirmed earlier findings that PAX3-FKHR was more common than PAX7-FKHR fusion (60% vs. 24%, $n = 121$), and that in metastatic aRMS, the fusion-negative cohort showed a more favorable outcome than the fusion-positive one. The PAX3-FKHR group demonstrated adverse prognostic factors in age and stage distribution despite no differences in survival compared with those with the PAX7-FKHR fusion.[50]

Davicioni et al. molecularly characterized 160 RMS (70 aRMS, 78 eRMS, and 12 non-RMS) samples from patients enrolled in IRS IV and V. eRMS did not demonstrate PAX-FKHR translocation but had recurrent allelic imbalances, such as loss of heterozygosity (LOH) 11p15.5.[51] Chromosome 11 LOH is also seen in Wilms' tumor and hepatoblastoma, and alterations in this chromosome region are also noted in BWS.[52] A five-gene classifier (TFAP2β, CDH3, CNR1, MYOG, and CDH15) was useful in differentiating fusion-positive aRMS, fusion-negative aRMS, and undifferentiated sarcoma. Those genes that were overexpressed in PAX-FKHR-negative tumors were overrepresented by genetic loci on chromosome 8 to include an increased frequency of LOH 8q.[51]

Williamson et al. characterized subgroups of fusion-negative aRMS, fusion-positive aRMS, and eRMS for 101 RMS patients treated on European Soft Tissue Sarcoma Study Group protocols MMT 89, 95, IV 89/91, and 98. Fusion-negative aRMS was similar to eRMS with statistically significantly improved OS and EFS compared with fusion-positive aRMS, with the relative risk of death with fusion-positive aRMS of 2.5. Identifying few genes consistently distinguishing fusion-negative aRMS from eRMS, the authors identified that metagene expression is distinct between fusion-positive and fusion-negative aRMS, but not between fusion-negative aRMS and eRMS, and genetic expression analysis correctly characterized fusion-positive aRMS and eRMS in 99% and 95% of cases, respectively, while 100% of fusion-negative aRMS were genetically classified as eRMS. Additionally, chromosome 8 gains had a similar high frequency in fusion-negative aRMS and eRMS, but not in fusion-positive aRMS.[53] Fusion-negative aRMS appears to behave clinically more closely to eRMS than to fusion-positive aRMS, and on genetic mapping, is a heterogeneous group that overlaps with eRMS.[1,51,53,54] Davicioni et al. further evaluated the genetic expression of RMS with a 34-metagene analysis and identified tertiles whose clinical outcome correlates with COG clinical risk stratification.[55] Ongoing research involves the validation of these gene signatures for clinical application as a potential prognosticator for risk stratification to determine treatment protocols.[56]

Genetic Therapy

Potential gene targets for novel treatment options in RMS refractory to current regimens include receptors and growth factors (such as IGF1R, IGF2, c-Met, PDGFR, C-Kit, and FGFR1), intracellular signaling molecules (such as mTor), cell cycle (CDK4/CDK6), apoptosis (such as p53, Bcl-2, and TRAIL), angiogenesis (vascular endothelial growth factor [VEGF] and VEGF receptor [VEGFR]) and cancer-specific fusion proteins (PAX3-FKHR). Many of these therapies are under evaluation in current clinical trials.[57–60] MYCN gene amplification, associated with aRMS, is a direct downstream target of the PAX3-FKHR fusion protein and has been identified by Tonelli et al. as a potential tumor-specific therapeutic target utilizing gene therapy in the treatment of RMS.[61–63]

PATHOLOGY

The significant difference in survival between eRMS and aRMS makes accurate diagnosis imperative in order to predict the biological course of the disease and initiate appropriate therapy.

Embryonal RMS

eRMS represents the most common GU RMS variant. These tumors have variable amounts of spindle and primitive round cells, which may be either tightly packed or loosely dispersed in a myxoid background. The rhabdomyoblast, the more mature embryonal component, is characterized by bright eosinophilic cytoplasm and may appear in a variety of unusual shapes, termed "tadpole," "racquet," or "strap" cells.[10,64] Cross-striations are seen in 50%–60% of cases. These tumors rarely metastasize and respond well to current therapy. On fine-needle aspirate (FNA), the embryonal subtype is suggested in specimens

with large tissue fragments containing abundant eosinophilic material and small, tightly packed cells with oval nuclei.[65,66] eRMS stains positively for myoglobin, desmin, and vimentin. Classic eRMS with a polypoid growth pattern was associated with a more favorable prognosis than a diffuse intramural (endophytic) growth pattern in 65 cases of bladder and vaginal RMS (92% vs. 68% 10-year survival, $p = 0.02$).[67]

Botryoid Embryonal RMS

Botryoid eRMS tends to be a polypoid lesion filling a hollow viscus (vagina or bladder).[11] The International Classification of Rhadomyosarcoma (ICR) criterion for diagnosis of botryoid eRMS requires demonstration of a cambium (condensed layer of rhabdomyoblasts) tumor layer underlying an intact epithelium in at least one microscopic field (Figure 61.2). This microscopic criterion supersedes any gross demonstration of a "grapelike" tumor mass. An extensive degree of rhabdomyoblastic differentiation can be evident both in the cambium layer and elsewhere in the tumor. The importance of diagnosing this subtype is evident given its superior prognosis with a 95% 5-year survival. There remains debate as to whether bRMS is a distinct entity or a variant of eRMS, and biologic studies have not demonstrated a molecular distinction.[68]

Spindle Cell Embryonal RMS

The spindle cell variant of RMS also demonstrates a superior prognosis with an 88% 5-year survival rate. It has only been recognized in the literature since 1993.[69] This neoplasm has a fascicular, spindled "leiomyomatous" growth pattern that can show a marked degree of rhabdomyoblastic differentiation. Some tumors show marked collagen deposition. This variant occurs rarely outside the paratesticular region. These tumors are immunopositive for titin, a marker for terminal differentiation.[70]

Alveolar RMS

aRMS demonstrates a histologically distinct alveolar architecture with aggregates of small round undifferentiated cells separated by dense hyalinized fibrous septa. Crossstriations are uncommon. A review comparing IRSG pathologic diagnosis with institutional diagnosis performed between 1984 and 1997 showed concordance in only 63% of cases. The high level of discordant diagnosis (37%) reflects the need for better recognition of the solid alveolar variant of this RMS subtype. The classic cleft-like spaces lined by rhabdomyoblasts (Figure 61.3) that are traditionally described[10,12] for aRMS may merge with spaces filled with tumor cells that sit on thin fibrovascular septae. This latter solid variant is rarely present without the classic finding of cleft-like spaces and can be recognized with adequate tumor sampling. The key criterion is to recognize palisading tumor cells about fibrovascular cores. The tumor cells have a coarse chromatin pattern to their nuclei with less evident myogenesis than in eRMS.[10] FNA biopsies of aRMS demonstrate predominantly two architectural patterns, either completely dissociated cells or many chance formations of cells. However, this is nonspecific, and any RMS diagnosis on FNA requires immunohistochemical confirmation.[66]

The prognosis for both the classic and solid variants is poor, with only a 53% 5-year survival rate. Improved concordance of review and institutional diagnosis is crucial for this malignancy, as these patients receive intensified therapy on current protocols. On the analysis of 65 aRMS cases, Parham et al. concluded that there is limited correlation between the histologic assessment of aRMS and the PAX-FKHR fusion status.[71]

Anaplastic RMS

Anaplastic RMS also has a high rate (62%) of discordance.[12] Using the IRS I–III material, anaplastic RMS was defined by large, lobate hyperchromatic nuclei of at least three times the size of neighboring nuclei, and atypical multipolar mitotic figures.[12,72] It is also characterized further by its distribution as focal (group I), consisting of single or few anaplastic cells, or diffuse (group II), where anaplastic cells aggregate in clusters or form a continuous sheet.[12,72] The occurrence of anaplasia is independent of both RMS tumor site and histopathologic subtype, although it occurs

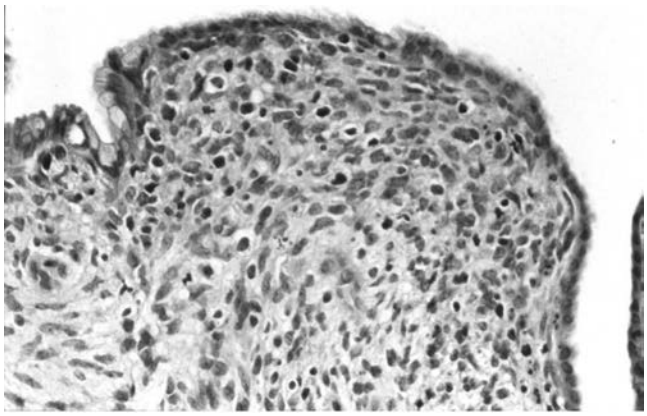

FIGURE 61.2 Botryoid embryonal rhabdomyosarcoma demonstrating the cambium (condensed layer of rhabdomyoblasts) tumor layer underlying an intact epithelium.

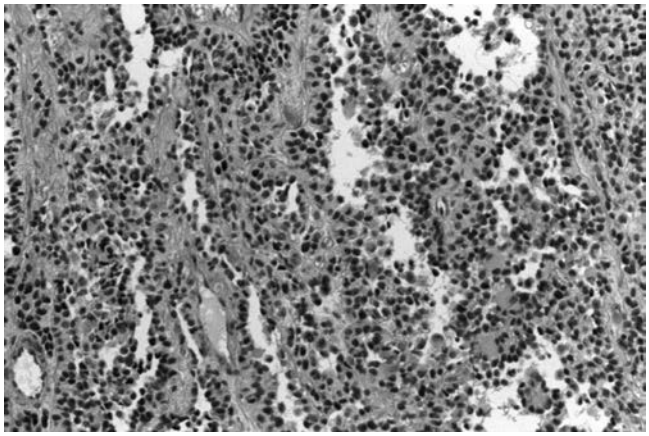

FIGURE 61.3 Alveolar rhabdomyosarcoma showing palisading of tumor cells with a coarse chromatin pattern about fibrovascular cores.

preferentially in eRMS. A recent COG analysis identified 13% of RMS cases with anaplasia, the presence of which, whether focal or diffuse, negatively influenced both OS and failure-free survival (FFS) in eRMS.[73]

Undifferentiated Sarcoma

Demonstrating a similarly high rate of discordance (62%),[12] undifferentiated sarcoma is included in the ICR system only because its response to therapy is similar to that of RMS.[10] These tumors are composed mainly of sheets of medium-packed cells with no discernible architectural structure except for delicate fibrovascular septae or a vague spindled-storiform pattern. Necrosis and inflammation are not prominent, cellularity is high with high mitotic activity (>10 mitoses per 10 hpf), and the nuclei are predominantly oval with prominent chromocenters and indistinct cytoplasm.[12,74] The tumors stain only with vimentin antisera (77%), if at all.

This entity is rare (3% of cases) and, similar to aRMS, occurs more often in males (62%) and in patients 5 years of age or older (65%), and is more common in the extremities (53%).[74] Survival with localized disease is 72%, but with disseminated disease is only 44%.[12] Early identification of this histologic subtype, enabling prompt, intensified therapy, is an important component of the IRS V studies.

Ectomesenchymoma

A rare malignant neoplasm, consisting of RMS with a neural component, ectomesenchymoma (EM) is likely underdiagnosed and has an outcome similar to that of the RMS component of the tumors. Boue et al., in their report of 15 cases, noted that there were previously only 21 other cases reported in the literature. They noted that of their 15 cases, only 2 had an originating institutional diagnosis of EM, with 12 diagnosed as RMS and 1 diagnosed as undifferentiated sarcoma. Five of these cases were of external genital origin, and six were pelvic and abdominal.[75]

Immunostaining

Ancillary histopathological tissue studies are useful for both diagnosis and prognosis. A comprehensive study using commercially available and experimental antibodies was undertaken as part of IRS IV, which included 100 cases of RMS representing all subtypes. Around 20% of RMS cases required the use of immunohistochemistry to establish the final diagnosis. Polyclonal antidesmin (P-DES) antibody was positive in all but one RMS (99%). Monoclonal antidesmin (M-DES) antibody was negative in many of the same tumors (38%). Anti-muscle-specific actin (MSA) antibody was positive in 94% of RMS. Anti-myoglobin antibody was positive in 78% and was negative mostly in the less differentiated tumors. Anti-α-smooth muscle actin (SMA) antibody reacted positively only in a minority (4%) of eRMS. The incidence of immunopositivity for the various antisera is summarized in Table 61.1.[12]

Myogenin is specific for rhabdomyoblastic differentiation and may help in the differentiation of small round cell tumors. It is strongly expressed in aRMS nuclei but demonstrates a variable staining pattern and intensity in eRMS. The extent of myogenin staining in RMS is much greater than in non-RMS tumors, making it a useful marker.[76–79] In contrast to other studies, Cessna et al. did note some rare non-RMS (7/107) focal nuclear reactivity to myogenin.[76] Pseudosarcomatous myofibroblastic tumors (PMTs) of the urogenital tract are rare benign tumors that may be mistaken for RMS. Myogenin is expressed in RMS but not PMT, and may be useful in differentiating these distinct clinical entities.[80]

MyoD1 expression is a distinguishing characteristic of RMS and reverse transcription polymerase chain reaction (RT-PCR) because *MyoD1* is highly sensitive and specific in detecting minimal residual disease, as well as bone marrow and peripheral blood stem cell involvement, regardless of histological subtype.[81]

The current approach at the IRSG Pathology Center in cases where the diagnosis of RMS is in question is to screen the case with immunostaining for three antibodies: P-DES, MSA, and MIC-2. The latter helps to rule out the diagnosis of an extraosseous Ewing's sarcoma primitive neuroectodermal tumor.[82] Around 14% of RMS stain positive to MIC-2 antisera, but this is only a weak granular intracytoplasmic immunopositivity, while Ewing's sarcoma and primitive neuroectodermal tumors show discreet plasma membrane staining.[82] Antibodies to the various myogenic transcription factors (MyoD1, etc.) are not tested because of their noted negativity with paraffin sections.[83]

While recent analysis of RMS tumor samples demonstrated only a 1.3% incidence of TP53 mutation,[84] immunopositivity at the grade 3 or 4 level (6% of RMS) was significantly associated with the occurrence of any anaplasia in aRMS and diffuse anaplasia in eRMS, independent of fusion gene status.[85]

TABLE 61.1 Incidence of immunopositivity for antisera in rhabdomyosarcoma diagnostic studies

Antibody	Percentage
Polyclonal desmin	99
Monoclonal desmin	62
Muscle-specific actin	94
α-Smooth muscle actin	4
Myoglobin	78
Wide-spectrum keratin	7
Epithelial membrane antigen	2
S-100 protein	19
Neuron-specific enolase	6
Leukocyte common antigen	0
MIC-2	14
p53	16

Posttreatment Pathologic Studies

The most difficult assessment by pathologists is the prognostic significance of residual rhabdomyoblasts in post-therapeutic RMS tissue specimens. Studies support the

concept that posttherapeutic cytodifferentiation occurs more frequently in bRMS or eRMS.[86–88] In bRMS, cytodifferentiation and decreased proliferation activity were associated with favorable outcome. Unchanged or increased posttherapeutic proliferation activity suggested aggressive biologic potential in eRMS or aRMS.

Smith et al. reported on the posttreatment cytodifferentiation and clinical outcome from 19/31 IRS IV cases that were adequate for evaluation. None of the 10 cases with extensive cytodifferentiation (2 bRMS and 8 eRMS) failed, while among the 5 cases with moderate cytodifferentiation, only the 2 aRMS patients failed, and all 4 patients (1 eRMS and 3 aRMS) with mild or no cytodifferentiation failed. The authors concluded that posttreatment cytodifferentiation is more common in both eRMS and bRMS than in aRMS, and postulated that this difference is due to different mechanisms to cellular response to therapy. They also noted that sparse persistent tumor cells in aRMS and bRMS did not appear to affect outcome.[88]

Myoglobin is specific for terminally differentiated myocytes and, as such, is a useful marker for differentiated tissue in organs such as bladder and prostate (BP), which normally do not contain skeletal muscle. As the expression of myogenin and MyoD is downregulated with terminal differentiation, they are less helpful to identify differentiated cells.[68] Sequential evaluation of six patients with pelvic (four bladder or prostate and two vulvovaginal) RMS who had persistent well-differentiated rhabdomyoblasts without mitotic activity during and after the completion of therapy demonstrated rhabdomyoblast persistence, but a decrease in number with time. All six patients were alive with no evidence of disease from 37 to 233 months after the completion of therapy. The authors conclude that while the biologic nature of these cells is not known, their presence is not an indication for further therapy.[89] Arndt et al. reached a similar conclusion upon reviewing the significance of persistent mature rhabdomyoblasts in 44 bladder or prostate RMS patients treated on IRS IV, identifying that these cells are not predictive of recurrence and their presence does not justify radical surgery.[90]

PRESENTATION

While varying with site and extent of disease, as well as the age of the patient, RMS may present as an asymptomatic mass found by patient or parents[2] and has no classic paraneoplastic syndromes.[6] Symptoms of GU RMS may include urinary tract obstruction or infection, hematuria, urinary frequency, urgency or incontinence, an abdominal mass, or constipation. Tumors of the BP typically are greater than 5 cm and invasive on presentation. Paratesticular RMS presents frequently as a scrotal or inguinal mass or swelling that might initially be diagnosed as a hernia, hydrocele, or varicocele.[6] Female genital RMS tends to be vaginal in very young girls, presenting as a mass or vaginal bleeding, while advanced uterine tumors tend to present in older girls.[6] Patients may also present with signs or symptoms of metastases (15%) or systemic signs of malignancy.[6]

A rare neonatal RMS presentation has been described with several cases reported in the literature. Frequently of alveolar subtype, it presents in neonates associated with multiple cutaneous metastases, lacking characteristic RMS translocations, and has been fatal with current therapy.[25,91] Generally, cutaneous metastasis of nonhematopoietic neoplasms is rare; however, on review, RMS was noted to be the most common pediatric neoplasm to metastasize to the skin.[92]

DIAGNOSTIC EVALUATION

In addition to a complete history and physical examination, evaluation of patients with suspected RMS should include complete blood count (CBC), urinalysis, electrolytes, calcium, phosphorous, alkaline phosphatase, lactate dehydrogenase, bilirubin A bone marrow biopsy or aspirate, and cross-sectional imaging.[6]

Imaging

The first diagnostic imaging in patients presenting with an abdominal or pelvic mass and/or symptoms of urinary obstruction is a pelvic and renal sonogram. In RMS, this will usually demonstrate a solid hyper- or hypoechoic tumor and will evaluate the status of the bladder, postvoid residual, and the upper tracts. Bladder bRMS may appear as a polypoid intraluminal mass resembling a cluster of grapes that is characteristic but not pathognomonic of this entity.[93]

The remainder of the radiographic evaluation determines the extent of the local and regional disease and identifies metastatic foci. MRI is replacing computed tomography (CT) as the examination of choice for accurate presurgical assessment of the extent and volume of disease. An accurate pretreatment tumor volume is necessary to plan for adequate radiation treatment if indicated. Extent of the tumor around the BP can be determined by MRI T2-weighted images with sagittal views demonstrating urethral tumor extent (Figures 61.4 through 61.7).[94] RMS has intermediate signal intensity on T1-weighted images and intermediate to high signal intensity on T2-weighted

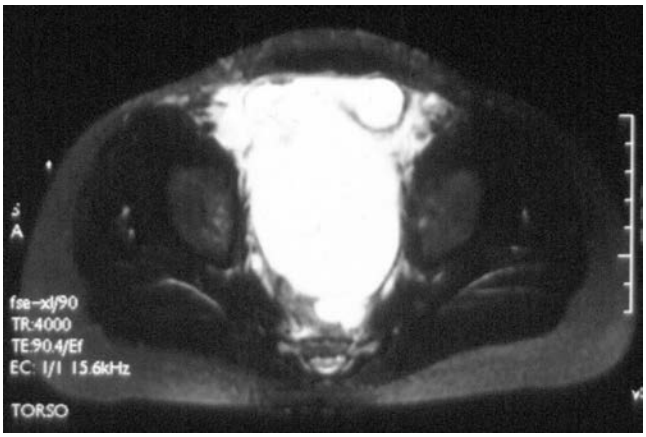

FIGURE 61.4 Magnetic resonance imaging scan finding in a 4-year-old male with embryonal group III rhabdomyosarcoma. On T2-weighted images, the extent of the tumor is well visualized.

FIGURE 61.5 Magnetic resonance imaging scan in a 4-year-old child with embryonal group III rhabdomyosarcoma. In this sagittal view, the extent of the tumor into the membranous urethra is well delineated.

images with significant enhancement with gadolinium–diethylene triamine penta-acetic acid (Gd-DTPA). aRMS demonstrates a lobular appearance on postcontrast images. While these characteristics are nonspecific and indistinguishable from other soft tissue sarcomas, MRI is useful for staging and therapeutic response assessment in RMS.[93]

FIGURE 61.6 Magnetic resonance imaging scan in a 6-year-old child with embryonal group III rhabdomyosarcoma. This sagittal view on T2-weighted image shows the extent of the tumor distally in the membranous urethra.

FIGURE 61.7 Magnetic resonance imaging scan in a 5-year-old child with embryonal group III rhabdomyosarcoma after 16 weeks chemotherapy. The tumor is visualized extending into the bladder and its extent into the urethra is also well seen.

Metastases occur most commonly to the lungs, bone, and lymph nodes, followed by bone marrow and liver. Prostatic primaries are more likely than bladder primaries to metastasize to the lungs or bone marrow.[93] A CT scan of the chest, an MRI or CT of the abdomen and pelvis, bone marrow aspiration, cerebral spinal fluid (CSF) evaluation, and if indicated, bone scan may be completed for metastatic assessment. Imaging may identify inguinal or retroperitoneal nodes, as well as pulmonary metastases. The absence of ascites does not exclude peritoneal involvement.[95]

Bone metastases in RMS are identified on imaging as ill-defined lytic lesions.[93] In a retrospective review of 301 consecutive patients from the UK Children's Cancer Study Group, only one asymptomatic patient had evidence of metastasis on bone scan in the absence of other identifiable metastatic disease. Based on these findings, McHugh and Pritchard suggest that routine bone scan may not be justified in patients without symptoms attributable to bone metastases (back or limb pain, limp, or hypercalcemia) or other demonstrable metastatic disease, but may be reserved for older patients or those with high-risk RMS, bone pain, alveolar histology, or poor prognostic sites outside of the head and neck.[96] These findings and recommendations were supported by Jager et al. in their study of 109 soft tissue sarcoma patients.[97] Bone marrow aspirate and biopsy are mandatory for IRS protocols, and bone marrow involvement at diagnosis is a poor prognosticator, with <10% survival. Any bone medullary defects noted on MRI require biopsy, even in the presence of a normal bone scan.[3] Routine CT or MRI of the head to evaluate for metastatic RMS of extracranial origin, required for IRS IV protocols, is now recommended only for clinically symptomatic patients or those with paraspinal tumors.[98]

F-18 fluorodeoxyglucose (FDG) positron emission tomography (PET)/CT scan has been gaining attention as a potential diagnostic tool that may assist with improved

staging of RMS. Ricard et al. retrospectively reviewed the clinical utility of the addition of PET/CT to imaging protocols in the 35 staging studies for 13 children with RMS. PET/CT modified lymph node staging in four and bone involvement in two patients, resulting in treatment alteration in two patients.[99] Similarly, Tateishi et al., in a retrospective review of 35 patients, identified that FDG-PET demonstrated significantly improved overall TNM staging, as well as M staging, compared with conventional imaging alone, with a diagnostic accuracy of 89% versus 63% for M stage.[100] The CT scan is still preferred for chest evaluation, as PET is not able to reliably detect lesions less than 1 cm.[101]

Biopsy

Tissue diagnosis of RMS is confirmed by biopsy. Specimens can be obtained either endoscopically or through a needle biopsy. For endoscopic biopsy, it is preferable to utilize cold-cup biopsy forceps or a cold knife to avoid coagulation-induced histological artifacts. Alternatively, a wedge may be cut endoscopically with scissors and retrieved with grasping forceps.[102] An ultrasound-guided needle biopsy through the perineum or the extraperitoneal suprapubic route may also be used. Vaginal tumors are diagnosed and biopsied endoscopically, and the extent of distortion and/or infiltration of the bladder by the tumor can be assessed cystoscopically. Uterine tumors can be biopsied through vaginoscopy or a cervical dilatation and curettage. Open biopsy may be indicated if endoscopic or needle biopsies are inconclusive. If a laparotomy is performed, sampling of the pelvic and retroperitoneal nodes should be completed at that time.[102] Ample tissue is obtained in order to identify the histological subgroups of RMS and allow accurate grading to direct therapy. There is no requirement to excise needle biopsy sites.[6]

Brahmi et al. effectively differentiated RMS from other malignant round blue cell tumors, including Ewing's sarcoma, neuroblastoma, non-Hodgkin's lymphoma, peripheral neuroectodermal tumor, and Wilms' tumor, but not from retinoblastoma on FNA utilizing nuclear image morphometry.[103]

Urinary Diversion

Preservation of renal function requires prompt treatment of urinary obstruction. Suprapubic catheter drainage should not be used in children with RMS who present in urinary retention, to avoid the risk of tumor spread along the suprapubic tract. Usually, a urethral catheter can be utilized until chemotherapy reduces the tumor burden and the child is able to void. If possible, internalized ureteral stenting is preferable to percutaneous nephrostomy drainage to manage ureteral obstruction.

STAGING OF RHABDOMYOSARCOMA

Both the surgically based clinical grouping system (CGS) employed by the IRSG and the site-based TNM staging system have been used.[104–106] The CGS (Table 61.2) is a surgicopathologic staging system based on extent of surgical resection, with modifiers related to clinical and pathological findings.[104,105] The TNM staging system (Table 61.3) takes into account tumor location, size, clinical lymph node involvement, and the presence or absence of metastases. It is used to plan therapy and is highly predictive of outcome.[104–106]

Evaluation of tumor resection margins and the distance of the tumor from the nearest resection margins are mandatory for adequate staging. Additionally, as it affects staging and outcome, three-dimensional tumor size must be recorded at presentation. The pathologist has an important role in the staging or grouping of RMS, as well as its histopathological classification to determine appropriate risk stratification. Current COG treatment protocols are based on risk-stratified staging, and the parameters for this categorization into low-, intermediate-, or high-risk

TABLE 61.2 Clinical grouping system for rhabdomyosarcoma

Clinical group	Extent of disease	
I	**Localized, completely resected**	
	A	Confined to site of origin
	B	Infiltration beyond site of origin; no regional nodal involvement
II	**Microscopic residual or regional spread, total gross resection**	
	A	Localized with microscopic positive margins, grossly resected
	B	Regional disease with complete resection, nodal involvement, or tumor extension into adjacent organ, most distal node negative
	C	Regional disease resected with microscopic residual or most distal resected nodes involved
III	**Gross residual**	
	A	Biopsy only
	B	Gross/major primary resection (>50%)
IV	**Distant metastasis at diagnosis**	Lung, liver, bone marrow, bone, brain, distant muscle, or positive cytology CSF, pleural fluid, peritoneal fluid

TABLE 61.3 TNM staging of childhood genitourinary rhabdomyosarcoma

Stage	Sites	Tumor invasiveness	Tumor size	Regional nodes	Metastases
1	Favorable site (Paratesticular vulva, vagina, uterus)	T1 or T2	a or b	N0, N1, or NX	M0
2	Unfavorable site (Bladder, prostate retroperitoneum)	T1 or T2	a	N0 or NX	M0
3	Unfavorable site (Bladder, prostate retroperitoneum)	T1 or T2 T1 or T2	a b	N1 N0, N1, or NX	M0 M0
4	All	T1 or T2	a or b	N0 or N1	M1

Note: Tumor: T1, confined to anatomic site of origin; T2, extension and/or fixative to surrounding tissue. Size: a, <5 cm in diameter; b, >5 cm in diameter. Regional nodes: N0, not clinically involved; N1, clinically involved; NX, clinical status unknown. Metastases: M0, no distant metastasis; M1, distant metastasis present.

groups include pretreatment stage, clinical group, site, and histology (Table 61.4).[11]

TREATMENT

Local Therapy: Results of Multi-Institutional Trials

Although RMS is a chemosensitive tumor, drugs alone cannot cure most children who have this disease. Surgical resection alone or in combination with irradiation is necessary for local control of the tumor, which is essential, as nearly half of those children who die of this tumor fail locally at the primary site.

Resection

The goal of surgical resection in RMS is complete excision of the primary tumor with a surrounding rim of normal tissue, in conjunction with preservation of function. To that end, if complete resection cannot be expected without significant functional detriment, initial surgical management should be biopsy alone, with a planned second-look procedure after protocol-driven chemotherapy and/or radiation. Margins should be oriented and marked on the operative field, and areas of concern for close margins should be biopsied to verify resection completeness. Suspected residual tumor should be marked with titanium clips. Lymph node sampling is indicated for clinical or radiographically positive nodes without the need for complete lymph node resection. In cases of residual tumor, poor therapy response, or incomplete initial resection, a repeat surgical procedure after chemotherapy and radiation may be indicated.[11]

TABLE 61.4 Risk-based stratification of rhabdomyosarcoma

Risk group	Pretreatment stage	Clinical group	Site	Histology
Low 1	1 or 2 1	I or II III	Any Orbit	eRMS eRMS
Low 2	1 3	III I or II	Favorable Unfavorable	eRMS eRMS
Intermediate	2 or 3 1–3	III I–III	Unfavorable Any	eRMS aRMS
High	4	IV	Any	Any

Note: Favorable sites are the GU, biliary, nonparameningeal head and neck, orbit.

GU: Bladder and Prostate

Bladder salvage may be anticipated in 50%–60%[102] of patients, and radical surgery should be delayed as long as there is continued partial response to therapy. If it is possible to preserve bladder function, such as in the case of a dome lesion, a complete resection may be performed at initial presentation through partial cystectomy with augmentation or ureteral reimplantation, if necessary. If tumor response to chemotherapy or radiation is poor, then radical cystectomy or cystoprostatectomy with continent urinary diversion may be required. On rare occasion, incomplete response of prostatic tumors to therapy may allow prostatectomy with complete gross and microscopic tumor removal and preservation of bladder function and continence. As up to 20% of cases will demonstrate positive lymph nodes, iliac and para-aortic nodes should be sampled during resection.[11]

Vulva, Vagina, and Uterus

Female genital tumors are generally responsive to primary chemotherapy, generally precluding the need for exenteration at any point in the treatment course. Nonresponsive distal vaginal lesions may not require hysterectomy; however, hysterectomy should be considered for proximal vaginal tumors, and those of the uterus as primary uterine tumors may be less chemosensitive. Ovaries should be preserved unless there is direct tumor involvement.[11] Vaginal tumors rarely spread to regional lymph nodes; however, uterine tumors are frequently quite extensive at diagnosis.[6]

Retroperitoneum and Pelvis

Typically large at presentation, and carrying a poor prognosis, retroperitoneal and pelvic tumors may be primarily resected if a safe resection is expected with preservation of function. A review of patients with clinical group III or IV RMS of the non-GU pelvis or retroperitoneum enrolled in IRS III or IV pilot identified that patients with eRMS who underwent a debulking procedure had improved 4-year FFS rates compared with the biopsy-alone group (72% vs. 48%).[107] In patients with localized RMS of the pelvis or retroperitoneum outside the GU tract in IRS IV, there was improved survival in those patients who underwent primary resection or debulking of at least 50% of the tumor burden compared with those with initial biopsy only and second-look operation following chemotherapy and radiation. Some concern has been raised that this particular group of patients had poor compliance with RT protocol, and this may have contributed to decreased local control for the biopsy group.[108] Therefore, cautious consideration may be given to a debulking procedure for tumors in these sites.

Perineum and Perianal

Often large at presentation, perineal and perianal tumors should undergo complete resection if function can be preserved, particularly continence. A temporary colostomy may be needed to manage anorectal obstruction.[11]

Paratesticular

Paratesticular RMS should be managed with radical inguinal orchiectomy, employing proximal spermatic cord control prior to cord and testicular manipulation. If indicated, biopsy should be obtained only after proximal cord control, with isolation of mobilized testicle and cord from the wound with nonpermeable drapes, and tumor spillage (to include hydrocele fluid) should be avoided. In any case where unprotected tumor spillage occurs, patients are classified as at least clinical group IIA.[109] Hemiscrotectomy should be completed at the time of orchiectomy for any patient who had a history of a transscrotal biopsy. All patients should undergo thin-cut staging CT of the abdomen and pelvis to assess for retroperitoneal node involvement. Patients less than 10 years of age with no clinical evidence of nodal involvement do not require retroperitoneal lymph node dissection (RPLND); however, those greater than 10 years or with evidence of retroperitoneal nodal disease on CT scan should undergo staging ipsilateral nerve-sparing RPLND to include sampling of suprarenal nodes, as positive suprarenal nodes result in upstaging to clinical group IV.[11] Tomaszewski et al. reported on a case series of three patients in whom laparoscopic RPLND was completed with the benefits of a rapid convalescence and minimal delay before commencing adjuvant chemotherapy.[110]

Chemotherapy

Primary chemotherapeutic agents in the treatment of RMS include vincristine, dactinomycin, and cyclophosphamide (VAC). Modifications of the standard VAC regimen based on risk stratification are ongoing through the COG to identify regimens with decreased treatment burden and preserved survival for patients with low-risk disease, and options for novel therapies and dose intensification to improve response and survival in patients with high-risk disease.

Additional Chemotherapeutic Agents

Doxorubicin

IRS I, II, and III randomized group III and IV tumor patients to VAC with or without doxorubicin with similar radiation therapy (XRT) with no benefit to doxorubicin detected.

Cisplatin and Etoposide

IRS III evaluated VAC versus VAC, doxorubicin plus cisplatin versus VAC, doxorubicin, and cisplatin plus etoposide, with all patients receiving XRT with no benefit of any of the additional agents over VAC alone.

Ifosfamide

Severe acute renal tubular toxicity was noted for ifosfamide when combined with carboplatin in children with sarcomas compared with ifosfamide alone or with cisplatin, while combination use with cisplatin was associated with delayed renal tubular toxicity.[111] Skinner et al. identified risk factors associated with nephrotoxicity from ifosfamide in 148 young sarcoma patients. Reduction of risk for nephrotoxicity was noted with doses less than 84 g/m^2, while doses greater than 119 g/m^2 were associated with a very high risk of severe toxicity.[112] Ifosfamide did not improve outcome for patients with nonmetastatic disease when substituted for cyclophosphamide in IRS IV.[113]

Melphalan

Melphalan is active in previously untreated RMS and was combined with vincristine in IRS IV in comparison with ifosfamide and etoposide (IE), and ifosfamide and DOX for metastatic disease in an up-front window. Despite high response rates, the melphalan group required more dose reduction of cyclophosphamide and had higher rates of secondary malignancy, with inferior OS.[114,115]

Topotecan

Chastagner et al. reported that topotecan potentiates the radiation response of two different human RMS tumors xenografted into nude mice.[116] Topotecan administered to 40 patients with stage 4 RMS resulted in 45% complete and partial response rates.[114] Fifteen patients with recurrent or refractory RMS were treated with a combination of topotecan and cyclophosphamide, with 10 achieving a partial or complete response.[117] Despite the apparent efficacy in metastatic and recurrent RMS, COG study D9803 did not identify a treatment advantage with the addition of topotecan to the treatment regimen for intermediate-risk RMS, with no improvement in FFS when alternating standard VAC with vincristine, topotecan, and cyclophosphamide (VTC).[118]

Irinotecan

RMS xenografts from untreated patients, as well as those that were resistant to vincristine, melphalan, and topotecan, have responded to irinotecan, a camptothecin analog.[119]

COOPERATIVE TRIALS

The outcome of children with RMS has improved dramatically over the past 40 years. In the 1960s, when therapy was local in the form of surgery and irradiation, only around one-third of all patients survived.[120] The subgroup of patients with tumors in selected primary sites, such as the bladder or the orbit, was treated with radical surgery with 70% survival.[121–123] During the 1960s, combined chemotherapy was initiated with VAC, yielding promising results.[124,125] These early encouraging results, combined with the heterogeneity and rarity of RMS, prompted implementation in 1972 of the first national cooperative trial.

IRS I–IV

The IRS committee has reported the results of four consecutive trials encompassing 3630 patients: IRS I (1972–1978, $n = 686$), IRS II (1978–1984, $n = 999$), IRS III (1984–1991, $n = 1062$), and IRS IV (1991–1997, $n = 883$).[9,113,126,127] The estimated 5-year OS rates steadily and significantly increased in each of the first three trials: 55% in IRS I, 63% in IRS II, and 71% in IRS III, while the fourth trial only showed benefit over prior studies in specific subgroups of intermediate-risk eRMS with a 3-year OS of 86%.[113] Highlighting the need for long-term follow-up of these cohorts, a recent long-term analysis of the Italian Cooperative Study RMS 79 (1979 through 1987), which initially identified a 63% 3-year OS, identified a decrease in OS to 53% at 20 years, with a median follow-up of 23 years. Characteristics influencing long-term survival were histology, tumor site and size, and IRS group.[128]

In IRS I treatment, assignment was based on the post-surgical extent of disease, with no stratification for specific risk subgroups. IRS II study recognized the prognostic significance of certain risk factors (clinical group, site, and histology) and stratified patients accordingly. Patients with primary tumors in "special pelvic" sites (bladder, prostate, vagina, and uterus) received VAC chemotherapy. IRS III further stratified patients into nine distinct risk subgroups according to extent of disease, primary tumor site, and histology. IRS IV evaluated new up-front window chemotherapy regimens and the effectiveness of hyperfractionated RT compared with conventional radiation.[113,129–131]

Clinical Group I

Given the overall expected excellent prognosis of clinical group I (completely resected) RMS, studies evaluated progressive options to decrease therapy burden. In IRS I, it was concluded that the 5-year OS and disease-free survival did not change with the addition of RT to VAC chemotherapy, resulting in the omission of RT for children with clinical group I tumors.[126] IRS II demonstrated equivalency between vincristine and dactinomycin (VA) chemotherapy and VAC chemotherapy for clinical group I patients. In IRS III, the 5-year progression-free survival (PFS) and OS for those treated with VA for 1 year were similar to those for VAC or VA for 2 years.[9] With an increased cyclophosphamide and ifosfamide intensity over IRS III, IRS IV demonstrated improved 3- year FFS in group I and II unfavorable-site eRMS from 71% to 86%.[132] These combined results produced treatment recommendations that patients with completely resected eRMS at favorable sites (GU nonbladder prostate) be treated safely and effectively with two drugs (VA) for 1 year. Those with bladder or prostate group I eRMS receive VAC, potentially at an intensified cyclophosphamide dose, and those with aRMS or undifferentiated RMS receive XRT in addition to VAC.[132]

Clinical Group II

Clnical group II RMS patients usually received postoperative RT at various time points during treatment, resulting in a local control rate of 90%.[9,126,127] Based on IRS I and II study results, VA with RT remained the therapeutic standard for children with clinical group II disease presenting with a favorable-histology tumor in a favorable site. IRS III compared VA plus adriamycin and RT with VA only plus RT. Even though there seemed to be an advantage to adding adriamycin, this was not statistically significant.[9] The CWS reviewed the benefits of RT for group II patients over four trials from 1981 to 1998. In this study of 203 group II patients, 110 received XRT and 93 did not. Local control rates were 83% with and 65% without RT ($p < 0.004$), while the OS difference was not statistically significant (84% vs. 77%). In these studies, the distribution of patients with unfavorable histology or sites was significantly higher in the groups that received RT than in those that did not, and despite this difference, the trends were for better outcome in the groups that received RT. This group was not able to identify a subset of group II patients in whom RT may be spared.[133]

IRS IV evaluated higher-dose cyclophosphamide, as well as IE, resulting in similar survivals for patients with local or regional tumors in all IRS IV treatment groups, with a lower overall toxic death rate in IRS IV (1%). However, IRS IV was associated with more improved OS and FFS than IRS III for the subgroup of patients with intermediate-risk (stage 2 or 3/group I or II) eRMS (93% vs. 76% 3-year FFS).[113]

As part of the Italian Cooperative Study RMS 88, 25 patients with microscopic residual RMS after primary excision were reviewed. Microscopic residuals were difficult to manage because of the lack of a measurable target. Primary reexcision with chemotherapy was the treatment of choice for children less than 3 years who could not receive radiation. It was not effective for tumors larger than 5 cm, where adequate RT and chemotherapy were found to be effective.[134]

Unfavorable-Histology Clinical Group I and II Tumors

The poor outcome for children with clinical group I aRMS was recognized in IRS I.[126] Therefore, these children received intensive VAC chemotherapy in IRS II, resulting in increasing the 3-year disease-free survival rate from 43% to 69%.[127] In IRS III, therapy was further intensified with the use of a regimen containing VAC with doxorubicin (VADRC), VAC, and cisplatin. The 5-year PFS ($71 \pm 6\%$) and OS (80 ± 6) rates were significantly improved over those for comparable patients treated on IRS II protocols.[9]

Despite an intensified chemotherapy regimen in IRS III compared with the first two studies, patients with unfavorable histology (alveolar or undifferentiated) who did

not receive radiation fared worse than those who received radiation in this study or historically. Pooled data from IRS I, II, and III on all undifferentiated RMS and aRMS demonstrated that radiation was associated with improved FFS (73% vs. 44%, 10 years, $p = 0.03$) with fewer local, regional, and distant relapses.[45] In review of IRS I, II, and III group I patients, Wolden et al. identified that tumors of >5 cm and alveolar histology were associated with poorer FFS. The GU primary site conferred both an OS and an FFS advantage for eRMS, but not for aRMS or undifferentiated sarcoma.[135] IRS IV found no improved survival in aRMS compared with IRS III.[113] Localized aRMS at any site is currently classified as at least an intermediate-risk tumor for COG protocols (Table 61.4).

Clinical Group III

This is the largest group of patients enrolled in IRS I, II, and III.[126,127,136] In IRS I, all group III patients were randomized to receive either VAC and radiation, or VADRC-VAC and radiation. Addition of doxorubicin failed to improve the 5-year OS.[126] IRS II patients were randomized to receive intensified VAC or VADRC-VA therapy. Prognosis was not different between those two regimens, but the intensified treatments were superior in inducing complete responses and prolonged survival compared with IRS I.[127] IRS III patients were randomized to receive either pulsed VAC or VADRC-VAC-cisplatin or VADRC-VAC-cisplatin-VP-16. At 5 years, the OS was the same for all three regimens.[9] Several patients among these study arms received alternate induction chemotherapy with one of three drug pairs (doxorubicin-dacarbazine, dactinomycin-VP-16, or dactinomycin-dacarbazine) and second-look surgery.[9,136] The outcome of these children was improved compared with that of patients who were treated in IRS II. IRS IV regimens including IE and higher cyclophosphamide doses than in IRS III resulted in similar outcomes for group III patients among the IRS IV treatment groups and between IRS III and IRS IV. The standard remains VAC and RT for these patients.[113] While unfavorable-site group III patients demonstrated no improvement in survival on IRS IV compared with IRS III, the subset of group III or resectable node-positive eRMS with a GU nonbladder or prostate primary improved from a 72% to 92% 3-year FFS.[132]

Clinical Group IV

With the exception of a subset of intermediate-risk patients (<10 years old, embryonal), the 5-year survival for patients with metastatic disease continues to be poor, in spite of intensified therapy and new drug combinations. The combined agent regimens in the first three IRS studies led to 5-year OS and PFS rates below 30%.[9,126,127]

In a pilot study for IRS IV, doxorubicin and ifosfamide were used in an up-front window prior to VAC for metastatic RMS, resulting in an ultimate complete response rate of 53% and 1/3 survival, similar to prior regimens. Factors in this study contributing to a better prognosis included age less than 10, embryonal histology, GU primary, lack of nodal disease, and absence of bone or bone marrow metastasis.[137] IRS IV evaluated the effectiveness of an up-front window of IE compared with vincristine and melphalan (VM) for metastatic presentations. This initial therapy was followed by VAC, surgery, and RT, and then a repeat of VM or IE in initial responders. While initial response in both groups was high, OS was better in the IE group, with a 3-year FFS and OS of 33% and 55%, compared with 19% and 27% for the VM group.[115] A retrospective multivariate analysis of 137 group IV patients enrolled in IRS IV identified the presence of two or fewer metastatic sites as a predictor of survival. The subgroup with embryonal histology and two or fewer metastatic sites demonstrated a 3-year FFS of 40% and OS of 47%, compared with 25% and 39% for all patients studied. The authors suggest that this subgroup, whose survival approaches that of selected patients with nonmetastatic disease, might not be appropriate candidates for consideration in highly toxic or unproven antitumor investigational regimens.[130]

Treatment of 48 patients with metastatic RMS with topotecan in an up-front window prior to VAC and continued for responders resulted in a 46% overall response rate with an acceptable toxicity profile. Particularly interesting was that efficacy was greater against aRMS than eRMS (65% vs. 28% response, $p = 0.08$).[138]

The European Collaborative Studies MMT 4-89 and MMT 4-91 failed to demonstrate a statistically significant improvement in the 3-year EFS comparing consolidative megatherapy (high-dose chemotherapy and stem cell rescue) and standard chemotherapy (30% vs. 19% of 53 and 44 patients) in the treatment of metastatic disease.[139] The lack of benefit of this modality was verified by Weigel et al., who completed a meta-analysis of 389 metastatic RMS patients treated with high-dose chemotherapy and stem cell rescue, and confirmed that this treatment conferred no survival advantage for stage 4 patients compared with IRS II and III.[140] Further evaluation of intensive chemotherapy in MMT 98[141] and RMS 4.99[142] conferred no additional benefit for poor-risk patients.

Regional Lymph Node Disease

Histologically proven lymphatic involvement in the presence of localized RMS with a grossly complete resection in IRS I and II was most common in prostate (41%) and paratesticular (26%) RMS, with an overall rate of 24% for GU sites.[143] IRS III identified nodal disease as an independent prognosticator only in stage 3 aRMS.[144] Rodeberg et al. evaluated the prognostic significance of regional lymph node disease for children enrolled in IRS IV with a comparison of N0 disease, clinically or pathologically confirmed N1 disease, and single-site metastatic disease. Poorer prognosticators were identified in the patients with N1 disease who were more likely to be older than 10, and have unfavorable primary sites, alveolar histology, higher stage and clinical group, and large invasive primary tumors. FFS for N1 disease was statistically significantly different from both N0 and single-site metastatic disease, falling between the two. Substratification by tumor histology results in outcomes for N1 aRMS similar to those of metastatic disease, with both significantly worse than N0 aRMS, while eRMS patients had similar outcomes regardless of nodal status, which were significantly better than those with a single metastatic focus. Outcome predictors differed between aRMS and eRMS, with node status being the only significant predictor of

FFS and OS in aRMS, whereas eRMS demonstrated patient age, tumor invasion and primary site, and metastatic disease as predictive factors. Gene array analysis in this study also noted increased expression of immune response genes in node-positive aRMS. The authors recommend consideration for treatment intensification for node-positive aRMS and conclude that node-positive disease is not being overtreated.[145]

Radiation Therapy

RT provides another option for local control in those patients whose primary tumor is not amenable to resection, or who have residual microscopic (group II) or gross (group III) disease after resection. In response to the results of several trials, RT doses now vary according to the patient age, tumor site, and amount of residual tumor.[8] Intensified chemotherapy and second-look surgery have decreased the use of RT and extensive primary surgery for patients with vaginal and vulvar RMS.[146] In addition, the use of early RT, aggressive chemotherapy, and second-look surgery has dramatically decreased the use of radical surgery to treat children with GU RMS.[9,146]

In IRS IV, RT of completely resected tumors with unfavorable features (large size, unfavorable site, and nodal involvement) was mandated, with gross residual disease requiring higher doses of 45–55 Gy, depending on the site and size of the tumor.[8,38] Further, to increase local control and decrease the acute and late adverse effects of RT, IRS IV evaluated hyperfractionated RT in patients with unresectable or metastatic disease. A total of 559 patients were enrolled with group III RMS, of which 478 were eligible for randomization to standard (239) or HFRT (239). There was no statistical difference in OS or FFS between the two radiation treatment methods, and no difference between the two treatment groups when analyzed for age, gender, tumor size, invasiveness, nodal status, histology, or primary site.[130]

Risk-Stratified Protocols

Meza et al. reviewed outcomes from IRS III and IV to identify prognosticators in nonmetastatic disease. Overall, aRMS had a worse outcome than eRMS (5-year FFS of 65% vs. 82%). FFS in aRMS was influenced by stage, grade, age of <1 year, and locoregional lymph node involvement. Three prognostic subsets of eRMS were identified from IRS III and IV to guide risk stratification in successive studies. Nonmetastatic eRMS at favorable sites are completely resected eRMS at nonfavorable sites are low-risk tumors that were classified into two subsets. Subset A (stage 1/group I or IIA, stage 2/group I and group III orbit), with a 5-year FFS of 90%, had an excellent outcome with modest therapy on IRS III–IV. Subset B (stage 1/group IIB or IIC, stage 1/group III nonorbit) demonstrated a 5-year FFS of 87%; however, those in the subset who received two-drug therapy (VA) had poorer outcomes and were excluded from analysis. Subsequent protocols including VAC therapy resulted in a similar excellent outcome for subset B patients. The remaining patients (stage 2 or 3/group III eRMS) were classified as intermediate risk (5-year FFS of 73%).[144]

IRS V, now also named the Soft Tissue Sarcoma Committee of the COG, continued cooperative studies with the recently completed D series (D9602, D9802, and D9803) focusing on risk-adapted therapy.[147] This approach continues with the current risk-stratified protocols ARST0331 (low risk), ARST0531 (intermediate risk), and ARST0431 (high risk) (Table 61.4).

FFS is estimated to be 90% at 5 years for low-risk RMS[144] and 70% at 4 years for intermediate-risk RMS.[118] The 3-year OS is estimated to be 30% for high-risk RMS.[101,148]

Low-Risk RMS

Given their relatively excellent survival estimates, the objectives of low-risk protocols are primarily to decrease treatment burden. COG D9602 (1997–2004) was designed to decrease toxicity in localized, grossly resected eRMS by reducing RT and eliminating cyclophosphamide. The lowest-risk patients, subgroup A (stage 1/group I or IIA, stage 2/group I and group III orbit) received VA with a 5-year FFS of 95% and subgroup B (stage 1/group IIB or IIC, stage 2/group II, stage 3/group I or II) received VAC with a 5-year FFS of 85%. Group II or III patients received RT that was reduced compared with IRS IV from 41.4 to 36 Gy for the lower-risk stage 1/group IIA patients. The 5-year FFS rate of 89% for subgroup A and 85% for subgroup B were similar to those of IRS III, despite lower RT doses; however, they were decreased from those of similar patients in IRS IV who received VA plus cyclophosphamide.[149]

Breneman et al. reviewed the efficacy of RT dose reduction on local control for these patients. Low-risk patients were substratified for different RT doses. Group I received no RT, and group III underwent second-look operation. Postoperative RT was given for residual gross or microscopic tumor for group III vaginal RMS patients, and other group III patients received a second-look operation if complete resection was possible without significant functional or cosmetic deficit, followed by fractionated RT with a 1.5 cm margin. Group IIA patients received reduced-dose RT at 36 Gy. Groups IIB and IIC received 41.4 Gy, and group III without second look received 50.4 Gy. After the second-look procedure, patients received 36–50 Gy, with the exception of girls with vaginal tumors, who were spared RT if second-look operation had negative margins. RT dose reduction to 36 Gy, from 41.4 in IRS III and IV, with cyclophosphamide chemotherapy for the unfavorable-site group IIA tumor patients resulted in no local failures at 5 years compared with 14% and 7% in the two prior trials, suggesting no increase in local failure with RT dose reduction for this subgroup of patients.[147] Based on a subgroup analysis identifying 60% locoregional failure rates in girls with group IIA RMS vaginal primaries with protocol-specified omission of RT, current trials mandate RT for group II or III vaginal tumors at 36–50.4 Gy.

The current low-risk protocol COG ARST0331 redefines the low-risk subsets based on the subgroup analysis of D9602, demonstrating that within subset B, patients with stage 1/group IIB or IIC or stage 2/group II had similar OS rates with VA on IRS III and VAC on IRS IV. This subgroup has been shifted to the lowest-risk subset. The two low-risk eRMS subsets to be evaluated include

subset 1 (stage 1 or 2/group I or II) and subset 2 (stage 1/group III, stage 3/group I or II). The lowest-risk patients (subset 1) will receive VAC for four cycles with a reduced dose of cyclophosphamide, followed by VA for four cycles with radiation, resulting in a reduction of therapy length to 22 weeks. Subset 2 will be treated with an additional eight cycles of VA for a total of 12 after the VAC with reduced cyclophosphamide. Additionally, the protocol will assess lower-dose (3600 cGy) radiation for node-negative patients with microscopic residual disease and dose–response radiation dosing after second-look surgery for group III patients.

Intermediate-Risk RMS

From 1999 to 2005, COG D9803 randomized 516 intermediate-risk patients to VAC or VAC alternating with VTC. Patients received response-adjusted RT according to stage, group, and histology at diagnosis, as well as disease status at second-look surgery. The 4-year OS and FFS were unchanged from those of IRS IV on any treatment regimen. VAC was associated with a higher incidence of febrile neutopenia. The trial confirmed prior findings of higher failure rates with increased stage and group and with alveolar histology.[118] Twenty patients in this protocol (2.2%) demonstrated early disease progression and did not receive planned protocol RT (19/20 at the primary site), with a 5-year OS for this group of 32% compared with historical data for recurrent disease (OS of 20%). The authors theorize that earlier RT timing might result in better local control.[150]

Lin et al. compared the outcome of patients enrolled in COG D9803 and treated with intensity-modulated radiotherapy (IMRT) with those treated with three-dimensional conformal radiotherapy (3D-CRT) and did not identify any significant difference in locoregional control or FFS; however, they did identify that IMRT resulted in improved target dose coverage. Improved dose coverage with IMRT may enable a lower treatment dose with preserved efficacy in future trials.[151]

Dharmarajan et al. studied the toxicity and efficacy of irinotecan and carboplatin delivered concurrently with RT for intermediate- and high-risk RMS in a single-institution pilot phase II trial from 2003 to 2011, with preliminary results demonstrating local control rates of 89% at 2.5 years, comparable to D9803 despite the inclusion of high-risk in addition to intermediate-risk patients in this trial. In addition to excellent local control rates, the regimen resulted in a favorable toxicity profile.[152]

COG trial ARST0531 is currently enrolling intermediate-risk patients in a trial evaluating the response rates and FFS for those treated with VAC or VAC alternating with vincristine and irinotecan (VI), and early versus late RT.

High-Risk RMS

International Society of Pediatric Oncology (SIOP) study MMT 95 evaluated intensified chemotherapy for 457 high-risk nonmetastatic RMS and soft tissue sarcoma patients to receive ifosfamide, vincristine, and dactinomycin (IVA) or an intensified six-drug regimen of IVA plus carboplatin, epirubicin, and etoposide. The 3-year OS was similar between the two arms (82% IVA and 80% six-drug), with a significantly greater treatment toxicity in the six-drug group.[153]

In successive trials COG 9802 (19 patients) and 9802R (50 patients), irinotecan and then irinotecan in combination with vincristine were assessed for efficacy and toxicity in the treatment of metastatic RMS in an up-front window trial. After the initial treatment window, partial and complete responders continued to receive irinotecan with or without vincristine alternating with VAC, while nonresponders continued with VAC. Irinotecan alone resulted in a window response rate of 42%, but a progressive disease rate of 32% resulted in the closure of COG 9802 (irinotecan alone) and modification to 9802R (irinotecan and vincristine), with improvement in the window response to 70% and reduction in progressive disease to 8%. This response rate surpassed that of the prior window trial and demonstrated lower disease progression than VAC alone, despite no improvement in survival. The primary toxicity of the window treatment was gastrointestinal (predominantly diarrhea and abdominal pain), and there were fewer grade 3 and 4 toxicities in the window treatment group (50%) than in the VAC group (80%). The authors conclude that the lack of cross-resistance and the overlapping toxicity profiles of VI and VAC, in combination with the response rate to VI, warrant irinotecan in combination with vincristine integration into RMS treatment protocols.[154]

COG ARTS0431 is evaluating the efficacy of intensive interval compression of known RMS effective agents (including ifosfamide, etoposide, doxorubicin, and irinotecan, in addition to VAC) to improve early disease control and the feasibility and side effects of irinotecan administered in combination with radiation.

Despite improved outcomes for localized disease, the prognosis for patients presenting with metastatic disease has not improved significantly over the past 20 years, with an overall cure rate below 30%.[148] Oberlin et al. pooled data from IRS II–V, IRS D9501, Italian Group (RMS 4.99), SIOP MMT (84 and 98), and European Intergroup (MMT 89–91) to evaluate prognostic factors for 788 patients presenting with metastatic RMS and treated between 1984 and 2000.[148] Metastases were most common to the lung (47%), with this being the only metastatic site for 18%, followed by bone marrow, bone, and distant nodes. The estimated overall 3-year EFS and OS were 34% and 27%, respectively, with no significant difference between American and European groups. Multivariate analysis identified age less than 1 or greater than 10 years, unfavorable primary site, bone or bone marrow involvement, and three or more metastatic sites as independent risk factors decreasing EFS. The 3-year EFS decreased from 50% for no risk factor to 42%, 18%, 12%, and 5%, respectively, for the addition of one to four risk factors.

Special Pelvic Tumors

Early in the IRS studies, it became apparent that certain pelvic tumors (bladder, prostate, vagina, and uterus) responded better to therapy than other sites. In IRS I, treatment for BP RMS included primary exenteration, followed by a 2-year course of chemotherapy and local RT.[155,156] The 5-year OS in this group of patients was

74%. However, this outcome was achieved at the expense of numerous bladder extirpations for patients with GU tumors, and only 23% of the patients had functional bladders 3 years after therapy.[156] In IRS II, the treatment strategy changed to primary chemotherapy with 4 months of VAC, followed by delayed radiation and/or surgery. This treatment approach failed to improve the bladder salvage rate, with a 3-year bladder retention rate of only 25% and a survival rate similar to that of IRS I.[157,158] Outcomes were similar to those of SIOP and the Italian Cooperative Group (ICG), where radiation treatment was delayed until after the chemotherapy response was assessed, and only instituted if there was inadequate response to chemotherapy.[131] In IRS III, patients in clinical group III received an intensified VADRC-VAC regimen plus cisplatin to induce a complete response. Second-look surgery was recommended at 20 weeks. Alternate induction therapy with dactinomycin and VP-16 was initiated if tumor remained. The 3-year bladder preservation rate (60%), 5-year PFS estimate ($74 \pm 5\%$), and OS (83 ± 4) were strikingly superior to those of IRS I and IRS II.[9,126,127]

Bladder and Prostate

Prior to multiagent chemotherapy, BP RMS was treated with radical cystectomy or pelvic exenteration. Encouraging results with primary chemotherapy have prompted a paradigm shift toward organ preservation when possible, without negatively impacting long-term survival. While outcomes for RMS have improved across the four IRS trials, outcomes for nonmetastatic BP RMS have been relatively constant, with 78%–82% survival.[129,159] This is similar to international cohorts (SIOP, ICG, and CWS), which demonstrated an OS rate of 84%.[129,160,161] Survival rates have remained stable despite a marked decreased in the rate of cystectomy from 78% to 9%.[129,159] Improvements in chemotherapy regimens have imparted better OS rates despite less aggressive surgery resulting in higher bladder retention rates.[129,131]

Heyn reviewed the outcome of 28 patients with group III bladder RMS. All received 20 weeks of multiagent chemotherapy and 4 weeks of RT. Of these, 13 underwent cystectomy. Cystectomy specimens demonstrated diminished tumor cells with varying degrees of maturation. They concluded that primary bladder RMS is very responsive to chemotherapy and RT, and that these tumors show further maturation following treatment, thus allowing preservation of larger proportions of bladders with residual disease.[86] Similarly, Lobe et al. examined the role of conservative surgery in localized prostatic RMS and showed a high cure rate with relatively good bladder salvage rate without aggressive early surgery.[162]

Arndt et al. reported the results from IRS IV and reviewed bladder function retention with a bladder preservation approach in patients with nonmetastatic BP RMS. Of 90 patients with nonmetastatic BP RMS, 88 had sufficient information for review. Tumor characteristics included 70% arising from the bladder, 80% favorable histology (eRMS or bRMS), 69% greater than 5 cm in diameter, 84% group III, and 56% invasive T2 tumors. All patients received alkylating-based chemotherapy, and 74 received radiation. As one of the goals of the protocol was organ preservation, initial radical resection was not recommended. Patients underwent initial biopsy with initial complete resection only if organ preservation was possible. Extirpation was reserved for biopsy-proven residual disease after completion of therapy, or progression of disease and early treatment failure after chemotherapy and XRT. OS and EFS rates at a median follow-up of 6.1 years were 82% and 77%. Events included 3 second malignancies, 1 toxic death, and 18 relapses (14 [78%] deaths with relapse). The bladder preservation rate was 83%, with 55% of retained bladders maintaining normal bladder function (lack of incontinence, dribbling, hydronephrosis, or enuresis after age 10) at a median follow-up of 9 years. Of all the patients entered in the study, 40% (36 of 88) survived event-free with apparently normal-functioning bladders. The authors advocate conservative delayed surgery in this group of patients and, recognizing that radiation treatment may have late effects, state that more precise long-term evaluation of bladder and sexual function will be required, using such tools as urodynamic studies and validated patient surveys.[129]

A retrospective chart review of 309 patients with BP RMS treated on IRS IV, SIOP MMT 84 and 89, Italian Cooperative Group RMS 79 and 88, and the German Cooperative Weichteilsarkonstudie 91 and 96 protocols resulted in 164 patients with enough data to assess late sequelae. Seventy-nine percent of 145 patients retained all or part of their bladder. Forty-three (69%) out of the 62 patients who did not undergo cystectomy and were older than 6 years had no recorded continence issues, while 19 (31%) cited at least one issue with bladder function, including nighttime incontinence, daytime incontinence, frequency, and urgency. Additional urologic sequelae included recurrent urinary tract infections, renal insufficiency, chronic hematuria, hydronephrosis, vesicoureteral reflux, urolithiasis, and hydroceles. Of males old enough to assess sexual function, 25/27 were capable of attaining erections, and 16/20 were capable of ejaculation. Two patients developed secondary tumors, including a breast cancer and a schwannoma of the leg.[163]

Seitz et al. evaluated the outcomes of patients with localized BP eRMS enrolled across 42 institutions in the CWS 96 trial between 1996 and 2002. The trial enrolled 69 patients with localized BP eRMS, with six exclusions due to incomplete data. The treatment protocol included risk-adjusted chemotherapy regimen of at least three drugs. Standard risk tumors were treated with IVA, and high-risk tumors were randomized to vincristine, ifosfamide, doxorubicin, and dactinomycin (VAIA) versus carboplatin, epirubicin, vincristine, dactinomycin, ifosfamide, and etoposide (CEVAIE). The majority were IRS group III patients, and radiographic response was assessed after 9 weeks, with subsequent local treatment driven by tumor volume reduction. Hyperfractionated accelerated radiotherapy (HART) was risk stratified based on chemotherapy response or postoperative tumor status. Complete or good responders with eRMS were treated with 32 Gy, and poor responders received 44.8 Gy. HART noncandidates received conventional fractionation at 39.8 or 50 Gy. Clinical group I patients did not receive RT. Thirty-eight (60.3%) patients were irradiated with equivalent EFS and OS between the risk-stratified dosing

groups, demonstrating no decrease in response with lower doses in the lower-risk group and a 50% early complication rate from treatment. Initial tumor biopsy was completed in 51 patients with a 9.8% complication rate, and 25% of the 12 who underwent primary tumor resection had a complication. Secondary surgery was completed in 45 patients with a 28.8% complication rate, and bladder preservation was not possible in 17 of them. The 5-year OS for all patients was 76% and was equivalent across all treatment groups except for the primary incomplete resection group treated with postoperative radiochemotherapy, which was significantly lower (84%–88% vs. 40% 5-year OS). Fourteen patients suffered a local relapse (6/14 after incomplete primary or secondary resection with no RT) at a rate higher than IRS IV. Given the unfavorable outcome, risk of incomplete resection, and a complication rate 2.5 times higher than in other groups, the authors recommend biopsy as the primary surgical approach, rather than primary surgery, unless a complete resection with negative microscopic disease is feasible. Secondary local control may be completed with risk adaption protocols to limit treatment-related morbidity.[159]

Rodeberg et al. compared the outcomes for BP RMS across four international study groups comprising 379 protocol patients treated from 1979 to 1998: IRS IV, SIOP Malignant Mesenchymal Tumors Committee (SIOP MMT 84 and 89), ICG RMS 79 and 88, and German CWS 91 study. Across protocols, patients received similar chemotherapy regimens, with recommendation for avoidance of radical resections. RT differed among the studies, with IRS and CWS patients receiving risk-stratified RT for incomplete resection. SIOP treated with RT those patients without complete response radiographically, and ICG required a negative histologic second look to avoid RT. Primary tumor resection was grossly complete in 5% of all cases and attempted in only 12% (40% successful complete primary resection). Forty-eight percent of SIOP and ICG and 85% of IRS IV and CWS localized BP eRMS patients received RT as initial treatment of primary tumor. The 5-year FFS was 75%, with the OS estimated at 83%. Multivariate analysis identified a tumor size of >5 cm (RR 2.3) and tumor invasion (RR 1.6) as independently predictive of FFS, and a tumor size of >5 cm as predictive of OS. The 5-year FFS differences among protocols (ICG 81%, IRS 79%, SIOP 65%, and CWS 70%) were not statistically significant, and the 5-year OS was similar among all groups (79%–83%). As expected, nonembryonal localized BP RMS and metastatic BP RMS resulted in poorer outcomes (5-year FFS and OS both 47% for non-eRMS and 41% and 44% for metastatic). Similar to other sites, metastatic BP RMS was associated with larger invasive tumors, and positive nodes in children less than 1 year or greater than 10 years of age. Identifying that while the FFS is decreased for those patients who did not receive RT initially, the OS is similar, the authors conclude that disease progression or relapse in those patients may be salvaged with later RT. These data differ from earlier protocols where delayed RT was associated with a worse prognosis for BP RMS; however, those inferior results were also on older chemotherapy and local control protocols. Treatment for local failure includes more aggressive chemotherapeutic regimen, in addition to RT, potentially increasing the therapy burden over what it would have been with initial RT without relapse, with the potential benefit of avoiding RT altogether. The authors suggest that there is a need to identify those who need upfront RT in order to spare those for whom its toxicity will not be of benefit.[131]

Evaluating an alternative for radical surgery and external RT for local control of BP RMS, a group in France reported results of conservative surgery (bladder neck and urethral preservation) in combination with 60 Gy brachytherapy. Twenty-six patients were treated between 1991 and 2007, with initial risk-based chemotherapy on SIOP protocols (MMT 89, 96, and 98) or European protocol RMS 2005. Patients were selected for the local treatment protocol according to response to first-line chemotherapy. Candidates included prostate tumors or those with no bladder extension above the trigone (outside field of brachytherapy), and surgical procedure was partial prostatectomy with urethral preservation or partial cystectomy of the bladder neck or trigone with extravesical ureteral reimplant, if needed. Plastic tubes for brachytherapy were implanted intraoperatively, and 60 Gy brachytherapy was delivered at a rate of 10 Gy daily. Twenty-six boys were treated with no resection considered microscopically complete, and 11 with macroscopic residual at tumor resection. Only four patients had no viable tumor, and three of them had metastatic disease. At a median follow-up of 4 years, 24/26 patients were alive, and only one of the survivors had undergone cystecomy, which was secondary to severe bladder dysfunction and associated hydroureteronephrosis. One patient with bone and nodal relapse responded to chemotherapy. One death was related to pulmonary relapse, and the other relapsed locally, outside the brachytherapy field, as well as in the lungs. Local treatment complications included rectal bleeding that resolved spontaneously, recurrent bladder stones in one patient, and ureteral stenosis treated with short-term stenting in another. Continence results are reported for 18 boys older than 4 years, and 15 demonstrated normal daytime continence responsive to anticholinergics and bladder education. The authors postulate that given that there was no relapse in the field of brachytherapy, even in the presence of gross residual disease, consideration may be given to biopsy alone, followed by brachytherapy for local control of RMS of the prostate and bladder neck.[164]

Female Genital Tract

From 1972 to 1996, with the advent of effective chemotherapeutic regimens, the rate of surgical tumor resection for vaginal or uterine RMS decreased from 100% to 13%. Management with chemotherapy and restrictive surgery has demonstrated excellent long-term survival and frequent uterine preservation. Arndt et al. reviewed the 151 patients with RMS of the female genital tract out of the 4272 RMS patients enrolled in IRS I–IV. The 5-year OS was 82%. Chemotherapy was primarily VAC based. Local control was surgery alone in 42%, surgery and RT in 19%, biopsy and RT in 12%, and biopsy without RT in 21% (no local therapy). Many with primary vaginal tumors received delayed RT or had it omitted

with excellent outcome. Hysterectomy rates decreased from 48% in IRS I or II to 22% in IRS III or IV, with an increase in RT from 23% in IRS II to 45% in IRS IV. There was no significant difference in survival over the course of the four trials for patients with localized embryonal or botryoid tumors. Prognostic factors included improved prognosis for ages 1–9, embryonal histology, N0 disease, noninvasive tumors, and the use of IRS III or IV treatment protocols. Patients outside of the 1- to 9-year age range particularly benefited from the intensified treatment of IRS III or IV (5-year survival 67% IRS I or II vs. 90% IRS III or IV). Treatment toxicity was the cause of 43% of deaths in patients with group I–III tumors. Unlike RMS at other sites, in this subgroup of patients, 67% of those who developed recurrent disease were salvaged with multimodal treatment, including chemotherapy, surgery, and RT, if not previously received. The authors recommended continued use of primary chemotherapy of VA for group I or II eRMS and VAC for group III disease, with individualized local treatment plans based on tumor site and histology. Those with nonembryonal female genital tract RMS should receive intensified chemotherapy, as they are of intermediate recurrence risk. Delayed RT is recommended for selected patients, such as those with positive margins after chemotherapy and local surgery, those with vulvar eRMS group II or III tumors, and all those with eRMS who are lymph node positive.[165] Subsequent elimination of RT and cyclophosphamide from treatment of vaginal eRMS in COG D9602 (1997–2004) resulted in a reduction of local control rate to 50% from 14% and 7% from IRS III and IRS IV. Therefore, future study mandates include RT for girls with group II or III vaginal tumors and evaluation of a low-dose cyclophosphamide to decrease chemotoxicity while maintaining efficacy.[147]

The COG enrolled low-risk eRMS patients in ARST0331 starting in 2004 with a protocol similar to that of D9602, with a slight delay in RT and utilization of a lower-dose cyclophosphamide in patients with nonresected localized vaginal RMS than in D9602. A high rate of local recurrences, primarily in the group III vaginal tumor patients, resulted in the suspension of enrollment in these studies for stage 1/group III and stage 3/group I or II vaginal RMS patients in these protocols. Between the studies, 41 patients with localized vaginal RMS were enrolled in 1997–2008. Primary site disease progression occurred in four group IIA or III N0 prior to local therapy and in 8/31 patients with group IIIA or III N0 who completed protocol therapy, in addition to 1/2 group I patients who developed disease progression during protocol therapy. The 5-year local recurrence rate for group IIA or III N0 vaginal RMS was 26%, and the 2-year local recurrence rate was 43% for group III N0 vaginal RMS in ARST0331. These results compared unfavorably both for the local recurrence rate on the same study for group IIA or III N0 at sites other than vagina (14%) and for similar patients on IRS III or IV (5-year FFS of 83%). These poorer outcomes were attributed to the delay or avoidance of RT in patients with unresected vaginal RMS who received low-dose or no cyclophosphamide. While local control was worse than at prior series, the OS was excellent with intensified chemotherapy, radical surgery, and RT. Identification of these differences has resulted in amending ARST0331 to include RT in the local therapy of girls with group II or III vaginal RMS, with the permitted omission of RT for children less than 24 months if potential toxicity is considered unacceptable. (https://www.ncbi.nlm.nih.gov/pubmed/21298768)

Late Effects of Therapy

Because of the improved long-term survival and the use of intensified chemotherapeutic regimens, several serious and potentially life-threatening therapy-related complications have emerged. In IRS IV pilot studies, the incorporation of ifosfamide into front-line therapeutic protocols for children with unresectable tumors was associated with a 14% incidence of renal toxicity. Factors that contributed to that toxicity included high doses of ifosfamide (>72 g/m^2), age younger than 3 years, and preexisting renal abnormalities, such as hydronephrosis. https://www.ncbi.nlm.nih.gov/pubmed/1548524; https://www.ncbi.nlm.nih.gov/pubmed/8157032. Toxicities for the final IRS IV trial included greater than 90% myelosuppression, 55% severe infections, and only 2% severe renal toxicity. Toxic deaths were highest in the VAC regimen in patients with preexisting renal abnormalities (3/56), with rates for other regimens less than 1% (neutropenia with septicemia = 6, metabolic = 1, and other = 1).[113]

Of the 109 patients with BP tumors who were treated in IRS I and II, 29% developed posttherapy hematuria, 29% showed evidence of delayed pubertal development, and 10% had growth retardation.[161]

The occurrence of second malignant neoplasms is one of the most devastating sequelae of successful contemporary therapy. Of the 1770 patients enrolled in IRS I and II, 22 developed second malignant neoplasms (10-year cumulative incidence rate of 1.7%). The most common malignancies were bone sarcomas ($n = 11$) and acute nonlymphoblastic leukemia ($n = 5$). The median time to development of these neoplasms was 7 and 4 years, respectively.[166] In the IRS III trial, acute myeloid leukemia occurred in 5 of the 1062 patients enrolled. All the patients received the alkylating agent cyclophosphamide, and four received etoposide. The median time to development of acute myeloid leukemia was 39 months; median follow-up was 3.7 years.[167] IRS IV had 10 second malignancies in the initial report (myelodysplastic syndrome or acute myeloid leukemia = 4, acute lymphoid leukemia = 1, lymphoblastic lymphoma = 1, osteogenic sarcoma = 1, leiomyosarcoma = 1, undifferentiated sarcoma = 1, and primitive neuroectodermal tumor = 1) for a 3-year cumulative risk in locoregional disease on IRS IV of 2%.[113] A large review of secondary malignancies in long-term survivors of childhood RMS was performed by Scaradavou et al.[168] They reported on 130 patients with a median follow-up of 9 years. Seven patients (5.4%) developed secondary malignancies, including three with acute nonlymphoblastic leukemia and four with solid tumors. This study identified an increased risk of secondary neoplasms in patients receiving the chemotherapeutic agents carmustine and doxorubicin. They did not find RT to be a significant risk factor, in contrast to the findings from the Late Effect Study Group, which reported an increased incidence of secondary neoplasms within prior radiation

fields. Additionally, there are case reports in the literature of other secondary malignancies after RMS treatment, including adenocarcinoma of the colon associated with radiation colitis 13 years after treatment for bladder RMS, bladder transitional cell carcinoma 8 years after cyclophosphamide for eRMS, and Hodgkin's disease after childhood RMS therapy.[169]

A recent long-term evaluation (23-year median follow-up) of the Italian Cooperative Study RMS 79 (1979–1987) identified 6/163 patients who developed second malignant tumors, with 2 of those patients dying from the secondary malignancy. RMS was a GU primary in three patients with secondary malignancies of rectal carcinoma, angiosarcoma of the heart, and breast carcinoma after primary vaginal, bladder, and bladder RMS, respectively. Factors predictive of late events (second malignancy, late recurrence, and treatment-related effects) included tumor site and IRS group.[128]

Residual Disease

Even with a good histological tumor response to chemotherapy, a residual mass may retain a large amount of stromal tissue and residual mass dimensions may not be indicative of cancer burden.[102] FDG-PET and CT scan are useful for staging RMS. Dharmarajan et al. evaluated serial PET/CT for correlation with local control by imaging at baseline, just prior to radiation, and after RT. The median SUV of the primary site in 58 patients with evaluable data at baseline was 7.0, and the authors identified that complete resolution of abnormal FDG-PET uptake is predictive of local relapse-free survival across all stages, clinical groups, sites, and histologic subtypes.[170] COG protocol ARST0531 for intermediate-risk RMS will be evaluating serial FDG-PET uptake values at weeks 1, 4, and 15 of treatment and correlating them with FFS.

Recurrence

Review of IRS I–III for group I patients found 86/439 patients relapsed with a median follow-up of 12.9 years for IRS I, 9.1 years for IRS II, and 4.6 years for IRS III. Relapses in these patients occurred within 1 year in 48% and 3 years in 93%, while two patients relapsed as late as 10 years after diagnosis.[135] In IRS III, the estimated 5-year cumulative incidence of local failure was 19%, the regional nodal recurrence was 2%, and the distant recurrence was 11%. Lymph node involvement at diagnosis was the single factor most predictive of increased total local failure risk (5-year cumulative incidence of 32%) compared with children with negative nodes or unknown node status (16%). The 5-year FFS and OS rates were 70% and 78%, respectively.[171]

IRS IV had a 3-year estimated cumulative incidence of local, regional, and distant failures of 10%, 4%, and 7%, respectively.[113] Retrospective analysis of survival for 605 patients after relapse in IRS III and IV revealed that 5-year survival depended significantly on histology (64% of botryoid, 26% of embryonal, and 5% of alveolar). eRMS stage and group at presentation affected the probability of relapse survival (52% stage 1/group I and 12% stage 4/group IV), but the type of relapse was only influential in initial stage 1/group I disease, with survival for local relapse 72% and distant relapse 30%. Relapse in aRMS was associated with better survival after an initial group I tumor compared with other initial presentations, despite location of recurrence (40% vs. 3%).[172]

From the IRS trials III, IV pilot, and IV, the estimated 10-year late-event (disease recurrence, second malignant neoplasm, or death from other causes) rate was estimated at 9%. The estimated cumulative incidences of the specific subtypes of failures at 5 and 10 years were 2.4% and 2.7% for recurrence, 1.9% and 2.4% for second malignant neoplasms, and 0.8% and 3.5% for death as a first event. Patients with both advanced disease (groups III and IV) and large primary tumors at diagnosis (>5 cm) were at the highest risk for late events. The probability of a late event in the high-risk group of patients was 19%.[173]

Bisogno et al. completed a long-term review of 163 patients enrolled in RMS; 79 were treated with cyclophosphamide, adriamycin, and vincristine (CAV) alternating with VAC. Patients with group II or greater tumors at presentation were eligible for RT. At a median follow-up of 23 years, 83 patients were alive with no evidence of disease. Forty patients had experienced a tumor recurrence at less than 3 years, with an additional eight recurrences at greater than 3 years, and two of those at greater than 5 years (8.6 and 8.7 years). Most of the late (>3 year) relapses (seven) were local, while one patient had a combined metastatic and local relapse, and only one of the seven relapsers who demonstrated a second complete treatment response was alive at 22 years after the event. The poor prognosis for late relapse (more than 3 years after initial diagnosis) is different than that for other shorter-term studies, which identified that prognosis improved with recurrence further removed from treatment completion. The additional late relapses increase the recurrence rate to 29% with long-term follow-up.[128]

Relapse in aRMS continues to have a dismal clinical outcome, prompting ongoing evaluation of novel therapies. Dagher et al. evaluated the effectiveness and toxicity of a peptide-pulsed vaccination targeting the break point region of fusion proteins administered concomitantly with continuous interleukin-2 (IL-2) infusion. Treatment did not alter the poor outcome for all 16 translocation-positive Ewing's sarcoma and aRMS patients, who continued to have progressive disease after immunization. All patients in this trial were significantly immunocompromised and had large, bulky tumors.[174]

Ninety-two patients with measureable disease and unfavorable prognosis at relapse (initial diagnosis of aRMS, stage 1/group I eRMS with distant recurrence, or initial diagnosis of eRMS stage 2 or greater/group II or greater) were enrolled in COG protocol ARST0121 (2002–2006) and randomized in a phase II window trial of irinotecan and vincristine to one of two treatment schedules (prolonged or short). The treatment resulted in a 32% overall response rate with no significant difference between the two regimens, and no improvement over historical reports.[119]

In a review of their results in the treatment of recurrent RMS, Hayes-Jordan et al. identified that 37% of patients who underwent surgical resection of recurrent disease were alive with no evidence of disease at a mean follow-up period of 4.9 years after surgery, and recommend that aggressive surgical resection of recurrent disease is warranted.[175]

Investigational

Differentiation therapy is a novel approach for cancer treatment in which the principle is to transform malignant cells into mature cells and decreases side effects of classical chemotherapy, such as drug resistance and cytotoxicity. This technique has shown in vitro effectiveness utilizing GR-891 and QF-3602 (5-fluorouracil acyclonucleoside derivatives) against RMS cell lines by inducing terminal myogenic differentiation with no cytotoxicity, increased adhesion capability, and no induction of MDR1, a gene that induces multidrug resistance.[176,177] Muscle-specific microRNAs miR-1 and miR-206 have been identified as potential promoters of muscle differentiation with low expression in RMS cells. Additionally, when RMS cells were exposed to a differentiation medium, miR-1 and miR-206 were not induced, and the reintroduction of miR-1 and miR-206 to RMS cells promoted myogenic differentiation.[178]

Antiangiogenesis therapy is a novel treatment approach of great research interest. The angiogenesis stimulators VEGF, basic fibroblast growth factor, and IL-8 all have been identified as products of eRMS, and effective antiangiogenic therapies may require multiple drugs to target several angiogenic factors.[179–181] Landuyt et al. induced tumor necrosis in subcutaneous RMS in rats using the angiogenesis inhibitor TNP-470, with both tumor volume and drug dose affecting treatment outcome and therapy found to be potentially useful to treat progressive tumor growth and large tumors.[182] Antibodies to VEGF have been shown to decrease growth of RMS cell lines; however, there is upregulation of host VEGF in response to hypoxia, indicating a need to completely block VEGF for maximum tumor inhibition.[183] VEGF and VEGFR2 (fetal liver kinase 1 [Flk-1]) play a role in tumor angiogenesis. Dc101, an anti-Flk-1 antibody in conjunction with doxorubicin, demonstrated greater antitumor activity in RMS cell lines xenografted in immunodeficient mice than doxorubicin alone.[184]

An alternative method of targeting tumor-specific vascularization is antivascular therapy, which would target inadequate and ill-structured tumor vasculature. Combretastatin A4 phosphate (CA4P) is an antivascular drug that, when administered systemically to rats, induced growth delay in solid RMS with a greater effectiveness with larger tumor volume.[185] Further investigations of CA4P have utilized this agent in a dual-targeting approach, with CA4P utilized to induce tumor necrosis and then treating with necrosis-avid I131-tagged hypericin, resulting in a radiotherapeutic response to kill residual cancer cells and inhibited tumor regrowth.[186]

PROGNOSTIC FACTORS

Presentation

Among patients with nonmetastatic RMS, multiple factors have been identified to be associated with poorer outcome, including age less than 1 year or greater than 10 years, alveolar histology, tumor size greater than 5 cm, tumor invasiveness, nodal disease, advanced clinical group, and unfavorable primary site.[101,144,187] Among those factors, age and unfavorable site, in addition to greater than or equal to two metastatic sites and bone or bone marrow involvement, have been noted to be associated with a particularly unfavorable outcome.[101,148]

Infants and Adolescents

Age has been demonstrated as a prognosticator in RMS. Specifically, ages less than 1 year and greater than 10 years have been identified to be associated with decreased EFS in metastatic[148] as well as localized[187] RMS.

In addition to poorer prognosis,[148,188] adolescents have also demonstrated less improvement in survival rates over recent years[189,190] than their younger counterparts. Joshi et al. analyzed pooled data from IRS III, IV pilot, and IV (1983–97, 2343 patients) and identified age as an independent risk factor for RMS treatment failure, with a significantly worse prognosis identified in patients less than 1 year or greater than 10 years than those age 1–10 years (5-year FFS of 53%, 51%, and 72%).[188] Bisogno et al. analyzed the results for patients enrolled in serial Associazione Italiana di Ematooncologia Pediatrica (AIEOP) Soft Tissue Sarcoma Committee protocols from 1988 to 2005 as a function of age (<15 years classified as children and 15–19 years classified as adolescents). Adolescents had a longer delay from onset of symptoms to diagnosis (median 8 vs. 4.6 weeks), more GU non-BP tumors (37% vs. 13%), an alveolar histology (47% vs. 33%), lymph node involvement (36% vs. 22%), and metastases at diagnosis (30% vs. 18%).[191] As they were enrolled in the same protocols, both age groups received similar treatments consisting of surgery, RT, and chemotherapy. However, with a median follow-up of 8.8 years, adolescents demonstrated a worse 5-year OS (57% vs. 69%, $p = 0.006$) and PFS (48% vs. 64%, $p = 0.02$) than children. When substratified for localized compared with metastatic disease, outcomes for those with localized disease were similar between the groups; however, the differences for metastatic disease were more pronounced, with adolescents demonstrating decreased OS (25% vs. 32%) and PFS (6% vs. 10%) compared with children. In addition to favorable tumor site and absence of lymphatic or metastatic disease, on multivariate analysis, an age of <15 years was an independent prognostic factor for OS and PFS.

Given the historically poorer outcomes for infants with RMS, Malempati et al. reviewed the outcomes for 76 infants (<1 year of age at diagnosis) with nonmetastatic RMS treated on IRS IV and IRS V protocols D9602 (low risk) and D9803 (intermediate risk) from 1991 to 2005 compared with 1767 children older than 1 year. Protocols recommended that infants receive initial 50% doses of chemotherapy with dose escalation if no significant toxicity resulted. RT was directed for all group II and III and aRMS patients. eRMS was the most common histology, followed by aRMS (21%), with other histologies, such as undifferentiated sarcoma and EM, comprising a minority of cases. More than half of infants had group III tumors. The local failure rate for infants was 30% compared with 13% for all patients, particularly remarkable for group III tumors, with a rate of 42% for infants compared with 17% for all group III patients. Among the infant group III tumor failures, one-third received RT and nearly two-thirds (11/18) received no local therapy. Despite worse

local control, group III RMS infants in whom RT was withheld experienced similar OS rates, suggesting that many are salvaged after local recurrence, and therapeutic options must be individualized, balancing long-term morbidity with increased rates of local failure and death.[192]

CONCLUSION

The advances in understanding the biologic and genetic features of RMS, as well as the development and scheduling of new drugs, have improved the survival of these children. However, several challenges still remain. The refinement of risk-directed therapy based on the understanding of newly recognized, biologic, and clinical features is ongoing to limit the most significant treatment toxicities to those children whose survival requires more toxic therapies. Utilization of newly developed hematopoietic growth factors will allow dose intensification, and may offer improvement in children with metastatic or recurrent disease. Genetic abnormalities, such as translocation (PAX3-FKHR and PAX7-FKHR) in some alveolar tumors, may provide molecular targets for future therapies, as well as better direct therapies based on risk stratification.

OTHER PELVIC TUMORS

While RMS is the most common pediatric bladder tumor, pediatric bladder masses may represent many other entities. A retrospective review of 98 bladder lesion specimens from 65 patients over a 21-year period was completed at the Children's Hospital of Philadelphia, confirming RMS to be the most common lesion (32 cases and 15 patients), followed by non-RMS/nonurothelial neoplasms (25 cases and 16 patients), which included most frequently fibroepithelial polyps (7 cases and 7 patients). Additional nonurothelial neoplasms included inflammatory myofibroblastic tumor, pseudosarcomatous myofibroblastic proliferation, paraganglionoma, neurofibroma, leiomyoma, leiomyosarcoma, and a necrotic spindle cell lesion. Eleven cases of urothelial neoplasm were diagnosed in 6 patients (2 patients with urothelial papilloma, 2 papillary neoplasms of low malignant potential [PUNLMPs], 1 inverted papilloma, and 1 low-grade papillary urothelial carcinoma), and the balance of cases were categorized as reactive or inflammatory (20 cases and 20 patients), malformation (2 cases and 1 patient), or normal (8 cases and 7 patients).[193] A review of the Surveillance, Epidemiology and End Results (SEER) database identified 140 cases of bladder tumors in children under 18 years of age, with the most common being PUNLMP, followed by eRMS. Of note, however, RMS (and eRMS in particular) predominated in children of <12 years of age, and urothelial tumors were more common than RMS in the 13- to 18-year age group.[194]

Urothelial Carcinoma

Urothelial carcinoma in the first two decades of life is rare, has a male predominance, and is typically a low-grade tumor that seldom recurs or progresses.[195–202] Some of these tumors occur secondary to cyclophosphamide therapy.[136,203–206] In more than 90%, the lesions are solitary. Pathologically, 80% of these tumors are grade I or papilloma, 20% are grade I or II tumors, and only 3% are invasive through the lamina propria. The recurrence rate is low (2%–5%).

Presenting symptoms include gross hematuria (80%), irritative voiding symptoms or recurrent urinary tract infections (15%), and microscopic hematuria (8%).[207] In a recent series, Fine et al. reviewed 23 patients with urothelial neoplasms presenting under 20 years of age. None had a history of cancer, family history of bladder cancer, exposure to radiation or chemotherapy, or parents with occupational exposure to bladder carcinogens. Twelve tumors were urothelial papillomas or PUNLMPs, while 11 were noninvasive urothelial carcinomas (8 low grade and 3 high grade). Among the 3/21 patients who recurred, initial pathology was papilloma, noninvasive low-grade urothelial carcinoma and PUNLMP with recurrences demonstrating benign papilloma and PUNLMP.[208]

Wild et al. analyzed urothelial tumors from 14 patients ranging in age from 4 to 19 years for FGFR3 and TP53 mutations, using comparative genomic hybridization, UroVysion fluorescent in situ hybridization (FISH) analysis, PCR for human papilloma virus, and LOH for chromosomes 9p, 9q, and 17p. Genetic alterations that are frequent in adult urothelial carcinomas were rare in this pediatric cohort, and the author concluded that pediatric urothelial neoplasms appear to be biologically distinct from adult counterparts, lacking in most cases genetic instability.[209]

Recurrent urothelial carcinoma has been reported in association with Costello syndrome, a rare autosomal dominant condition that has also been associated with eRMS. Hematuria in a patient with Costello syndrome warrants evaluation for a bladder tumor.[210,211]

Previously attributed to a history of radiation or cyclophosphamide exposure, patients and families with hereditary retinoblastoma demonstrate an increased incidence of urothelial carcinoma. The recognition that this predilection occurs even in a patient who has not been exposed to high-dose radiation or cyclophosphamide resulted in the conclusion that urothelial carcinoma appears to be part of the hereditary retinoblastoma spectrum.[212]

The initial diagnosis of urothelial carcinoma can be made by ultrasound, which in some series was found to be 100% sensitive. Intravenous pyelogram and CT scans may not be able to detect small tumors. Cytologic evaluation is of limited value, as most of these tumors are low grade.[196,207] Cystoscopy allows definitive diagnosis, staging, and treatment of these tumors; however, its role in surveillance of the pediatric patient remains ill defined, as it requires general anesthesia in the setting of a low risk of recurrence.

Bladder Augmentation–Related Urothelial Carcinoma

Patients with a history of bladder augmentation appear to have a predisposition to epithelial bladder tumors.[195] Soergel et al. reported three cases of urothelial carcinoma in patients at 29, 37, and 44 years of age who had undergone augmentation cystoplasty for neuropathic bladder an average of 19 years prior to presentation and did not have

any other known risk factor for development of urothelial carcinoma. Based on an assumption of a 10-year lag time for tumor development, in their series of 483 bladder augmentations, the estimated cancer risk was 1.2%. They recommend endoscopic surveillance of bladder augmentation in patients starting at 10 years after initial surgery.[213] Hamid et al. prospectively evaluated the efficacy of routine surveillance cystoscopy for patients with a history of bladder augmentation for benign disease. The protocol included annual cystoscopy for augmentation patients starting at 10 years after augmentation for 92 consecutive patients, 53 of whom consented to also undergo bladder biopsies at the time of cystoscopy. With a median follow-up of 15 years (10–33), no cancer was identified. During the period of the study, one patient who had a previously normal surveillance cystoscopy presented with intermittent hematuria and recurrent urinary tract infection and on evaluation was diagnosed with a malignancy. They conclude that routine surveillance cystoscopy in the first 15 years is not necessary, as it did not detect any cancers in their series, and did not result in early diagnosis of the one patient who did develop a malignancy. They do recommend that development of hematuria, suprapubic pain, or recurrent unexplained urinary tract infection in a patient with a history of a bladder augmentation warrants a full evaluation to assess for bladder tumor.[214]

Appanna et al. analyzed biopsy specimens from augmentation cystoplasties with comparative genomic hybridizaton and identified that genetic abnormalities were much greater in the vicinity of the enterovesical anastamosis than in areas distant to the suture line.[215] Ivil et al. identified significant chromosomal numerical abnormalities on FISH at biopsy sites from the enterovesical anastomosis of ileocystoplasty patients that did not exist in the native bladder biopsies of these patients.[216] They also identified p53 mutations at the enterovesical anastomosis in 7/38 patients, and none in the native bladder of those patients.[217] These studies all support that the enterovesical anastosmosis is a site of significant genetic instability in the presence of a bladder augmentation. This instability may result in tumor formation.

Attempting to identify a potential etiology for this evidence of genetic instability, Dixon et al. compared the effects of hyperosmolar environments on intestinal epithelial cells with those of bladder transitional epithelial cells and identified that the hyperosmolar environment inhibited activation of the DNA damage signaling and repair pathways in the intestinal epithelium, whereas these pathways were preserved in bladder transitional cells. The authors theorize that enteric epithelial exposure to urine in the case of augmentation cystoplasty may result in failure of adaptive pathways, thereby placing these tissues at an increased risk for malignant degeneration.[218]

Sung et al. evaluated the histological and immunohistochemical characteristics of four patients who presented at a mean age of 37 years with high-grade invasive urothelial carcinoma at a mean time from bladder augmentation of 19 years, and who died of disease at a mean of 5 months from diagnosis. Histologically, all tumors demonstrated brisk mitosis and tumor necrosis and demonstrated characteristic chromosomal abnormalities on UroVysion FISH analysis, identifying this as a potential surveillance strategy in patients who undergo augmentation cystoplasty.[219]

While a definitive surveillance protocol has yet to be defined, patients with a history of enterocystoplasty appear to be at increased risk for aggressive secondary tumors of the augmented bladder.

Nephrogenic Adenoma of the Bladder

Nephrogenic adenoma is a rare, benign lesion of the bladder, occurring as an epithelial response to infection, inflammation, or trauma. It presents as a papillary lesion resembling a low-grade, low-stage urothelial carcinoma.[220–223] Most children with nephrogenic adenoma will present with symptoms of gross hematuria, dysuria, and bladder instability. In a case series and literature review encompassing 21 patients, the lesion was more common in girls than boys (5:1); all patients had a history of prior bladder surgery, and 80% recurred.[220] Final diagnosis is established after cystoscopy and histopathologic review of a tumor biopsy specimen. Therapy consists of transurethral resection, long-term antibiotic therapy, and periodic cystoscopy.

Leiomyosarcoma

Leiomyosarcoma is rare in the pediatric age group and accounts for less than 2% of all soft tissue sarcomas. Diagnostic features and biological behavior in children appear similar to those in adults. The most important features in assessing malignant potential are tumor size and mitotic counts. Local excision usually provides adequate therapy.[224–227]

Urachal Adenocarcinoma

Urachal adenocarcinoma is a very rare tumor accounting for only 0.17%–0.34% of all bladder neoplasms. It usually occurs in adults, but there are several reported cases in children. This mucin-producing or colloid adenocarcinoma arises from the juxtavesical segment of the urachus and invades the bladder. The presenting symptoms may include hematuria, bladder irritative symptoms, or balls of mucous in the urine. The primary treatment is surgical resection. As its location predisposes to extensive local spread before detection and diagnosis, the prognosis is poor.[228,229]

Carcinoma of the Exstrophied Bladder

Bladder carcinoma with the history of bladder exstrophy occurs more frequently in adults than in children. It has been reported in both reconstructed and nonreconstructed bladders, as well as in patients who have undergone early cystectomy. Histologically, bladder carcinoma with a history of bladder exstrophy is most frequently reported to be adenocarcinoma; however, urothelial, squamous cell, and mixed carcinomas have also been reported.[230–242] In adenocarcinoma, the epithelial lining of the bladder is replaced with colonic epithelium with colon-specific mucin histochemistry and contents of carcinoembryonic antigen.

Mesonephric Adenocarcinoma of the Female Genital Tract

This is a rare and highly malignant tumor that can occur at any age. Approximately 30% of such tumors occur in children. Evidence that these tumors originate from the mesonephric (Wolffian) rests includes their tubular structure and their occurrence along the tract of the mesonephric duct or its remnants (vagina, cervix, uterus, and salpinx). The clinical, gross pathologic, and radiographic presentation of vaginal mesonephric carcinomas may be indistinguishable from that of eRMS. The presenting symptoms are vaginal bleeding or a vaginal mass. Radiographic features are similar to those of RMS and include grapelike clusters of tumor nodules within the vagina. Treatment includes radical excision, RT, or both.[243–246]

Clear Cell Adenocarcinoma of the Vagina or Cervix

Maternal diethylstilbestrol (DES) prior to 18 weeks' gestation has been implicated in the etiology of clear cell adenocarcinoma of the vagina or cervix. The age of the DES-exposed patients has varied from 7 to 34 years, with the highest frequency from 14 to 22 years. The risk among the exposed is in the order of 1 in 1000.[247–249] Similar to mesonephric adenocarcinoma, the presenting symptom is that of vaginal bleeding or mass. The rarity of this tumor among exposed women suggests that DES is not a complete carcinogen, but that some other factors are also involved in the pathogenesis of clear cell adenocarcinoma of the vagina and cervix.[249–256]

Cavernous Hemangiomas of the Bladder

Bladder cavernous hemangioma is a rare benign mesenchymal tumor that may present with gross hematuria and abdominal pain. In about 30% of cases, it is associated with angiomatous lesions in other parts of the body. The diagnosis may be suspected on ultrasound examination, but it is generally made at cystoscopy.[257–260] Blood pool scintigraphy using (99m)technetium–human serum albumin combined with DTPA usually reveals an area of increased activity in the bladder.[261] Biopsy and transurethral resection must be avoided because of the risk of hemorrhage. Laser treatment of hemangiomas has been reported and should be the initial management.[261] Should laser coagulation fail, partial cystectomy appears to be the most effective method of treatment.[262]

CHAPTER 62

Exstrophy and Epispadias

Linda A. Baker and Richard W. Grady

INTRODUCTION

The exstrophic diseases, referred to collectively as the exstrophy–epispadias complex,[1] are considered a spectrum of embryological anomalies related by certain principle anatomic features. This complex includes

- *Epispadias*—The urethra is a partial or complete open plate on the dorsal surface of the phallus.
- *Classic bladder exstrophy (CBE)*—The bladder is an open plate on the low abdominal wall, and the urethra is epispadic.
- *Cloacal exstrophy (CE)*—The bladder and the ileocecal junction of the bowel are an open plate on the low abdominal wall associated with other malformations.
- *Exstrophy variants*—Partial manifestations are seen of the above malformations.

Formal historical descriptions of exstrophy date back to at least 1597, with Sherk von Grafenberg's description of this congenital defect; possible depictions of exstrophy also exist on Assyrian tablets from 2000 BC. Chaussier first coined the term *exstrophie* to describe this defect in 1780, following detailed descriptions of it by Mowat in 1748. CBE is typically a nonlethal defect at birth; further, its natural history is known and has been well described in untreated adults. Since the nineteenth century, various efforts to manage exstrophy have been described. Because exstrophic conditions are rare, these approaches were empiric and often unsuccessful. Until the twentieth century, no effective surgical remedy was available to consistently ameliorate the morbidity associated with CBE.

As we enter a second century of surgical care of the child affected by CBE, epispadias, or CE, a review of this history shows that great strides in management have been made. These anomalies are some of the most complex that pediatric urologists manage at birth, childhood, and adulthood. As well, caregivers of these patients with lifelong health issues continue to experience significant stress.[2] Clearly, significant challenges remain at every step, including the formidable process of transitioning these complex patients to adult urologists with expertise in genitourinary congenitalism.[3]

ANATOMIC PATHOLOGY

Classic Bladder Exstrophy

Brock and O'Neill describe exstrophy as "if one blade of a pair of scissors were passed through the urethra of a normal person; the other blade were used to cut through the skin, abdominal wall, anterior wall of the bladder and urethra, and the symphysis pubis; and the cut edges were then folded laterally as if the pages of a book were being opened"[4] (Figure 62.1). CBE and epispadias are not typically associated with anomalies in other organ systems away from the vicinity of the exstrophy, and these children are typically intellectually normal. However, the genitourinary tract and adjacent bony and soft tissue body parts are altered, suggesting either an epithelial or mesodermal defect in the pathogenesis.

Bladder

Anatomic features of bladder exstrophy include the anterior abdominal wall defect containing the exposed urothelium of the small nonspherical open bladder in the mons and infraumbilical regions. The umbilical stalk is at the upper edge of the bladder plate and is characteristically low in position relative to the iliac crests. The bladder plate can be large and evert with Valsalva—this would indicate a favorable bladder plate for reconstruction. The small rigid bladder plates are worrisome even before surgery. At birth, the exstrophic urothelium can be normal in appearance. However, ectopic bowel mucosa or polypoid lesions consistent with cystitis cystica and/or glandularis may be present. If left untreated and without meticulous protection after birth, the exposed urothelium will undergo squamous metaplasia in response to acute and chronic inflammation. Other inflammatory changes, such as cystitis cystica and/or glandularis, will also be seen.[5] When left chronically exposed to the environment, the areas of squamous metaplasia often undergo malignant degeneration to adenocarcinoma or squamous cell carcinoma, which can be a cause of early death.[6–12] The exstrophy detrusor has similar muscarinic receptor density and binding affinity as controls,[13] fewer myelinated nerve fibers than controls,[14] and overexpression of inflammatory genes and underexpression of developmental genes, suggesting detrusor "immaturity" on expression microarray

analysis.[15] Alterations in specific signaling pathways have been noted, which may contribute to the etiology (see the "Theories of Pathogenesis of Exstrophy" section).

Kidneys and Upper Urinary Tract

At birth, renal anomalies can occur with bladder exstrophy but do not occur at increased frequency and are not characteristic. Reported renal abnormalities include cystic dysplasia, ureteropelvic junction obstruction, pelvic kidney, megaureter, renal hypoplasia, and horseshoe kidney.[16] In contrast, the ureterovesical junction is abnormal in essentially all with CBE; vesicoureteral reflux is universally present after exstrophy closure due to the minimal ureteral intramural tunnel and inferior approach of the ureters into the bladder trigone from the abnormally deep pouch of Douglas.

Genitalia

Males

In CBE newborns, the misshapen penis sits at the immediate base of the extrophic bladder plate with an open urethral plate extending from the bladder plate to the glans on the dorsal penile side. The penis is deflected dorsally and may have true intrinsic dorsal chordee or urethral tethering (Figure 62.2). The foreskin is dorsally absent but sizable and hooded ventrolaterally. The glans is bivalved, being flattened and splayed by the dorsally positioned urethral plate. The penis is broad and variably foreshortened because of the varying degree of diastasis associated with exstrophy. The corpora cavernosa are proximally splayed laterally due to the pubic diastasis since each crus remains normally attached to the distracted ischiopubic rami bones. Further, magnetic resonance imaging (MRI) studies of the penile length of adult male exstrophy and epispadias patients reveal that the total corporal length is significantly shorter than in a control population. This corporal shortening apparently results from a foreshortened anterior segment (distal to the pelvic attachment); the posterior corporal segment is unaffected in exstrophy patients (Figure 62.3).[17] It has been anecdotally noted that the length of the penis and the size of the exstrophic bladder plate are inversely related.

The short urethral plate and dorsal penile curvature cause the glans penis to lie in close approximation to the prostatic veru montanum. The ejaculatory ducts empty at the veru exposed on the urethral plate. The vas and ejaculatory ducts are probably unaffected in classic exstrophy unless iatrogenically damaged.[18] Innervation to the penis is also preserved. The cavernosal nerves are located on the lateral aspects of the corporal bodies. In the normal situation, these nerves can be found on the dorsal aspect of the penis after they traverse the posterolateral aspects of the prostate and the membranous urethra.[19] At birth, the volumetrically normal prostate does not encircle the urethra but is posterior to it and is wide and flat in exstrophy.[20,21] There is an increased distance between the base of the penile shaft and the scrotum, covered by smooth skin. The scrotum is basically well formed but characteristically is broad, with its rugations oriented at a ~45° angle to the midline raphe instead of the usual horizontal lie. The testes may be retractile, undescended, or descended, and inguinal hernias are present in up to 86%, necessitating repair at birth.[22] Because of the underlying bladder neck anomalies and lack of muscular support of the posterior urethra, exstrophic males may have impaired fertility. A particular problem is retrograde ejaculation if the

bladder neck does not close completely following bladder reconstruction.[23–25]

Females

In CBE cases, the mons pubis is absent, with the centrally depressed bladder plate leading to the epispadic urethral meatus (Figure 62.4) that separates the bifid hemiclitori and split clitoral hood. The anteriorly splayed labia majora are laterally displaced. The urethral meatus is not vertically slit-like but is often horizontal, striped, and gaping. The vagina and introitus are also displaced anteriorly from their usual position. The vaginal opening may be congenitally or postsurgically stenotic in these patients, but postpubertally, the vagina tends to be J shaped, hooking ventrally with a long perineal body. Internal female genital structures (uterus, cervix, fallopian tubes, and ovaries) are typically normal in girls with CBE. Uterine or vaginal wall prolapse due to deficient pelvic floor support has been observed in up to 38% of older exstrophy patients and poses particular problems with pregnancy.[26–28] Early primary bladder reconstruction with pelvic closure may decrease this risk, but this is debated.[29] A uterine suspension procedures such as sacrocolpopexy can be employed in these situations as well with pelvic osteotomy.[30]

FIGURE 62.4 Female epispadias in a 5-year-old. Chronic perineal skin changes are due to lifelong frank urinary incontinence. Note the depressed mons pubis, bifid clitoris, outwardly rotated labia minora, and open gaping urethral meatus just above the vaginal introitus.

Anorectal and Intestinal Abnormalities

The anus is often located anteriorly in CBE. Surgical procedures involving these patients should preserve the anal sphincter mechanism. However, some exstrophic patients will have insufficient anal continence due to the underlying abnormalities of the pelvic floor support structures, including the levator ani and puborectalis muscles. Anal sphincter weakness not only impacts fecal continence but also limits the use of ureterosigmoidostomy and its

FIGURE 62.5 Plain abdominal radiograph demonstrating pubic diastasis in a patient with bladder exstrophy.

variants, i.e., rectal bladder, ileocecal ureterosigmoidostomy, etc. In untreated patients, rectal prolapse also can occur due to insufficient pelvic floor support. This is usually definitively treated with formal exstrophy repair that corrects the lack of anterior pelvic support. In the interim, most rectal prolapse is intermittent and reducible.[31,32]

Skeletal Abnormalities

Diastasis of the pubic symphysis occurs as part of the exstrophy complex (Figure 62.5). This results from outward rotation of the innominate bones along both sacroiliac joints. Outward rotation of the pubic rami at the iliac and ischial junctions is seen as well. Sponseller et al. have quanitfied the differences in the pelvic anatomy of patients with exstrophy, noting (1) a 12° external rotation of the innominate bones on the sagittal axis, (2) retroversion of the acetabula, (3) an increased distance between the left and right triradiate cartilage, (4) 18° external rotation and shortening (by 30%) of the anterior segment of the iliac bone, and (5) external rotation of the posterior segment of the ileum (Figure 62.6).[33] These pelvic bone abnormalities contribute to splaying of the penis noted with exstrophy and epispadias and cause the penis to appear foreshortened. Sixteen percent will have developmental dysplasia of the hip.[34] Gait abnormalities in these children arise as a consequence of these bone abnormalities. Many of these children learn to ambulate with a wide waddling gait. This gait abnormality resolves as the children grow, most without long-term hip sequelae.[35] Orthopedic procedures to reapproximate the pubis symphysis do not appear to offer any long-term benefits to these patients from an orthopedic viewpoint. Osteotomies to reapproximate the pubis symphysis do, however, increase the chance of successful primary bladder closure in selected patients and may have a significant role in securing continence and support of the pelvic diaphragm and female internal genitalia.[30,36,37]

Fascial Abnormalities

Fascial abnormalities include the rectus fascial deficit associated with the exposed bladder. Inferiorly, the pelvic floor support structures are also compromised, which in females contributes to the uterine prolapse. At the inferior portion of the fascial defect, these patients possess an anteriorly located intersymphyseal ligament or band representing the attenuated urogenital diaphragm. The rectus muscles diverge laterally with the widened pubis symphysis. This abdominal defect is most severe in CE. Umbilical hernias also uniformly occur with exstrophy and are repaired at the time of the primary repair. An omphalocele can also be found in association with CBE, although this is rare.[38]

As previously discussed, inguinal hernias are commonly associated with exstrophy in both male and female patients (Figure 62.7).[39,40] The majority are indirect hernias. They likely occur as a consequence of the enlarged internal and external inguinal rings noted in these patients in conjunction with compromised fascial support and lack

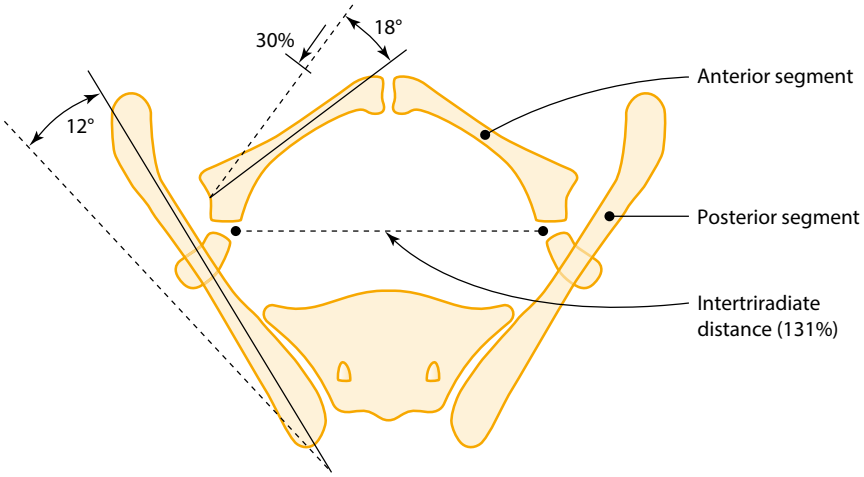

FIGURE 62.6 The anatomy of the normal bony pelvis is seen in transverse view. Superimposed are the deviations observed in the pelvis of classic bladder exstrophy patients. In the posterior segment, each half is externally rotated 12°. The acetabulae are retroverted, yielding an increased intertriradiate distance. In the anterior segment, each half is externally rotated 18° and is on average 30% shorter.[18]

FIGURE 62.7 Evidence of an inguinal hernia in this newborn male with bladder exstrophy, as demonstrated by the inguinal bulge.

of obliquity of the inguinal canal.[41,42] As several series have found inguinal hernias in up to 85% of patients, with cases of incarceration during the exstrophy closure recovery, it is recommended that these hernias be repaired at the time of primary bladder closure.[22,43] Reinforcement of the transversalis and internal oblique fascia during hernia repair decreases the incidence of later direct inguinal hernias.

Neurologic System

Spinal cord abnormalities are the exception rather than the rule in CBE. Occult spina bifida and even myelomeningocele can be seen in combination with bladder exstrophy, but this is a rare occurrence.[44]

Cloacal Exstrophy

CE, also known as the OEIS (omphalocele, exstrophy of the bladder, imperforate anus, and spinal defects) complex is a multisystem malformation. In contrast to CBE, patients with CE uniformly have associated anomalies outside of the genitourinary system and adjacent soft tissues.[45,46] These anomalies can affect the upper urinary tract, gastrointestinal tract, skeletal system, and neurologic system.

Bladder and Hindgut Plate

The bladder plate associated with CE is divided in half by the hindgut plate; the hindgut plate represents the deformation in the development of the colon that occurs with CE. Ileum enters and intussuscepts into the middle of the hindgut, creating the "trunk of an elephant's face" appearance, with appendiceal appendages located laterally to give the impression of "tusks on the face of the elephant" (Figure 62.8).[47]

With CE, the bladder neck (internal urethral sphincter) and external urethral sphincter are not fully developed due to the failed development of the bladder and urethral remnant located on the anterior and dorsal surfaces of the

FIGURE 62.8 Newborn male with cloacal exstrophy. The omphalocele is small. The terminal ileum is intussusepted and is the long 'trunk' to the patient's left. Each hemipenis is small, the left being smaller than the right.

body wall and penis, respectively. However, because the innervation to these structures is usually intact, anatomic closure theoretically offers the possibility of achieving urinary continence.[13,26,48] This may depend, however, on the status of the spinal cord. The urethral plate is characteristically short as well.

Kidneys and Upper Urinary Tract

Renal anomalies are much more common with CE. They include anomalies of location, such as pelvic kidneys or crossed fused ectopia. Horseshoe kidneys, renal agenesis, and ureteropelvic junction obstruction may occur as well.[26]

Genitalia

At birth, some may be confused as to the sex of the infant, as the genitalia are quite distorted. The exstrophic tissue may bulge downward over the penis or clitoris, but these structures can be seen when this is lifted up. Even though laterally displaced, typically the scrotum is rugated and baggier than the smooth tight labia majora.

In CE, the penis is often completely separated into two hemiphalluses due to the wide pubic diastasis, and they may not be equal in size (Figure 62.8). This can make subsequent reconstructive efforts technically more challenging if a male phenotype is preserved. Cryptorchidism is the rule with CE. The scrotum may be fused or bifid with significant ectopy.

For girls, in addition to the genital pathology described above with bladder exstrophy, uterus didelphys and other fusion anomalies of the Müllerian duct structures are seen in up to two-thirds of CE patients. Vaginal agenesis occurs in a third of girls with CE. The internal and external female genital anatomy should be defined at the time of early surgeries, as incomplete delineation can lead to postpubertal hematometrocolpos, which typically necessitates yet another surgical intervention.

Gastrointestinal Abnormalities

Associated intestinal abnormalities specific to CE include imperforate anus, foreshortening of the midgut, bowel duplication, malrotation, intestinal atresia, and Meckel's diverticulum.[26] These are in addition to the exstrophy of hindgut, ileal intussusception, and exposed appendices that are considered part of the primary pathology of CE. In cases with large omphalocele, the liver can herniate.

Skeletal Abnormalities

In addition to the features seen with bladder exstrophy, up to 50% of patients with CE can have other skeletal abnormalities. Anomalies include vertebral anomalies, congenital hip dislocation, talipes equinovarus, and a variety of limb deficiencies.[33]

Fascial Abnormalities

The fascial anomalies associated with CE include those described above for bladder exstrophy. Further, omphaloceles often occur in association with CE.[49,50] These can be closed during the initial bladder closure if they are small. If the omphalocele is large, it may require closure as a primary procedure, with the reapproximated bladder halves acting as a silo to decompress intra-abdominal pressure. Alternatively, omphaloceles may be treated with antiseptic paint to promote skin overgrowth. Our preference is to proceed with a staged surgical omphalocele correction, with primary reconstruction of the bladder at a later date if the infant is a surgical candidate. In our experience, intra-abdominal pressure following omphalocele closure determines whether we may proceed with primary bladder closure at the same time as the omphalocele repair or whether these operations must be staged. Aggressive one-stage closure of a CE can lead to organ ischemia from increased intra-abdominal pressure (abdominal compartment syndrome). Rupture of an omphalocele clearly requires immediate attention in these patients and would take precedence over other considerations. Fortunately, this rarely occurs.

Neurologic Abnormalities

Neurologic involvement of the lower spinal cord in the CE population is reported to occur in 50%–100% of patients.[50–52] Most patients have lumbar or sacral cord involvement, but thoracic-level myelodysplasia has been reported.[50] Management of CE in these situations must be coordinated with neurosurgical plans to close the neural tube defect. In addition, one-third of CE patients have an intracranial anomaly, such as hydrocephalus, Chiari, or another anomaly, warranting screening, especially in CE patients with a spinal dysraphism.[53]

Epispadias

Epispadias can be considered the least severe form of exstrophy. It does not involve the body of the bladder. However, in males, the urethra is represented as a plate of tissue located dorsally on the penis (Figure 62.9). The genital anomalies described above are noted with epispadias.

FIGURE 62.9 Penopubic epispadias in a 3-month-old male. Skin demarcation is due to chronic urine contact dermatitis in this patient.

These include lateral splaying of the penis and dorsal chordee in boys. In affected girls, the clitoris is bifid, the perineal body is broadened, and the vagina is anterior to its orthotopic or typical position (Figure 62.4). Widening of the pubic diastasis occurs as well. Importantly, the bladder neck is also frequently involved—it is often wide and incompetent. This directly affects the continence mechanism, bladder cycling and growth, and the ability to achieve urinary continence. In boys with epispadias, primary continence is possible if the epispadias is located distally and the bladder neck is normally formed. In girls, however, continence is invariably affected to some degree because of the associated urethral and bladder neck ectasia. Because the features of epispadias are shared with bladder exstrophy, clinicians consider these anomalies as part of a spectrum of the exstrophy–epispadias complex.

Exstrophy Variants

In the exstrophy–epispadias complex, variations in bladder plate size and compliance are commonplace, but no system to quantify these differences is currently in use. Phallic size and degree of phallic separation also vary from patient to patient. However, despite these variations the underlying features of this disease are consistent for classic forms of the exstrophy complex.

In contrast, patients with exstrophy variants have some, but not all, of the typical features of bladder exstrophy or CE, as well as other features not typically associated with it. These variants include covered exstrophy and superior vesical fissure. Patients with exstrophy variants may have anatomically normal genitalia despite their bladder and colon anomalies.

Bladder exstrophy variants include patients whose anatomic features resemble classic exstrophy in regard to the fascial and/or symphyseal defects but who do not have any significant anomaly associated with the urinary tract. These patients are considered to have pseudoexstrophy.[54,55] If these patients also have an isolated ectopic bowel segment in association with these findings, they are referred to as covered exstrophy variants.[56] Patients with superior

vesical fissure also have the muscular and skeletal defects associated with bladder exstrophy, but only the upper portion of the bladder is affected, so that the urethra is intact and the genitalia are less significantly affected than with classic exstrophy.[57] Duplicate exstrophy may occur. Patients with this variation have a superior vesical fissure associated with normal fascial abdominal wall development, so that components of the bladder remain ectopic, such as urothelial elements. These patients can have genital anomalies consistent with classic exstrophy as well, but this association is variable.[58–61]

CE variants also exist. These patients possess some of the features of cloacal exstophy, such as an exposed hindgut plate and bladder plate, but may not have the typical genital involvement.[62–64] Hypospadias has been described in association with CE, as well as normal genitalia, in both male and female patients. Some have been reported with intact anal innervation, permitting a Pena procedure.[65] These patients may also have other atypical features, such as accessory appendages or limb malformation. These findings, in association with prenatal ultrasound examinations that document twin gestations early in some pregnancies, suggest that aborted conjoined twinning may be the underlying cause of CE variation in some cases (Figure 62.10).[66–68]

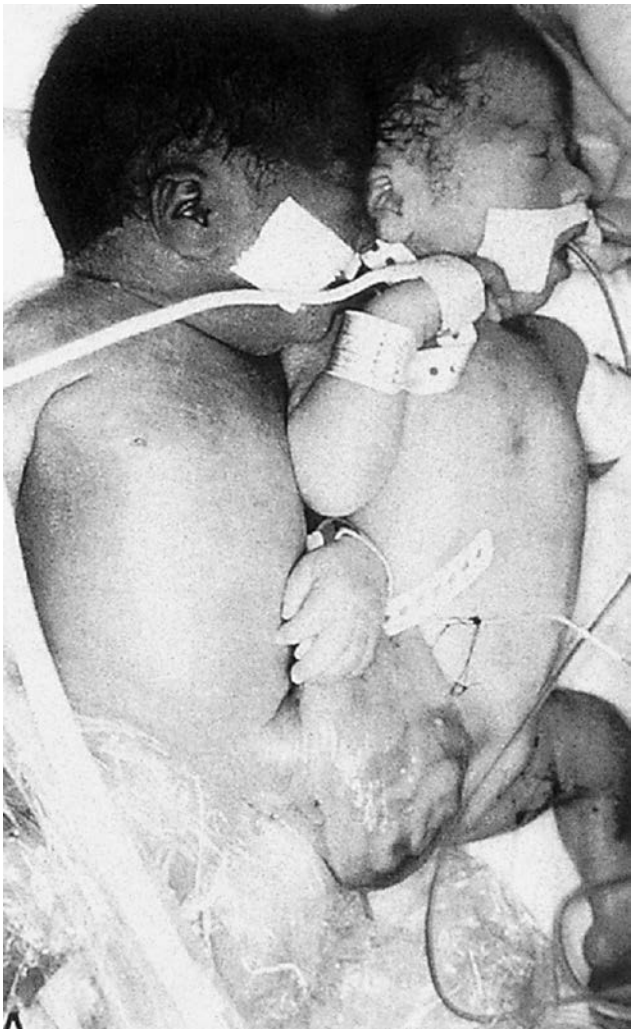

FIGURE 62.10 Conjoined twins connected by a membranous omphalocele sac containing a shared segment of distal ileum, cecum, and colon draining to a common exstrophic cloaca; an example of an exstrophy variant.

Embryology

Normal Bladder Development

Normal bladder development results in an organ that functions to store and evacuate urine. This process, known as bladder cycling, requires the bladder to store urine at low intravesical pressures during filling while maintaining continence at the level of the bladder neck. Subsequent evacuation of urine from the bladder requires a coordinated contraction of the detrusor in conjunction with relaxation of the bladder outlet. Both normal storage and emptying require intact innervation of the bladder, sphincter mechanisms, and urethra.[69]

During embryogenesis, the lateral body wall folds close the thoracic, abdominal, and pelvic portions of the ventral body wall during the fourth week of development.[70] Also, components of the urinary system, such as the ureteral buds, first appear during the fourth week of gestation. At this time, the bladder has not completely formed from the anterior urogenital sinus. Before the bladder is completely formed, mesenchyme grows inward toward the midline between the bilaminar (ectoderm and endoderm) layers of the cloacal membrane. This mesenchyme later differentiates into the abdominal wall musculature and fascia. Subsequent to this, the urorectal septum separates the bladder from the rectum by growing downward between them. Abnormalities in the appearance, timing, and function of the cloacal membrane are implicated in the creation of exstrophy. In this fashion, the urinary bladder arises during the eighth week of fetal development when the ventral portion of the urogenital sinus begins to expand.[69] With bladder filling, the mesenchymal tissue surrounding this structure differentiates into smooth muscle, which will eventually become the detrusor muscle. Ingrowth of neuronal tissue into this smooth muscle to form motor units is critical to the development of a functional bladder.[71] Embryogenesis of the pelvic floor is also important in normal fetal bladder development and function; the pelvic floor acts as a dynamic support for the bladder, which aids in both continence and volitional voiding.[72,73]

Theories of Pathogenesis of Exstrophy

CBE and CE are two of several congenital ventral body wall defects that include ectopia cordis, gastroschisis, and omphalocele.[74] Exstrophy can be considered a developmental field defect,[75] since the infraumbilical abdominal wall and genitalia react as a single unit to its perturbation in development by either a genetic mutation, environmental injury, or random factor. Improvements in our understanding of embryogenesis have led to some insight into the cause of exstrophy. In the premodern era, trauma to the unborn child or ulceration of the abdominal wall and bladder between the second and third months of life was felt to be the underlying cause of exstrophy. Through the years, many theories of embryonic morphological derangements

TABLE 62.1 Theories of embryonic morphological derangements to explain exstrophy malformation

Year	Authors	Morphological derangement
1952	Patten and Barry	Caudal positioning of primordia of the genital tubercle relative to the cloacal membrane blocks mesodermal migration
1962	Marshall	Persistence of cloacal membrane creates wedge effect, blocking mesodermal ingrowth
1964	Muecke	Abnormally large cloacal membrane blocks medial mesodermal ingrowth
1985	Thomalla et al.	Ventral hernia of the lower abdominal wall induces exstrophy
1988	Mildenberger et al.	Caudal insertion of the body stalk obstructs medial mesodermal ingrowth
1977	Beaudoin et al.	Incomplete rotation of the pelvic ring primordia
2005	Manner and Kluth	Aneurysmal dorsal aortic swellings distends the pelvis and infraumbilical abdominal wall
2005	Stephens and Hutson	Embryonic tail compresses the second sacral mesodermal stream that segments the cloacal–allantoic connection and the phallus
2008	Kulkarmi and Choudari	Cephalad origin of the genital tubercle acts as a wedge to obstruct medial mesodermal ingrowth
2011	Stec	Cellular or mechanical factors disturb mesodermal ingrowth, yielding an abnormally formed cloacal membrane that prematurely ruptures
2015	Satish Kumar et al.	Persistent pubic diastasis causes levator maldevelopment as a hammock that pushes the bladder outward and exstrophic, while the lengthening extruded midgut loop returns to the abdomen through the umbilical ring, raising intra-abdominal pressure

(Table 62.1) have been proposed that implicate an error in embryogenesis rather than an event of arrested development since the developing human embryo does not normally pass through a stage that corresponds to exstrophy.[76] The most widely supported combined theory is that abnormal cellular or mechanical factors act as a wedge, disturbing the medial mesodermal ingrowth of the body wall folds in the infraumbilical anterior abdominal wall around the cloacal membrane, yielding an abnormally formed cloacal membrane that prematurely ruptures.[73,76–80]

The bilaminar cloacal membrane, composed of endoderm and ectoderm, serves to separate the coelomic cavity from the amniotic space in early development. The cloacal membrane can first be identified during development at 2–3 weeks of gestation. By the fourth week of development, it forms the ventral wall of the urogenital sinus with the unfused primordia of the genital tubercles sitting cephalad and lateral to it. With further development, the genital primordia grow and fuse in the midline and mesoderm grows toward the midline, creating an infraumbilical abdominal wall. Simultaneous to this process, the urorectal septum develops medially and caudally to separate the cloaca into the urogenital sinus and rectum.[69] Some hypothesize that the cloacal membrane must rupture prior to 8 weeks' gestation to cause exstrophy, with earlier rupture giving CE and later rupture yielding bladder exstrophy.[75] However, evidence to the contrary is found in serial human fetal ultrasound cases of CE demonstrating late rupture of a documented intact cloacal membrane between 18 and 24 weeks.[81,82]

Animal models suggest that exstrophy results from pathophysiologic events involving the cloacal membrane. To study the persistent cloacal membrane wedge effect hypothesis, Muecke created an animal model of CE using the developing chick embryo.[358] By placing a plastic graft in the region of the tail bud, he created CE in these animals and concluded that exstrophy was due to persistence of the cloacal membrane, as Marshall had originally postulated.[76] Thomalla and coworkers developed a model of CE in the developing chick embryo by using a CO_2 laser to create an early dehiscence in the tail bud caudal to the omphalomesenteric vessels. Their results suggest that exstrophy may be caused by failure of the mesodermal ingrowth between the ectoderm and endoderm of the cloacal membrane, which later ruptures to produce exstrophy. They hypothesize that such an ischemic event could be caused by early hypoxemic infarction in the region of the tail bud, with subsequent cellular loss of the mesoderm and herniation of the developing bladder or cloaca.[78]

In 2005, a new maldevelopment theory was put forth for CE based on a suramin-exposed chick model.[83] When these chick embryos were examined at 1 or 2 days after pericardial injection of suramin, ~8% were noted to have a midline infraumbilical opening into the cloaca and allantois, abnormal leg bud abduction, a hypoplastic tail and allantois, a broad infraumbilical pelvic region, and large aneurysmal dilation of the paired dorsal aortae at the level of the leg buds. The aortic dilation is transient, resolving on the second or third day after drug exposure, but leaving maldevelopment. These authors implicate the aneurysmal paired dorsal aorta as the primary defect leading to CE in this animal model. The chick model to study bladder exstrophy has inherent limitations. Chicks normally possess a cloaca; thus, this precludes the creation of a bladder exstrophy versus a CE.

Other animal models to study bladder exstrophy have been difficult to create. Slaughenhoupt and colleagues created an exstrophy model using fetal sheep. A significant increase in the ratio of collagen to smooth muscle was noted in exstrophic versus normal control bladders ($p < 0.05$). There was no significant difference in the ratios of types I and III collagen in the two groups of sheep bladders. These histological changes are similar in part to changes seen in human bladder exstrophy tissue.[84,85] The underlying cause of human exstrophy remains in question, but recent advances in understanding the genetics may provide clues.

Incidence

Bladder exstrophy occurs at a rate of 1 per 10,000 live births to 1 per 50,000 live births.[86–89] Older studies have found this anomaly to occur more commonly in males than females, with a ratio of 3–6:1 reported in the literature,[90] while more recent work has found an equal male-to-female ratio.[88,89] CE incidence has ranged from 1 in 200,000 to 1 in 400,000 live births,[75,91] with the overall prevalence reported at 1 in 131,579 to 1 in 317,000 births.[92,93] It is higher in females and in stillborns at 1 in 10,000 to 1 in 50,000.[94]

Genetics

Genetic factors involved in exstrophy remain incompletely defined. Because of the associated physical anomalies with this condition, patients with bladder exstrophy often have to overcome significant obstacles to reproduce. Men may need to resort to assisted reproductive techniques (ARTs) (such as intracytoplasmic sperm injection[95]) because their seminal emissions drain from their ejaculatory ducts located at the base of their bladder plate, if at all. Further, sexual intercourse due to the accompanying deformity of the phallus can be difficult for some of these patients, although the majority have some capacity for satisfactory sexual relations. In the 1800s, the prevailing thought declared males with bladder exstrophy as completely impotent because of the associated deformities of the penis.[96] Women with exstrophy were (and still are) prone to uterine prolapse and miscarriage, but pregnancies have been successfully delivered vaginally or by Caesarian section. Difficulty with conception and pregnancy is still a problem today despite in vitro fertilization and careful obstetric care.[27,97] In addition, conception by ARTs has been associated with a more than eightfold increased risk of the exstrophy–epispadias complex compared with spontaneous conception (odds ratio [OR] 8.3, 95% confidence interval [CI] 4.6–15.0, $p < 0.001$).[98] The reproductive issues combined may explain, in part, why familial patterns of inheritance of exstrophy–epispadias complex are noted infrequently.

Several factors suggest a genetic basis to exstrophy: (1) a higher concordance rate among monozygotic versus dizygotic twin pairs in bladder exstrophy[99] and monozygotic and conjoined twins in CE,[80] and (2) familial recurrence has been seen in bladder exstrophy and CE. To date, about 30 familial cases of bladder exstrophy and one of CE have been reported.[100,101] Five bladder exstrophy cases of an affected parent–child pair have been reported.[100,102,103] Another 18 cases with bladder exstrophy have been reported in twin pairs.[100] In 1984, a survey of pediatric urologists and surgeons reported nine cases related to 2500 index cases of bladder exstrophy; this same series also reported on cases of twins and noted discordance in both fraternal and identical twinships.[102] In a study population of greater than 6 million births with 208 reported cases of exstrophy, no case had a family history for this anomaly.[104] Current recommendations on counseling about risk of recurrence in a sibling of a patient with exstrophy cite an estimate of 0.3%–2.3%[101,105] and a 1:70 chance of transmission to the progeny of an affected parent.[103] A Florida population-based study found multiple births had a 46% increased risk of birth defects, with bladder exstrophy being the fifth highest adjusted relative risk.[106]

Typically, bladder exstrophy is nonsyndromic. One notable syndromic exception is focal dermal hypoplasia (FDH) or Goltz syndrome (OMIM #305600), an X-linked dominant, multiorgan ectodermal dysplasia syndrome characterized by patchy atrophic or hypoplastic skin, teeth, and nails; eye anomalies; oligosyndactyly and syndactyly and split hand and foot skeletal or limb anomalies; and in some cases, ventral body wall fusion anomalies (pubic diastasis, omphalocele, bladder exstrophy, pentalogy of Cantrell, and limb–body wall complex).[107–110] Ninety percent of FDH patients are females, and for them, the severity of the manifestations is a function of tissue mosaicism by random X chromosome inactivation in survivors. For most males, it is embryonic lethal, except for the rare cases of postzygotic somatic mosaicism. Four female patients and one 47,XXY male patient with FDH and bladder exstrophy have been found to have deleterious mutations in PORCN.[111–113] FDH is caused by inactivating mutations of the PORCN gene on chromosome Xp11.23. PORCN encodes an enzyme that governs WNT protein palmitoylation, a necessary step for WNT protein trafficking to the extracellular membrane. PORCN knockout mice demonstrate early embryonic lethality and manifest body wall anomalies, confirming that PORCN is required for gastrulation and normal embryonic development of mesoderm and ectoderm-derived structures.[114–116]

This association between FDH, PORCN, and WNT signaling is interesting because of additional findings from human exstrophy genetic studies. In 2011, Vlangos et al. performed copy number testing and candidate gene screening on 13 CE patients, but no clear causal variants were identified, except possibly two variants in the 5′ untranslated region of the WNT3 gene.[117] Studying 218 DNA samples from bladder exstrophy patients, Reutter et al. detected a genome-wide association at a highly conserved 32 kb intergenic region containing regulatory elements between WNT3 and WNT9B.[118] Using a candidate gene approach, Baranowska Korberg et al. screened 10 WNT pathway genes in 20 bladder exstrophy patients, identifying 7 novel and 13 total potentially disease-causing variants. Further screening of 410 bladder exstrophy patients for WNT3 mutations found no other significant mutations.[119] To detect changes in gene expression in bladder tissue from humans with bladder exstrophy, Qi et al. performed genome-wide expression profiling on the bladder RNAs from three normal fetuses, three normal newborns, and three exstrophy newborns, detecting altered expression of genes in (1) desmosome-mediated cell–cell adhesion, (2) cystosketal architecture, and (3) p63, PERP, SYNPO2, and Wnt pathways.[120] Mutant mouse models and mouse expression studies add credence to the body of literature that WNT signaling is crucial to mesodermal and ectodermal ventral abdominal and thoracic wall closure.[118,121,122]

Intense efforts to identify a genetic cause for human bladder exstrophy and CE have taken several approaches, including karyotyping, candidate gene screening, whole-exome sequencing, genome-wide association studies (GWASs),

and copy number variation (CNV) screening. Of 37 cases karyotyped at Johns Hopkins, two patients with exstrophy–epispadias complex had anomalies, including 47,XYY and a balanced translocation 46,XY,t(8;9)(p11.2;q13).[105] Concerning X chromosome dosage, Ramaekers et al. identified two cases of triple-X syndrome with bladder exstrophy[123] and Soderhall et al. reported a female with bladder exstrophy, short stature, and maternally inherited 46,X,der(X)(pter->P22.12::q26.3->qter).[124] One case of a microdeletion involving OTX1 on chromosome 2p15 was reported by Jorgez et al.[125] Using a variety of molecular techniques, to date, nine bladder exstrophy patients have been identified with 22q11.21 duplications[101] with delineation of a 414 kb critical region containing three screened candidate genes.[126] A candidate gene on 9q13, contactin-associated protein-like 3 (CNTNAP3), was evaluated, but a causal relationship could not be proven in bladder exstrophy.[127] After identifying a 0.9 Mb microduplication on chromosome 19p13.12 in an exstrophy patient, Draaken et al. screened the WIZ gene and found no additional mutations in 112 exstrophy patients.[128] One report of a de novo unbalanced translocation yielding monosomy from 9q34.1-qter,[129] one report of a 13 Mb deletion at 3q12.2-q13.2,[130] and two reports of a terminal deletion of chromosome 1p36.33[131,132] may indicate potential genetic loci for CE. Within the 1p36.33 locus is the DVL1 gene, encoding a phosphoprotein mediator of WNT signaling.[133] Given the multiorgan maldevelopment in CE, it is not surprising that aneuploidies such as 47,XXX,[134] 45,XO/46,XX, or 47,XX,+21 have been found.[135,136] Alx4, Gli3, Hedgehog, Ap2, Msx, p63, and PERP became candidate genes for exstrophy after knockout mice demonstrated anomalous body wall development.[101] Unfortunately, in human exstrophy, no clearly causal DNA variants have been identified in these genes after screening by GWAS, CNV testing, or gene sequencing. Reutter et al. performed whole-exome sequencing on eight CE patients and did not identify any recurrent rare variants, although they consider SLC20A1 and CELSR3 candidate genes.[101] This same collaborative group of investigators has identified ISL1 (ISL LIM homeobox 1) gene as a candidate for bladder exstrophy after their second GWAS and meta-analysis with their first GWAS.[137,138] A recent extensive CNV analysis in 169 exstrophy patients by von Lowtzow et al. found several inherited CNVs but did not identify any recurrent micordeletions or microduplications, except one in 22q11.21.[139] The role of CpG loci imprinting was investigated by DNA methylation screening in 23 exstrophy–epispadias patients, detecting hypomethylation of the PLAGL1 locus in one patient; however, its significance is unknown.[140]

Based on these findings, the exstrophy–epispadias complex is not monogenic and appears to be multifactorial with a strong genetic predisposition for susceptibility. Collaborative efforts are underway to further investigate the causes of the exstrophy–epispadias complex. If environmental factors play a role, they have not yet been identified.

Antenatal Diagnosis

Prenatal detection of bladder exstrophy or CE and male epispadias is possible by ultrasound and fetal MRI. Ultrasonography can reliably detect exstrophy before the 20th week of gestation (Figure 62.11).[80,141–148] The absence of bladder filling in the presence of normal kidneys and in association with a low-set umbilical cord suggests the diagnosis.[149] Sonographic examination may also reveal a semisolid mass protruding from the abdominal wall in association with the findings above.[150,151] Gearhart and coworkers reviewed the antenatal ultrasonographic studies of 25 women who delivered live infants with bladder exstrophy and found

- An absent bladder in 71% of the studies
- A lower abdominal protrusion in 47% of the studies
- An anteriorly displaced scrotum with a small phallus in 57% of the male fetuses
- A low-set umbilical cord in 29% of the studies
- An abnormal iliac crest widening in 18%[143]

Amniotic fluid levels are normal since urine production is normal for these fetuses. Prenatal diagnosis is valuable in the management of the exstrophies because it allows optimal perinatal management of these infants at a center equipped to treat this unusual anomaly.[93] Unfortunately, only ~25% of affected fetuses are diagnosed antenatally by ultrasound, often despite clear indicators of the diagnosis.[152,153]

Antenatal diagnosis also allows the parents the opportunity to discuss termination of the pregnancy. It is our opinion that such a discussion should include a pediatric urologist experienced in the treatment of bladder exstrophy. The overall prognosis of these children is excellent if they are treated at medical centers with physicians experienced in the treatment of this disorder. Unfortunately, because of the rarity of bladder exstrophy, healthcare providers who lack insight and knowledge of this disorder often counsel prospective parents of these patients. For example, in one recent article, the authors state, "The point of termination (of the pregnancy) may be underlined by the poor long term results in boys, who mostly end up with severe sexual dysfunction."[103] Such recommendations are based on an outdated understanding of bladder exstrophy. The present authors believe that recommending abortion for exstrophy would be akin to recommending therapeutic termination in a child diagnosed antenatally with a cleft lip or palate or ventricular septal defect. Unfortunately, the counseling of these families by healthcare providers who are unaware of the true prognosis of patients with bladder exstrophy has led to an increase in the abortion rate of these fetuses who have a treatable condition with a satisfactory long-term outcome and life expectancy when appropriately managed.[147]

Treatment Philosophies

Goals of Reconstruction of Exstrophy–Epispadias

In the treatment of exstrophy, objectives for reconstruction can be placed broadly in the following categories:

Principle objectives

- Urinary continence
- Volitional voiding
- Low-pressure urine storage
- Preservation of kidney function
- Functional and cosmetic external genitalia

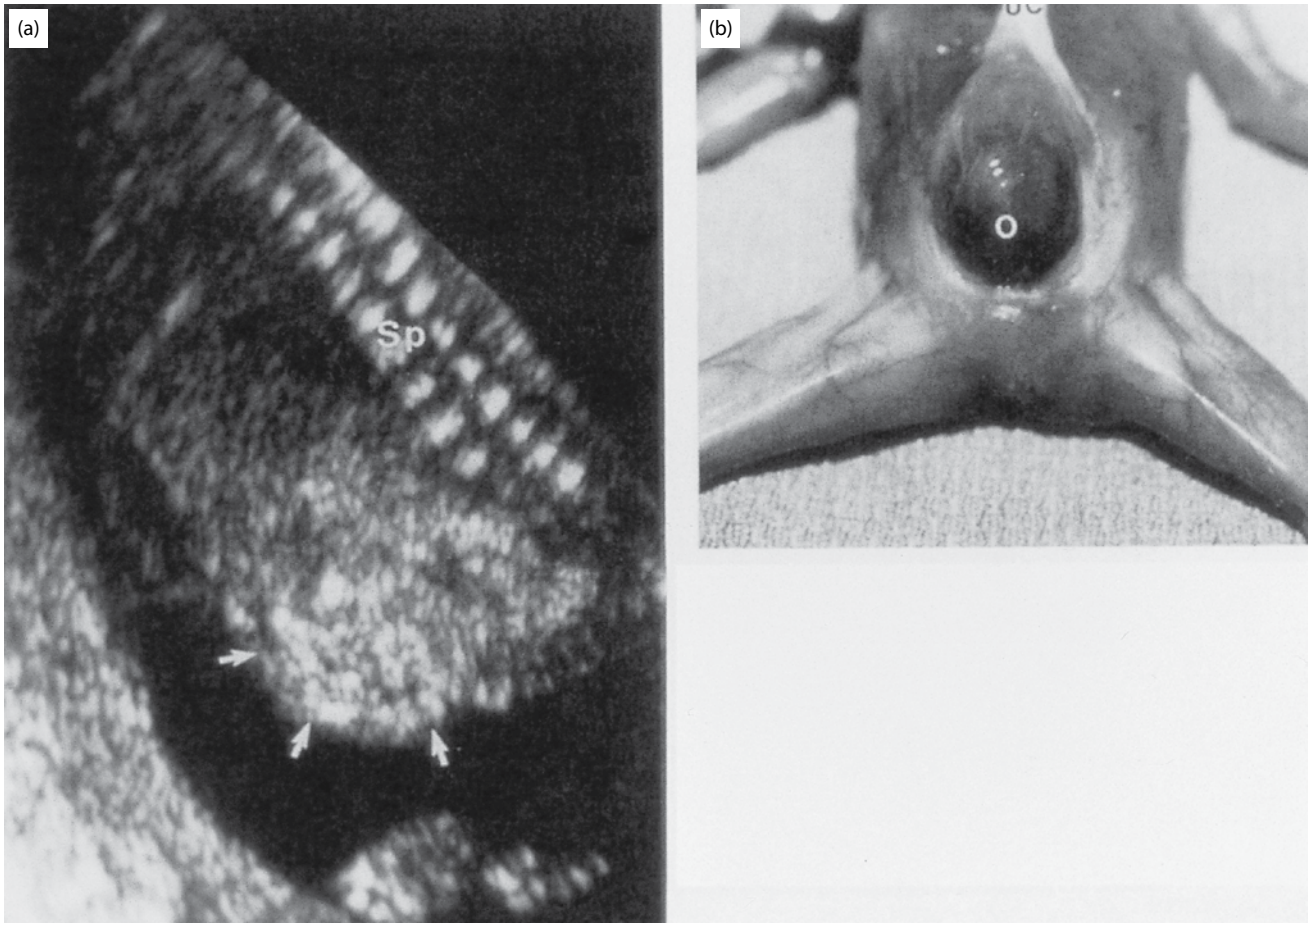

FIGURE 62.11 (a) Antenatal sonogram of a fetus with exstrophy. (b) Photograph of a fetus with confirmed exstrophy at autopsy. Sp = spine; O = omphalocele. (Adapted from Mirk P et al. *J Ultrasound Med* 1986;5(5):291–3. With permission.)

Secondary objectives

- Avoid urinary tract infections
- Reduce risk of urinary calculi
- Minimize the risk for malignancy associated with the urinary tract
- Preserve integrity of the abdominal wall fascia
- Preserve integrity of the pelvic floor

Successful achievement of these goals remains challenging. Numerous operations have been devised for the treatment of bladder exstrophy testing the ingenuity of the physicians and the resilience of the patients themselves. The objectives have expanded since the first operations were proposed and attempted in the 1800s. These objectives address the primary pathology and problems associated with exstrophy and its management. These problems include the following:

Primary pathophysiology (untreated)

- Urinary incontinence
- Urinary tract infection and renal scarring
- Urinary calculi
- Bladder malignancy
- Pelvic floor prolapse
- Inguinal herniation
- Inadequate phallus and ejaculatory dysfunction in males with subsequent sexual, social, and psychological sequelae

Potential complications (associated with management of exstrophy)

- Malignancy (related to the use of intestine in bladder reconstruction)
- Urinary tract infection
- Urinary tract obstruction
- Inadequate bladder emptying
- Urinary incontinence
- Uterine prolapse
- Severe penile shortening with dorsal chordee
- Ejaculatory dysfunction
- Urinary calculi
- Renal scarring
- Abdominal wall hernia
- Epididymo-orchitis

Natural History of Exstrophy

Bladder exstrophy–epispadias complex is not a lethal anomaly; reports exist of untreated patients with CBE living into

their eighth decade.[6] Far from debilitated, these children are often quite intelligent, with many achieving postgraduate education degrees. In contrast, until recently, patients born with CE died shortly after birth from electrolyte abnormalities and malnutrition. Because bladder exstrophy is a serious anomaly, the morbidity these patients experienced was often severe and included the problems noted above. Patients left untreated covered the exposed bladder with a variety of undergarments, including liniment-soaked rags and cotton and wool bolsters. The surrounding skin around the exstrophic bladder was often inflamed and broken down from urine contact dermatitis and secondary infection. These patients were often social pariahs because of the odor and hygiene problems. Up to the nineteenth century, many considered bladder exstrophy irreparable, as evidenced by these comments by Gross in 1876:

> Exstrophy of the bladder, unless the patient is willing to assume the (often mortal) risk of an autoplastic operation, is utterly irremediable; all that can be done is to palliate the patient's suffering by attention to cleanliness, and by the use of a closely-fitting flexible gutta-percha shield, furnished with a gum-elastic bottle for receiving urine.... When this cannot be obtained, the part must be kept constantly covered with a thick, soft compress, renewed as often as it becomes wet and disagreeable. The skin around may be protected, if necessary, with pomatum, simple cerate, or zinc treatment.[96]

Early Attempts at Surgical Reconstruction

The morbidity of exstrophy led surgeons to begin empiric approaches to the operative correction of this anomaly. Surgeons in the nineteenth century attempted urinary reconstructive or diversion procedures to treat these patients. Initial efforts were directed at partial reconstruction of the abdominal wall to allow the application of a urinary receptacle to collect urine. The first successful record of this form of repair is attributed to Dr. Pancoast in 1859. He used skin flaps from the abdominal wall:

> In the treatment of exstrophy of the bladder the principal objects aimed at are either to establish a channel for the conveyance of the urine to the rectum or perineum, or to cover its exposed and sensitive mucus membrane with flaps of skin, thereby protecting it from contact of the clothing, and preventing excoriation of the surrounding parts, as well as facilitating the adjustment of an apparatus for receiving the urine.[96]
>
> A flap is taken from one side of the abdomen or groin, dissected up, and turned over like the leaf of a book so that the epidermis comes into contact with the mucous membrane. A second flap is then taken from the groin on the opposite side and its raw surface applied to the raw surface of the former flap ... thus a thick bridge is formed over the cleft.[154]

Dr. John Wood and F. F. Maury also described variations on the use of *skin flaps* to reconstruct the abdominal wall.[96,155] Wood used a full-thickness skin graft from the abdominal wall, followed by a lateral, pyriform flap from each groin held in place with hare-lip pins, wire sutures, and broad straps of adhesive plaster that were removed

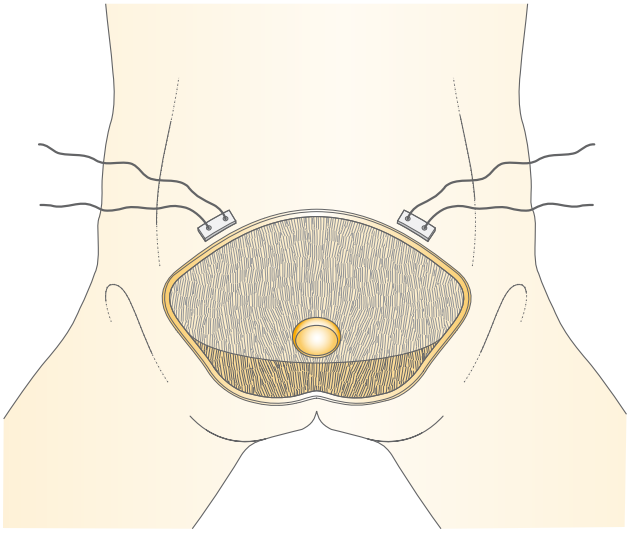

FIGURE 62.12 Early operation for bladder exstrophy, as proposed by Maury in the mid-19th century.

6–8 days after surgery (Figure 62.12). In contrast, Maury created perineal and scrotal skin flaps to repair bladder exstrophy. These procedures represented early attempts at anatomic closure but did not address the functional reconstruction of these bladders—namely, to achieve satisfactory storage and emptying of urine. V. H. Van Buren aptly stated the common sentiment of the time:

> The most that can be promised by operative interference is to leave behind a fistula, more or less large, over which a urinal must be constantly worn. The patient's virility is not returned to him, nor is his condition very materially bettered. A less dangerous and equally efficacious mode of treatment seems to be to adapt a suitable urinal to the parts as they are left by Nature, such a one as shall shield them from injury, and keep the patient dry and clean.[156]

Others, such as Simon, approached the surgical treatment by attempting *urinary diversion* in these patients through the creation of a ureteral sigmoid fistula. Results were poor; one patient died of peritonitis in the immediate postoperative period, and the other died of renal failure secondary to chronic pyelonephritis.[96]

These early efforts suffered from lack of understanding of the physiology of the urinary tract and bladder, and subsequently how these operations would affect urine storage and emptying, kidney function, electrolyte homeostasis, the propensity for urinary tract infection or calculus formation, fertility, and sexual function. Complications from these operations, as noted above, were often life threatening. The fact that patients were willing to assume the risk of surgical death demonstrates the impact this anomaly had on their lives.

Modern Era: Operative Procedures in the Management of Exstrophy

A host of operations for exstrophy have been proposed and attempted, which may be broadly characterized into two

approaches: (1) removal of the exstrophic bladder with replacement by a urinary diversion or (2) anatomic functional exstrophic bladder reconstruction either in multiple stages or in a single stage. Surgeon preference, patient anatomy, previous surgical procedures, availability of tertiary care facilities, and access to medical care all play a role in which operative procedure is chosen for a particular patient. Even in the twenty-first century, no standard of care exists for this patient population. However, because of the complexity of care involved and the rarity of this congenital defect, centers of excellence and specialists with an interest in the exstrophy–epispadias complex usually manage these patients most effectively.[88,89,93] Recently, a U.S. multi-institutional collaborative consortium has formed to maximize individual and collective surgeon experience and knowledge while standardizing management and surgical technique, with the ultimate goal of improving short- and long-term outcomes for these challenging surgical patients.[157]

Perioperative Care of the Patient with Exstrophy

Preoperative Care

With rapid referrals and, in some cases, prenatal diagnoses, neonates with bladder exstrophy should be evaluated for surgical reconstruction promptly. To prevent trauma to the exposed bladder plate after delivery, the umbilical cord should be ligated with silk suture rather than a plastic or metal clamp. An ideal protective covering for the exstrophic bladder is a hydrated gel dressing such as Vigilon®, if available. If a hydrated dressing is unavailable, covering the exposed bladder with plastic wrap (Saran Wrap®), especially for transportation, is an acceptable alternative. These protect the bladder plate effectively and allow handling of the infant with minimal risk of trauma to the bladder. In some circumstances, Vigilon has been used for more than 2 months with minimal inflammation of the bladder noted at the time of repair. The dressing should be replaced daily and the bladder irrigated with normal saline with each diaper change. Others advocate the use of a humidified air incubator with no dressing at all to minimize bladder trauma.[43] Often, the keratinized skin around the bladder plate becomes inflamed from the chronic urine exposure; barrier creams (zinc oxide) help prevent this.

Some exstrophic bladders are extremely small, acontractile, and nondistensibile.[158] Although bladder cycling is known to stimulate bladder growth, in some cases, an early attempt at closure will only result in upper tract deterioration. Although this is a subjective decision, delay of closure may give more time for bladder plate growth. Two reports have also indicated that exstrophy closure in the premature infant should be discouraged due to higher complication rates.[159,160]

Routine use of intravenous antibiotic therapy in the pre- and postoperative period decreases the chance for bacterial infection; however, candidal infection may supercede. A baseline sonogram should be obtained to assess the kidneys preoperatively for later comparisons. A preoperative kidney, ureter, and bladder (KUB) can delineate the extent of pubic symphysis diastasis. A spinal sonographic examination should also be obtained if sacral dimpling or other signs of spina bifida occulta are noted on physical examination in the child under the age of 6 months. After this age, MRI will be necessary to image the spinal cord. Orthopedic consultation is advisable to plan osteotomies if needed, and neurosurgical consultation is required for children with spinal anomalies.

Operative Considerations

Most children with epispadias and bladder exstrophy have no additional anesthetic risk factors, but CE patients often have comorbidities. CE patients with short gut will likely require long-term central venous access at the time of surgery. Exstrophy closure is performed using general inhalation anesthesia, avoiding nitrous oxide to minimize bowel and peritoneal distension and maximize surgical exposure. The use of a nasogastric tube to minimize abdominal distention is controversial.[14,161] Regional anesthesia can be achieved by a one-time caudal block to reduce the inhaled anaesthetic requirement during the operation or in the older child, via a continuous-infusion epidural.

General Comments on Osteotomies

Trendelenberg first recognized the importance of osteotomies in exstrophy closure at the turn of the century. Osteotomies optimize pubic symphysis apposition, diminish tension on the closure, and optimize anatomic placement of the bladder, bladder neck, and urethra in the pelvis. They also improve the reapproximation of the corporal and clitoral bodies. Finally, osteotomies may decrease the chance for later uterine prolapse because the anterior closure brings the pelvic diaphragm into a more normal anatomic position to offer more support.

The need for osteotomy is best determined under general anesthesia. Candidates for osteotomy include those more than 72 hours old, newborns with a wide pubic diastasis of >4 cm, newborns with CE, those with a nonmalleable pelvis not permitting pubic apposition, and patients who have had a previously failed closure.[162] Osteotomies are usually performed at the same setting as bladder closure to help secure the closure.

Osteotomies may be performed by an anterior or posterior approach or a combination of approaches.[163] Posterior iliac osteotomies are performed with the patient in a prone position, after which the patient is then repositioned for the bladder closure. However, increased blood loss and occasional malunion of the ileum have caused this approach to fall out of favor. Anterior iliac osteotomies offer the advantage of a single position and sterile field preparation (Figures 62.37 and 62.38). Anterior diagonal iliac osteotomies have been preferred by the Seattle group. Compared with posterior iliac osteotomies, an anterior approach has also been shown to result in less blood loss and better apposition and mobility of the pubic rami. The group at Johns Hopkins has advocated for bilateral combined anterior innominate and vertical iliac osteotomies (Figure 62.13) because of their experience of superior initial and long-term results compared with anterior iliac osteotomies alone.[32,164] Both osteotomies may be performed through the same anterior skin incision on each side and with minimal blood loss and a 4% complication rate (Figure 62.14).[164,165] McKenna has also described the use of a diagonal midiliac osteotomy performed through

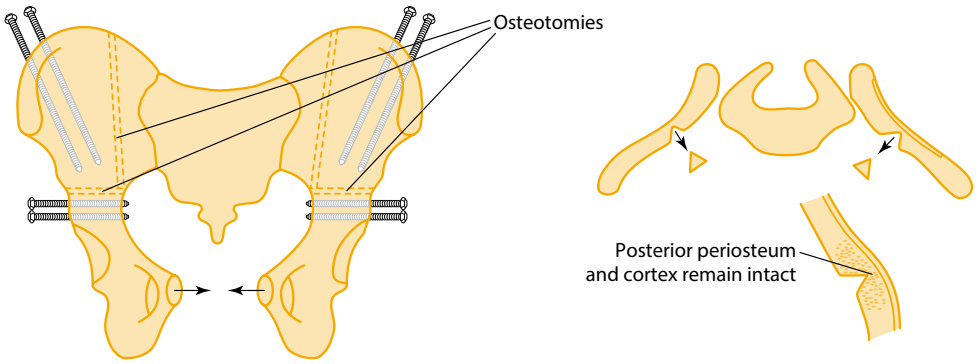

FIGURE 62.13 Osteotomy sites for combined vertical iliac and transverse innominate osteotomies showing the placement of intrafragmentary pins.[103]

the same incision as the exstrophy closure.[166] Division of the superior pubic ramus has also been described; it is not as effective as the other methods described but may be used in the newborn period.[167,168] In older children, a bone graft may be used to stabilize the osteotomy.[166]

Postoperative Considerations

Several methods have been used to maintain pelvic ring closure and prevent external hip rotation following bladder closure without osteotomies. Mummy wrapping can be unreliable, and some believe it should not be used.[14] High-volume exstrophy centers debate over the best method. The two most commonly employed in the newborn period are modified Bryant's traction for 4 weeks[1] (Figure 62.15) and spica casting for 3–6 weeks (Figure 62.16).[169] If osteotomies are performed, they are secured with interfragmentary pins and external fixation with light Buck's traction for 2–4 weeks (Figure 62.17). Some fit the newborn with a "sled" to be used when the child is out of traction for feeding and bathing in these situations. Traction does make performing daily activities and routine care difficult, but spica casting can permit more mobility of the infant pelvis.

Low-dose antibiotic prophylaxis is commonly prescribed, since vesicoureteral reflux is nearly universal. This is continued until vesicoureteral reflux is corrected or resolves spontaneously.

Postoperative factors recognized to increase the success of the initial reconstruction[170] include

- Use of osteotomies (in selected cases) or newborn closure (<24–48 hours)
- Postoperative immobilization
- Use of postoperative antibiotics
- Ureteral stenting catheters
- Adequate postoperative pain management
- Avoidance of abdominal distension
- Adequate nutritional support
- Secure fixation of urinary drainage catheters

Exstrophy Closure: Anatomic Reconstruction

The first efforts at anatomic reconstruction of the exstrophic bladder are usually attributed to Trendelenberg.[171] In 1881, he described an exstrophy closure emphasizing the importance of pubic reapproximation in front of the reconstructed bladder to achieve continence and prevent dehiscence. This effort ultimately proved unsuccessful. Because of discouraging results such as this, bladder reconstruction in exstrophy was largely abandoned and

replaced by urinary diversion, most notably ureterosigmoidostomy, in the early part of this century.

Not all attempts at bladder reconstruction for exstrophy were abandoned. Various surgeons reported occasional successful attempts at bladder reconstruction during this time. However, these results were uncommon and difficult to reproduce. For example, H. H. Young reported the first successful primary bladder closure in 1942. He achieved urinary continence after reconstruction in a young girl.[172] Primary reconstructive efforts by others remained inconsistent and largely unsuccessful during this period. Since Young's successful report in 1942, other investigators have intermittently achieved a satisfactory result with a one-stage reconstructive effort to repair the exstrophied bladder. Ansell reported on a one-stage closure in 1971 with a successful outcome in a newborn female.[173] Ansell was also one of the early advocates for primary closure of bladder exstrophy in the newborn period and reported 28 cases closed in this fashion.[174] Montagnani described a one-stage functional bladder reconstruction in two female babies aged 8 and 13 months. His bladder reconstruction procedure included inominate osteotomy, bladder closure, an antireflux procedure, and narrowing of the bladder outlet, followed by pubic reapproximation. Continence was achieved in one of the two patients. The second patient required further bladder neck reconstruction (BNR) to achieve continence.[175] Fuchs also achieved urinary continence in 8 of 15 patients who were also repaired in a single-stage effort.[176] However, several large series of patients who underwent single-stage reconstruction in the 1960s and 1970s reported continence rates of only 10%–30%.[177–182] Renal damage was as high as 90% in these series, generally because of bladder outlet obstruction.[178]

Because of these complications and the low rate of urinary continence, reconstructive surgical efforts were subsequently directed toward planned staged bladder reconstruction. Staged reconstruction with osteotomies was pioneered and advocated by Jeffs, Chisholm, and Ansell in the 1970s and further refined by Gearhart and others as the modern staged repair of exstrophy (MSRE).[36,174,183,184] An alternative staged reconstruction without osteotomies, the radical soft tissue mobilization (RSTM) technique, was reported by Kelly.[185] Recent advances in single-stage reconstruction for neonatal and older exstrophy have been advocated by Fuchs[176] and others; as such, the complete primary repair for exstrophy (CPRE) by Mitchell has gained favor.[186]

All approaches aim to reconstruct and achieve anatomic and functional normalcy with minimal surgical morbidity. In the subsequent section, the three currently favored surgical techniques, CPRE, RSTM, and MSRE, are detailed. In reality, closure of the female with bladder exstrophy is not significantly different in these methods; the end result is closure of the bladder, urethra, and abdominal wall. In contrast, closure of the male with bladder exstrophy is quite different in CPRE, RSTM, and MSRE. CPRE closes and repositions the bladder and entire urethra at one stage. In contrast, MSRE and RSTM close and reposition the bladder and posterior urethra at the first stage, with the remainder of the urethra closed at a later stage. CPRE and RSTM both completely disassemble the penis into its three components, while MSRE maintains urethral attachment to the glans.

Complete Primary Repair for Exstrophy

In the late 1980s, an anatomic approach to exstrophy repair that combined simultaneous bladder closure, bladder neck remodeling, and epispadias repair was initiated by Mitchell.[186] This operation evolved out of a technique developed for the treatment of epispadias—the complete penile disassembly technique.[187]

Complete primary reconstruction of the exstrophied bladder is best done in the newborn period. Primary reconstruction in the newborn period is technically easier than when done in an older child. It also offers theoretical advantages, as it may maximize the opportunity for "normal" bladder development and the potential for urinary continence. The bony pelvis remains pliable in the newborn period, so that osteotomies may be avoided in some cases—usually if closure can be performed within the first 72 hours of life.

Clinical experience with patients with posterior urethral valves suggests that early restoration of nonobstructive emptying and filling of the bladder allows the bladder to regain some or all of its normal physiologic and

developmental potential.[188] This, in turn, implies that the bladder progresses through developmental milestones that occur in the first few months of life and which may be irreversibly lost if missed. Precedence for this form of organ development is noted in the brain with the acquisition of language and visual perception. Finally, early primary bladder reconstruction creates a more normal-appearing baby that fosters improved bonding between the parents and infant.

In the complete primary repair or Mitchell technique,[186] the bladder, bladder neck, and urethra are moved posteriorly within the pelvis. This movement positions the proximal urethra within the pelvic diaphragm in an anatomically more normal position to maximize the effect of the pelvic muscles and support structures in the achievement of urinary continence. Posterior movement of the bladder neck and urethra also facilitates reapproximation of the pubic symphysis that in turn helps prevent anterior migration of the urethra and bladder neck and provides a more anatomically normal muscular pelvic diaphragm.

Total penile disassembly reduces anterior tension on the urethra because it is separated from its attachments to the underlying corporal bodies. These attachments otherwise pull the urethral plate anteriorly, preventing posterior placement of the proximal urethra and bladder neck in the pelvis. Tension reduction theoretically decreases the risk of bladder dehiscence and also temporarily reduces the dorsal tension on the corporal bodies that may contribute to dorsal chordee in males. Combining the epispadias repair with primary closure allows for the most important aspect of primary closure—division of the intersymphyseal ligament or band located posterior to the urethra in these patients. Advocates of CPRE feel that division of this ligament and deep dissection is optimized when the urethra is separated from the corpora cavernosa.

Neonatal closure employing this technique optimizes the chance for early bladder cycling and consequent normal bladder development. It may also obviate the need for a multistaged repair of the exstrophied bladder, including further BNR, bladder augmentation, and penile reconstructive surgery. This is not uniform however, as the Boston group found BNR needed in up to 40% of CPRE closures.[189]

Male CPRE Technique

The surgical technique of CPRE and the Mitchell complete penile disassembly technique for epispadias follow the same principles and thus are discussed simultaneously. After standard preparation of the surgical field, 3.5 French umbilical artery catheters are placed into both ureters and secured with a 5.0 chromic suture. A marking pen outlines the planned lines of dissection (Figures 62.18 and 62.19). Initial dissection begins superiorly and proceeds inferiorly to separate the bladder plate from the adjacent skin and fascia using fine-tip electrocautery (Colorado® tip). The umbilical cord usually needs to be mobilized on its vessels in a cephalad direction such that the resulting umbilicus will be at the level of a line drawn between the two iliac crests. The relocated umbilicus will also be the cutaneous site for bringing out the suprapubic tube. The dissection in classic exstrophy patients is extraperitoneally.

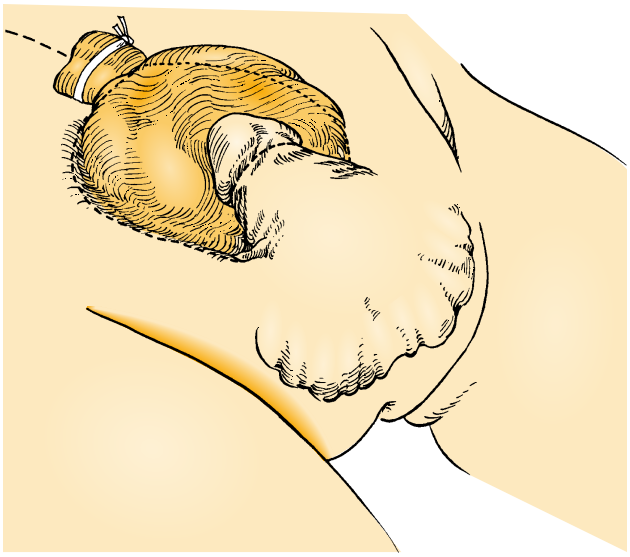

FIGURE 62.18 Initial lines of dissection for male complete primary exstrophy repair technique – ventral perspective.

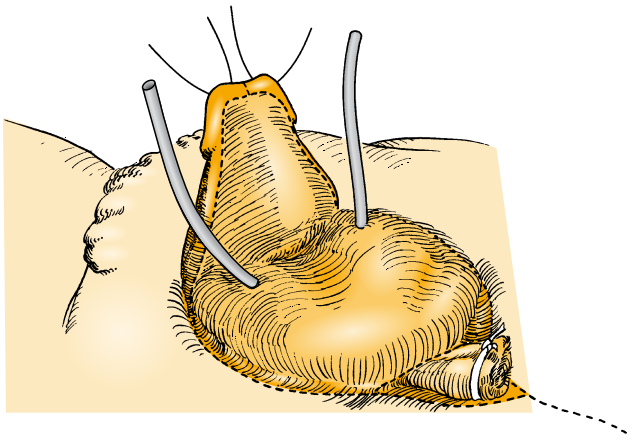

FIGURE 62.19 Initial lines of dissection for male complete primary exstrophy repair – dorsal perspective. Lines at the bladder neck indicate approximate tailoring that may be needed to exclude dysplastic tissue in this area.

To aid in dissection, traction sutures are placed into each hemiglans of the penis. These sutures are placed at the beginning of the operation and are initially oriented *transversely* in the hemiglans. The sutures will rotate to a parallel vertical orientation as the corporal bodies rotate medially following dissection of the corporal bodies and the urethral wedge (urethral plate plus underlying corpora spongiosa) from each other.

To begin the penile dissection, a circumcising incision is made along the ventral aspect of the penis. This should precede dissection of the urethral wedge from the corporal bodies because it is easier to identify Buck's fascia ventrally. The initial plane of dissection is developed just above Buck's fascia. *Buck's fascia stops at the corpora spongiosum during the dissection.* So, as the dissection progresses medially, the plane shifts subtly from above Buck's fascia to just above the tunica albuginea. Dorsally,

methylene blue or brilliant green helps differentiate urothelium from squamous epithelium. Injection of the surrounding tissues with 0.25% lidocaine and 1:200,000 μ/mL epinephrine also improves hemostasis, which assists the dissection. The margins of the dorsal urethra are usually obvious. The surgeon must take care not to narrow the urethral wedge, as this will be tubularized later. Urethral wedge dissection is carried proximally to the bladder neck. Careful lateral dissection of the penile shaft skin and dartos fascia from the corporal bodies is paramount; the lateral dissection of the penis is always superficial to Buck's fascia because the neurovascular bundles are located laterally in the epispadic penis. Medially, under the urethral wedge, the dissection plane is on the tunica albuginea of the corpora cavernosa.

The penis is surgically disassembled into three components—the right and left corporal bodies with their respective hemiglans and the urethral wedge (urothelium with underlying corpora spongiosa).[187] *This is done primarily to provide exposure to the intersymphyseal band and to allow adequate proximal dissection*. It is easiest to initiate the dissection proximally and ventrally (on the underside of the corpora cavernosa) (Figure 62.20). The plane of dissection should be carried out at the level of the tunica albuginea on the corpora. After a plane is established between the urethral wedge and the corporal bodies, this dissection is carried distally to separate the three components from each other (Figure 62.21). This maximizes the degree of freedom for the best repair. The corporal bodies may be completely separated from each other since they exist on a separate blood supply. It is important to keep the underlying corpora spongiosa with the urethral plate; the blood supply to the urethral plate is based on this corporal tissue, which should appear wedge shaped after its dissection from the adjacent corpora cavernosa. The urethral or corporal spongiosal component will later be tubularized and placed ventral to the corporal bodies. Paraexstrophy skin flaps should not be used for urethral lengthening because this maneuver may devascularize the distal urethra. Because the bladder and urethra are moved posteriorly into the pelvis as a unit, division of the urethral wedge should *never* be necessary. However, in some cases, a male patient will be left with a hypospadias that will require later surgical reconstruction (short distal urethra).

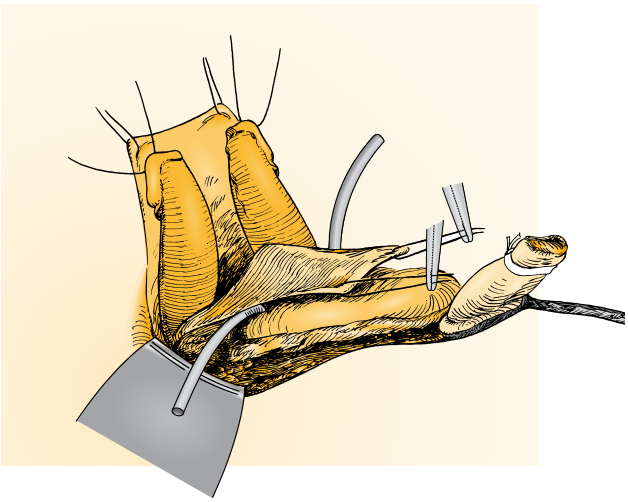

FIGURE 62.21 Distal separation of the corporeal bodies and urethral wedge. This maneuver may not always be required. Complete separation allows maximal exposure to the pelvis and optimizes the dissection and posterior positioning of the bladder, bladder neck, and urethra in the pelvis.

Proximal dissection of the urethral wedge from the corporal cavernosa bodies facilitates exposure of the intersymphyseal ligament, which must be incised. The dissection may be carried into the pelvis following the planes along the medial aspects of the corporal bodies (Figure 62.22). *Deep incision of the intersymphyseal ligaments posterior and lateral to each side of the urethral wedge* is absolutely

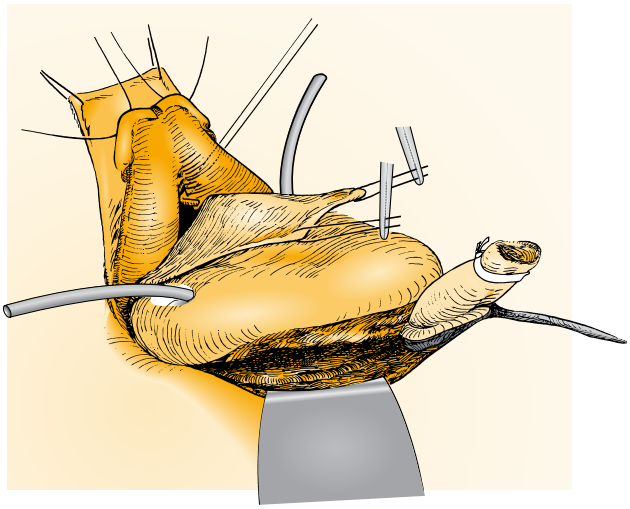

FIGURE 62.20 Disassembly of the urethral wedge (urethral plate with underlying corpora spongiosa) from corporeal bodies. The plane of dissection should remain on the corporeal bodies to allow the corpora spongiosa to remain with the urethra.

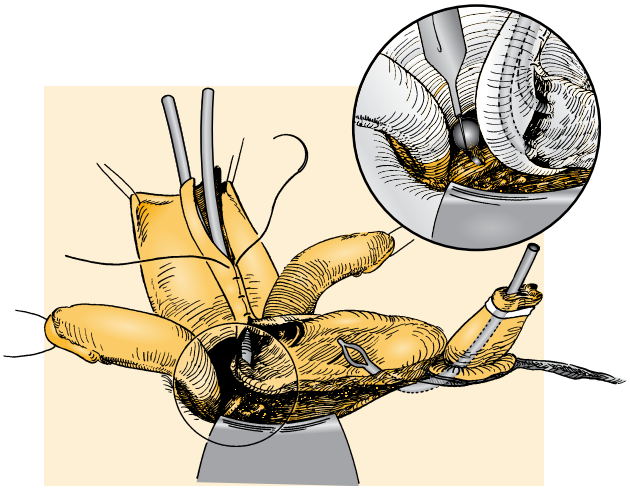

FIGURE 62.22 Division of the intersymphyseal band (condensation of anterior pelvic fascia) and deep pelvic dissection. The inset demonstrates division of the intersymphyseal band. Division of this band allows posterior placement of the bladder without tension.

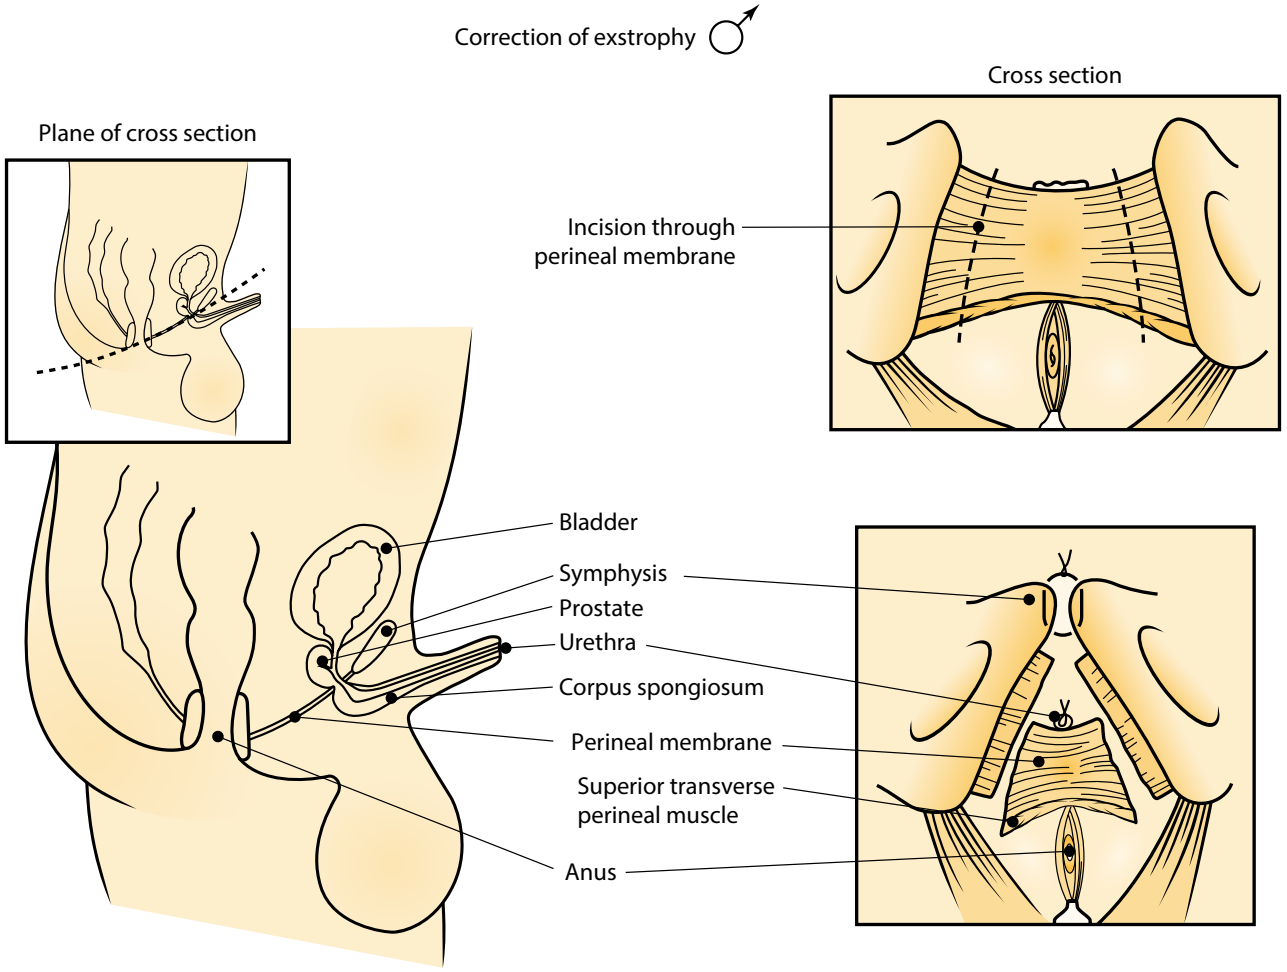

FIGURE 62.23 This cross section represents an idealized positioning of the urethra and bladder neck in the pelvis.

necessary to allow the bladder to achieve a posterior position in the pelvis (Figure 62.23). This dissection should be carried until the pelvic floor musculature becomes visible (i.e., the intersymphyseal ligament is completely incised). Computerized tomography of the pelvis demonstrates that these ligaments lie posterior to the bladder neck and urethra. Failure to adequately dissect the bladder and urethral wedge from surrounding structures will create anterior tension along the urethral plate and prevent posterior movement of the bladder in the pelvis.

Once the bladder and urethral wedge are adequately dissected from the surrounding tissues, the majority of the procedure is done and the closure is straightforward and anatomic. The importance of recognizing the proper location of the bladder neck is key (in boys proximal to the verumontanum and in girls just distal to the trigone). Prior to reapproximating the bladder, a suprapubic tube is placed and brought out through the umbilicus. The primary closure of the bladder is achieved using a three-layer closure with monofilament absorbable suture (i.e., Monocryl® and Vicryl®). The urethra is tubularized using a two-layer running closure with monofilament and Vicryl suture as well (Figure 62.24). The tubularized urethra is then placed ventral to the corpora in an anatomically normal position.

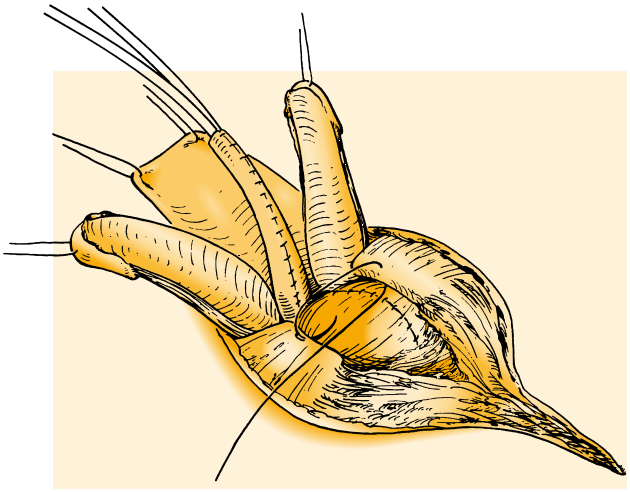

FIGURE 62.24 The bladder and urethra are closed in two layers using absorbable suture. The ureteral catheters are brought out throught the urethral closure. The suprapubic tube may be brought out through the umbilicus.

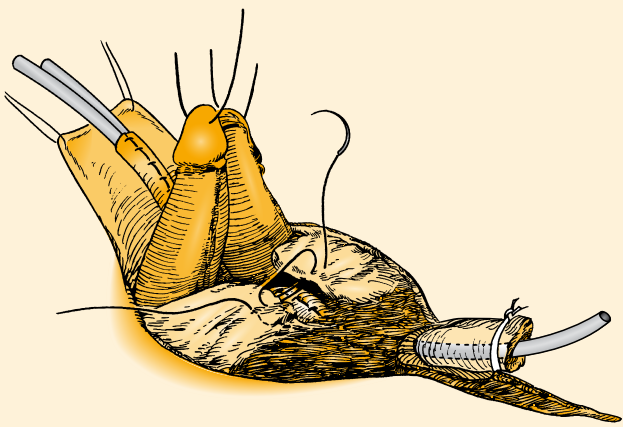

FIGURE 62.25 Reapproximation of pubis symphysis using absorbable suture. Note medial rotation of glans that occurs after dissection.

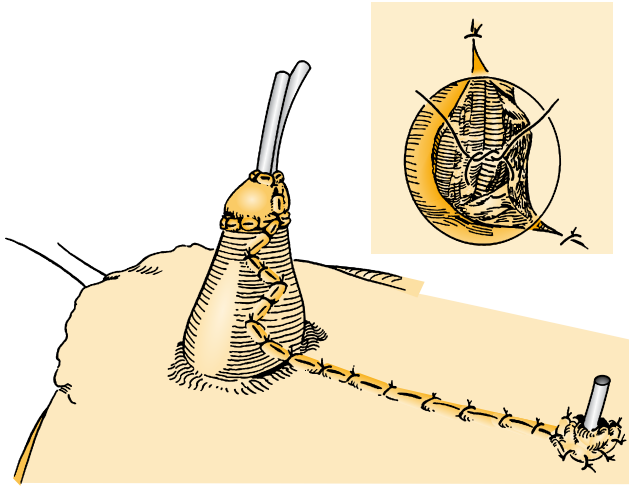

FIGURE 62.26 Skin reapproximation can be challenging. Tacking sutures placed between the dermal tissue and the corporeal bodies can assist in anchoring the penile shaft skin to the base of the penis. Z-plasty incisions can also be useful to approximate the shaft skin ventrally.

Then the pubic symphysis is reapproximated using a 0.0 polydiaxonone-interrupted figure of eight sutures. Knots are anterior to prevent suture erosion into the bladder neck (Figure 62.25). Rectus fascia is reapproximated using a running 2.0 polydiaxonone suture. Penile shaft skin is reconfigured using either a primary dorsal closure or reversed Byars flaps, if needed, to provide dorsal skin coverage. Skin covering the abdominal wall is reapproximated using a two-layer running closure of absorbable monofilament suture.

The corporal bodies will tend to rotate medially with closure when the lateral margins of Buck's fascia of each corpora cavernosa are approximated. This rotation will assist in correcting the dorsal deflection and can be readily appreciated by observing the vertical lie of the previously horizontally placed glans traction sutures. Occasionally, significant discrepancies in the dorsal and ventral lengths of the corpora will require dermal graft insertion. However, this is rarely needed in the newborn closure. The corpora are reapproximated with fine interrupted suture along their dorsal aspect.

The urethra can then be brought up to each hemiglans ventrally to create an orthotopic meatus (Figure 62.26). The glans is reconfigured using interrupted mattress sutures of polydiaxonone suture (i.e., PDS®), followed by horizontal mattress sutures of 7.0 monofilament suture (i.e., Maxxon®) to reapproximate the glans epithelium. The neourethra is matured with 7.0 braided polyglactin suture (i.e., Vicryl) similar to a standard hypospadias repair. In some, the glans tissue is reduced to create a conical-appearing glans. In roughly half of cases, the urethra lacks enough length to reach the glans. In this situation, the urethra may be matured along the ventral aspect of the penis to create a hypospadias (Figure 62.27). This can be corrected at a later date as a second-stage procedure, and options for hypospadias repair are detailed in other chapters. The redundant shaft skin is maintained ventrally in these patients to assist in later penile reconstructive procedures.

Female CPRE Technique

The principles and timing of repair are analogous for boys and girls (Figure 62.28a and b). To perform this technique, the lines of initial dissection are depicted in Figure 62.29. *In an effort to clearly define the bladder neck, the bladder neck dissection is tailored*. The bladder neck, urethra, and vagina are mobilized as a unit. The dissection is achieved with a tungsten-tip electrocautery (Colorado tip) to minimize tissue damage while achieving hemostasis. The appropriate plane of dissection is found anteriorly along the medial aspect of the bifid clitoris and proceeds posteriorly along the lateral aspect of the vaginal vault (Figure 62.30). *The vagina is mobilized with the urethral plate and bladder neck. The urethra and bladder neck should not be dissected from the anterior vaginal wall*, as this will compromise the blood supply to the urethra.

During the posterior lateral dissection, the intersymphyseal band will be encountered and should be deeply incised to allow the vagina, urethra, and bladder neck to move posteriorly. The posterior limit of the dissection is

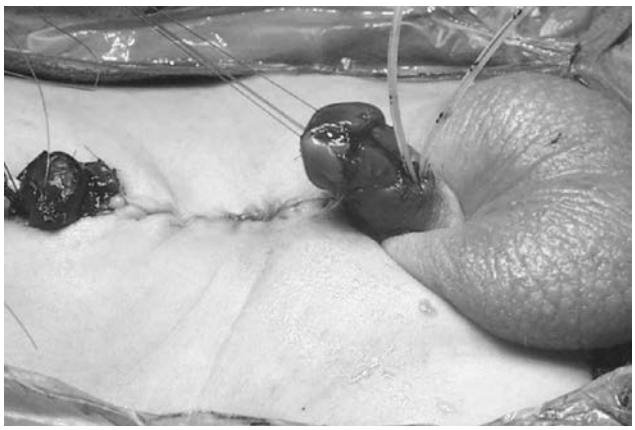

FIGURE 62.27 Hypospadias occurs in this situation because the urethra is too short after the bladder has been positioned posteriorly in the pelvis.

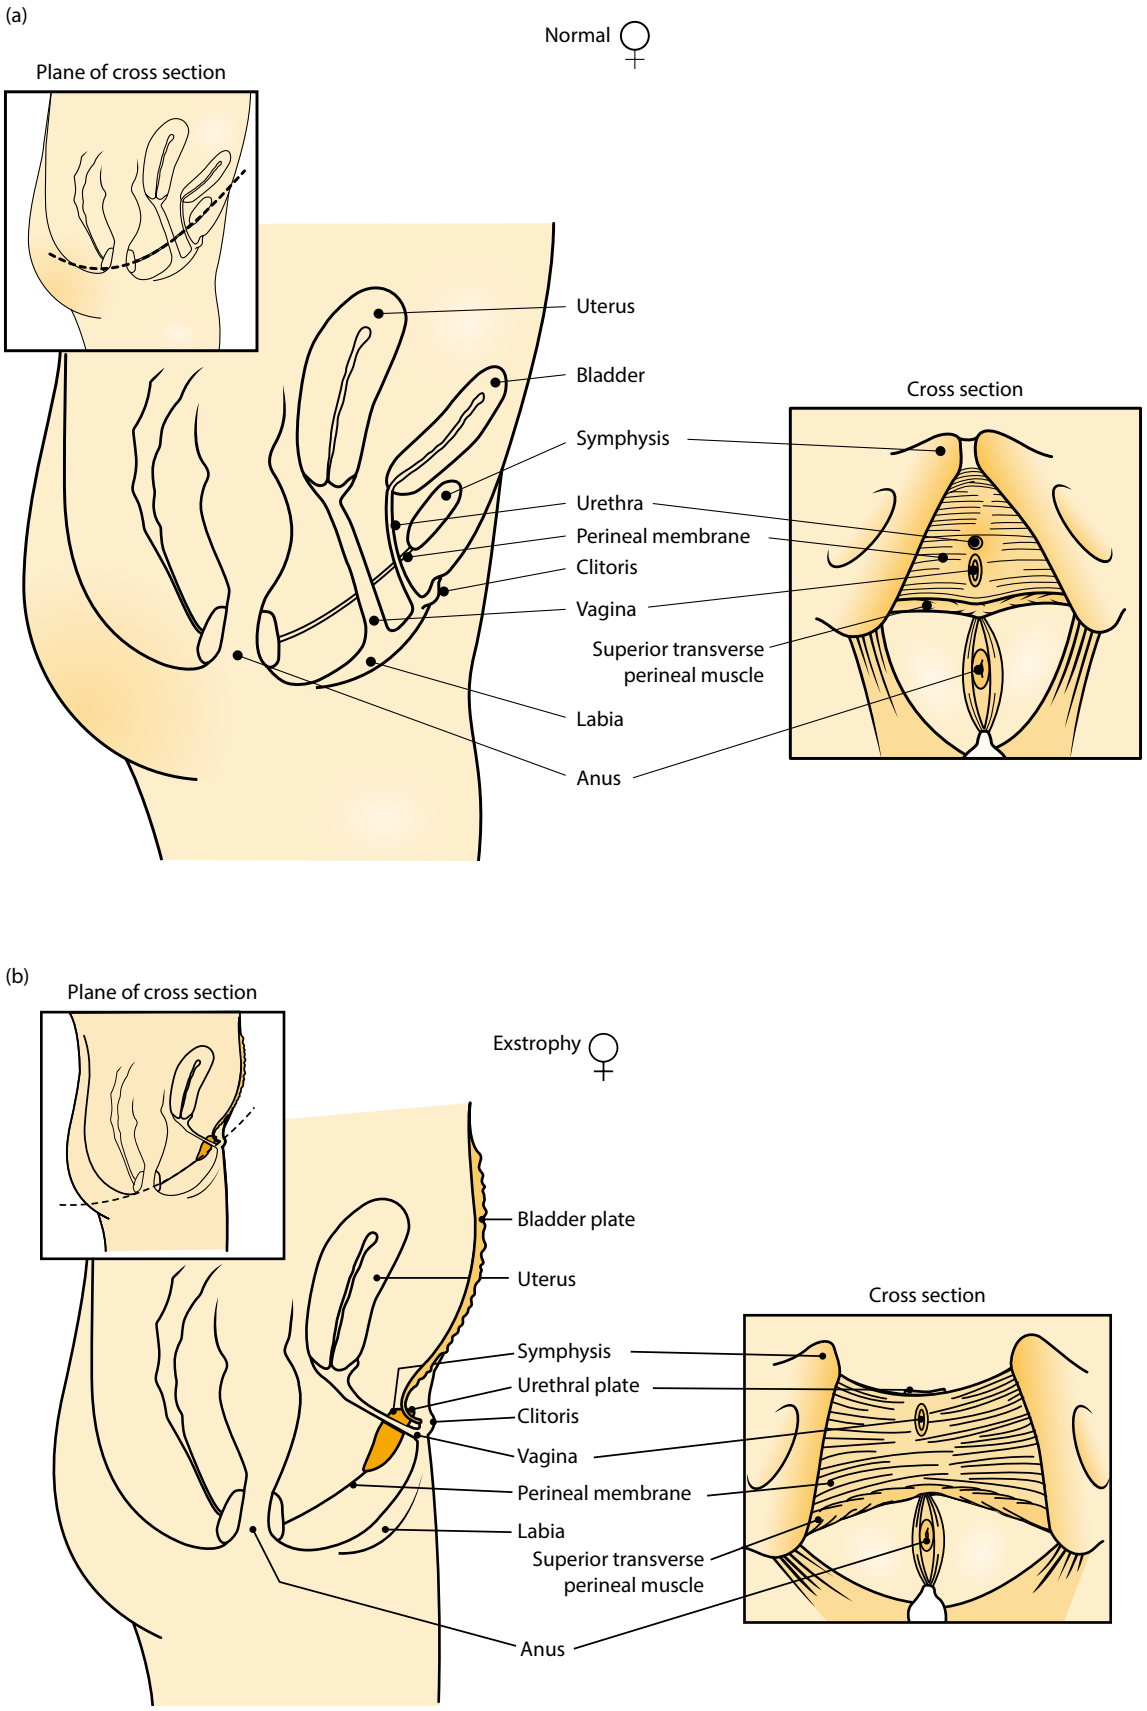

FIGURE 62.28 Cross section of (a) normal female anatomy compared with (b) exstrophic female anatomy.

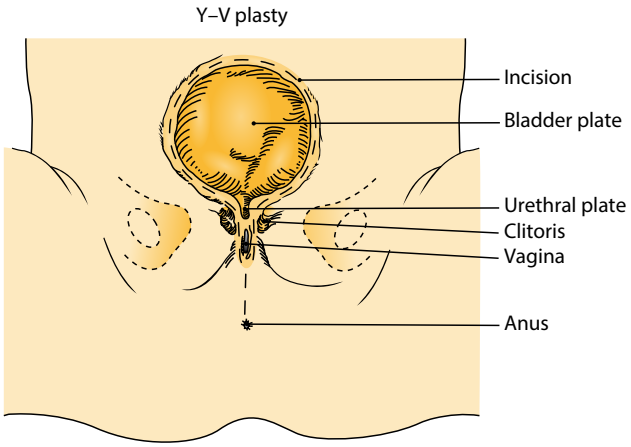

FIGURE 62.29 Initial lines of dissection for female complete primary exstrophy repair technique. Of note, the dissection is carried around the vaginal vault inferiorly to mobilize the vagina and urethra together.

reached when the pelvic floor musculature is exposed. The proximal urethra can be lengthened to some degree with parallel incisions in the bladder plate toward the trigone. As importantly, lateral dysplastic tissue should be removed from the region around the bladder neck when the bladder neck is created.

Following adequate dissection, the vagina and urethra are moved posteriorly in the perineum with a Y-V plasty. The urethra is then tubularized using a two-layer closure of absorbable suture (Figure 62.31). Prior to the urethral closure, a suprapubic tube is routinely placed to provide postoperative urine drainage (Figure 62.32). The bladder, bladder neck, and urethra should be positioned deeply in the pelvis and traverse the pelvic diaphragm (Figure 62.33). The pubis symphysis is then reapproximated using two 0.0 PDS figure eight sutures (Figure 62.34).

As in the repair in the boy, *osteotomies may be necessary* when a wide pubic diastasis prevents a low-tension reapproximation of the pubic symphysis. Mitchell and Grady use anterior iliac osteotomies in these situations.

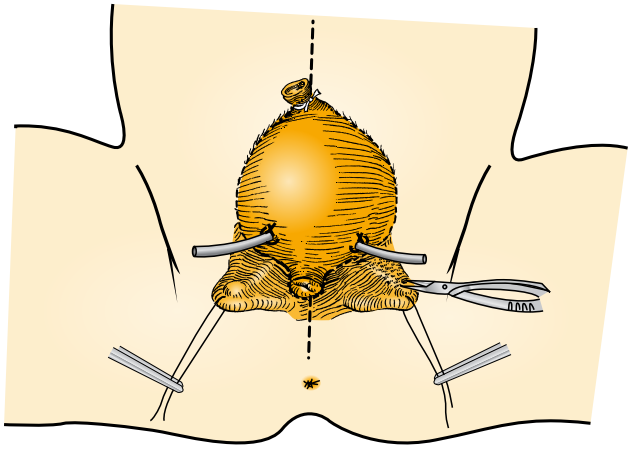

FIGURE 62.30 The lines of dissection are marked in this drawing of a newborn girl with classic bladder exstrophy. Please note stay sutures placed in clitoral bodies to assist with exposure.

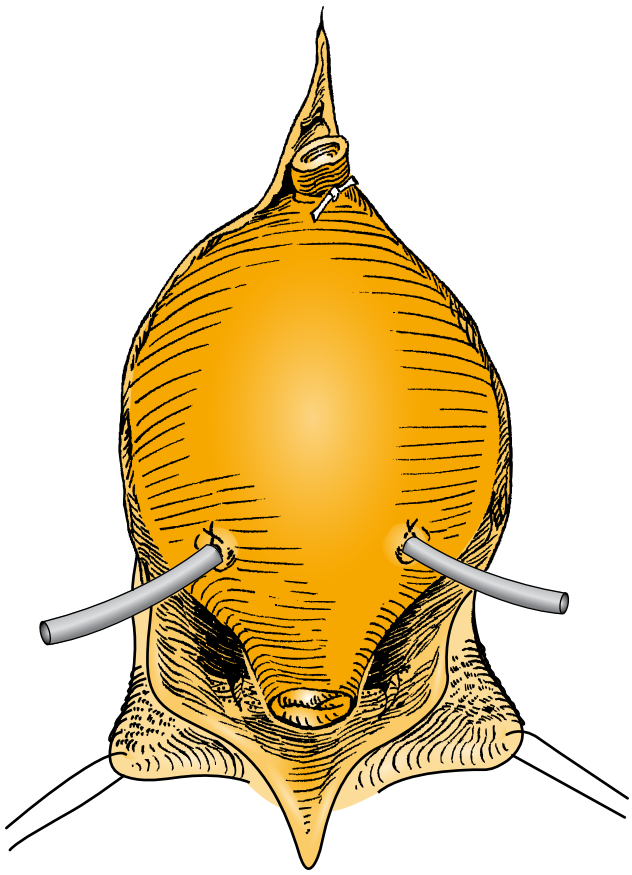

FIGURE 62.31 The appropriate plane of dissection is found anteriorly along the medial aspect of the bifid clitoris and proceeds posteriorly along the lateral aspect of the vaginal vault. This allows for deep pelvic dissection to place the bladder, bladder neck, and urethra into the pelvis without tension.

The rectus fascia can then be closed in the midline. The neourethra is matured with 5.0 Vicryl sutures and reapproximates the already denuded bifid clitoris medially so that they fuse together after suturing with 7.0 Maxxon suture. The labia majora is advanced posteriorly to the perineum at this time to improve cosmesis of the external genitalia (Figure 62.35). A Z-plasty skin closure can be employed as well.

Modifications of the CPRE Technique

In an effort to improve the results of the CPRE technique, several authors have reported modifications. Caione and colleagues described the use of an electrical muscle stimulator during deep pelvic dissection to preserve and reconfigure the periurethral muscle complex. Long-term results of this patient series have not yet been reported; preliminary results are promising.[190]

El-Sherbiny and Hafez have described a modification of the penile disassembly technique preserving the connection between the distal urethral wedge and the corporal bodies to decrease the incidence of hypospadias.[191] Proposed by Emir and colleagues, one solution for intraoperatively anticipated hypospadias is to generate parameatal-based inner preputial skin flaps that do not require anastomosis to the urethral plate.[192]

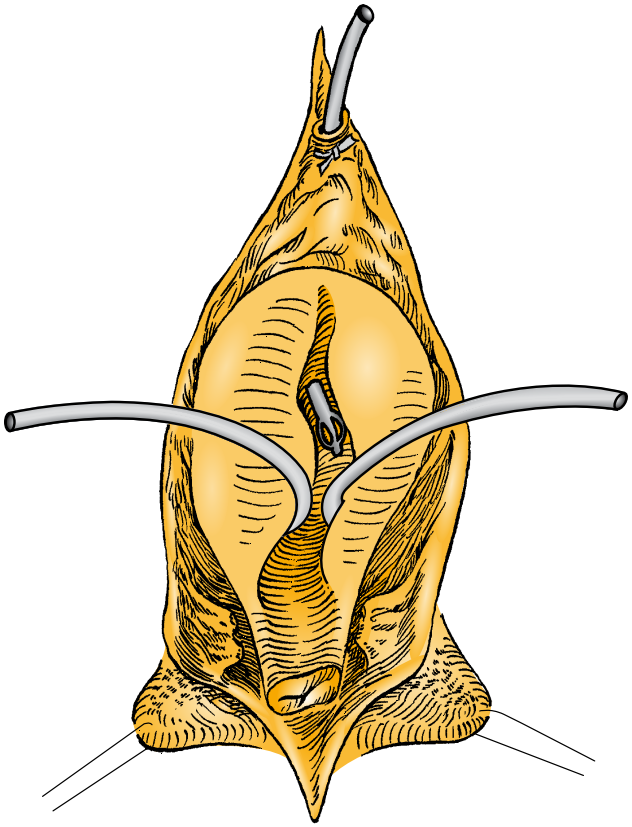

FIGURE 62.32 Prior to the urethral closure, we routinely place a suprapubic tube to provide postoperative urine drainage. The suprapubic tube is brought out through the umbilicus. Ureteral catheters are left in place and brought out through the urethra. All tubes are left to gravity drainage.

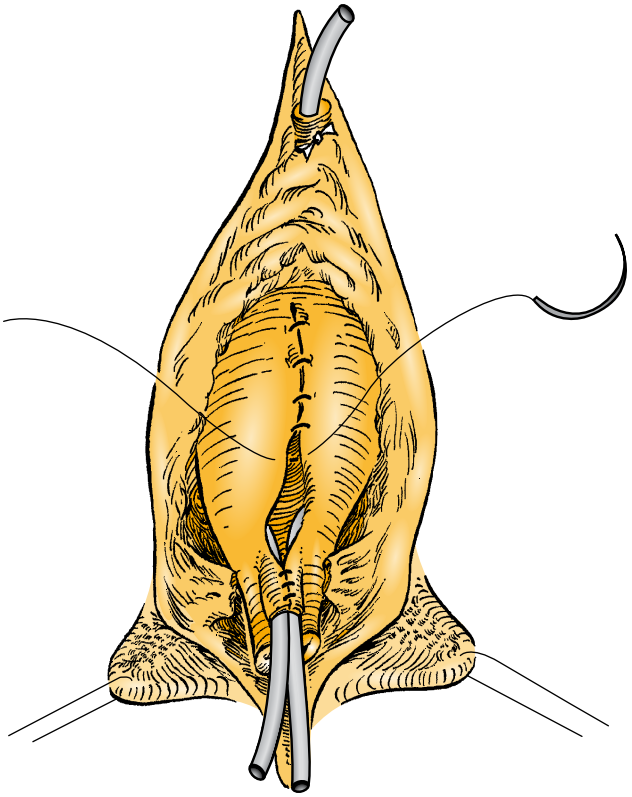

FIGURE 62.33 The bladder, bladder neck, and urethra should be positioned deeply in the pelvis if an adequate dissection has been performed.

Other primary modifications include the technique pioneered by Dr. Kureel. By employing a novel midline scrotoperineal approach, he has been able to more readily identify the nerves in the perineal region to facilitate an innervation preserving sphincteroplasty and radical corporal detachment for reconstruction of exstrophy–epispadias.[193,194]

Outcomes of CPRE

The longest series reporting outcomes of CPRE is from Seattle Children's Hospital, spanning 20 years. Of 39 patients, the median follow-up is 106 months for the original group reported in 1999 and 58 months for the entire series. Of the children older than 4 years of age, 74% have gained daytime continence with volitional voiding. Of these children, 20% of boys and 43% of girls have achieved incontinence without the need for BNR or tailoring. In the remainder, bladder neck modification was performed prior to achieving continence. The majority of these bladder neck modifications were performed at the same time as ureteral reimplantation procedures and were performed using a Mitchell bladder neck technique. An 18% complication rate has been noted in this series.[195] One other report from the Boston group provides an 8-year follow-up of CPRE outcomes. Borer and colleagues noted that 5 of 8 patients (63%) 4 years old

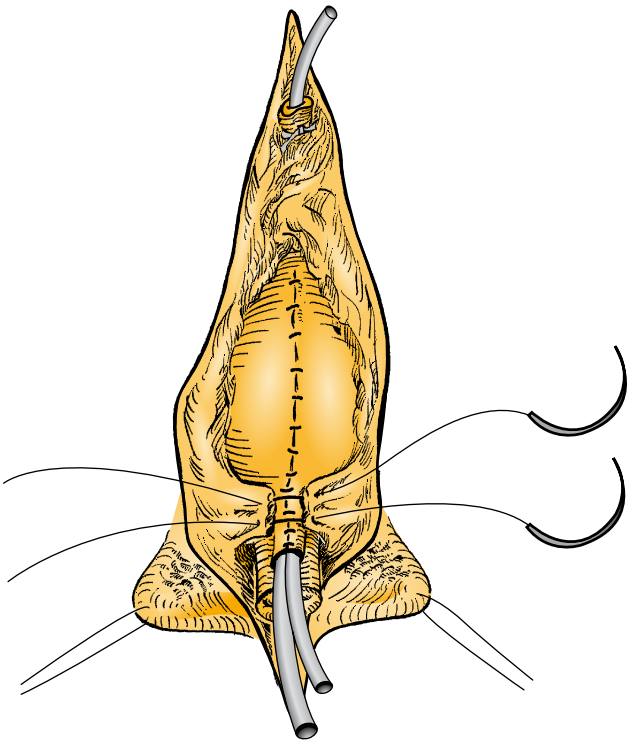

FIGURE 62.34 Reapproximation of symphysis pubis using interrupted sutures. Lateral dissection may be required to reapproximate the rectus fascia in the midline.

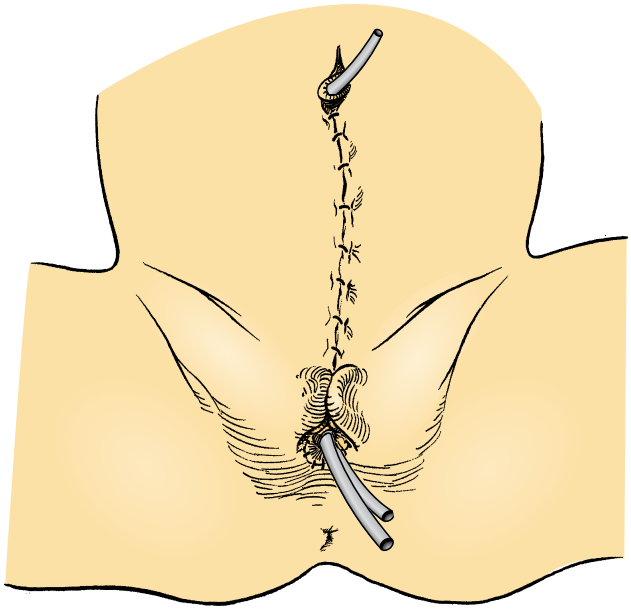

FIGURE 62.35 Skin closure. Denuding the skin medial to the clitoral bodies minimizes the bifid appearance of these structures postoperatively. The labia majora may also be advanced inferiorly to create a more normal cosmetic appearance.

or older had grossly inadequate bladder outlet resistance and either had or will require BNR. This same group also reported on urodynamic findings between patients who had undergone exstrophy repair using a complete primary repair technique compared with a modern stage repair technique. They found that patients undergoing a complete primary repair universally had better bladder stability and bladder compliance than those who had been repaired with a staged technique. Bladder capacity was equivalent between the two groups. Interestingly, patients repaired with a complete repair technique also had normal electromyelography (EMG) results during this study.[160]

Potential Complications and Unique Aspects of the CPRE Repair

Borer and colleagues reported that 75% of 16 males and 29% of 7 females undergoing newborn CPRE required blood transfusion.[160] After CPRE, hypospadias rates have ranged from 50% to 82%.[160,186,196] Borer and colleagues have decreased this rate by using interrupted urethral sutures instead of running ones.[160] Reconstruction of the hypospadic defect can be challenging[160,197] due to the paucity of skin. Hafez and El-Sherbiny have found tubularized penile flap urethroplasty to be superior to Thiersch–Duplay urethroplasty.[197] Bladder neck fistulas have been observed in as many as 41% of CPRE repairs,[198] 78% of which required fistulectomy.

Partial or complete hemiglans and/or corporal loss has been reported by several authors,[198–200] which is likely the most feared complication. Possible contributing factors to this complication include congenitally altered vascular supply, intraoperative use of epinephrine, aggressive dissection and detachment of the corpora and its neurovascular bundle from the ischiopubic ramus and Alcock's canal, and/or diminished arterial perfusion or venous drainage from either corporal kinking, pelvis compression at the time of approximation of the pubic symphysis or corporal rotation, or progressive postoperative edema. This requires aggressive management intraoperatively with relaxation of the symphysis closure. If noted postoperatively, two successful reports of the use of medicinal leeches on the dark glans suggest that the major problem is venous engorgement, suggesting medicinal leeches should be considered for use in this situation.[201,202] However, this complication is not unique to CPRE, as it has been seen in any bladder exstrophy closure method, with a significant number of bilaterally affected cases.[200,203]

Similarly, bladder rupture has been reported in nonaugmented as well as augmented CBE patients, and this complication has been seen in all exstrophy closure methods.[204] While it can be managed nonoperatively with great caution, it can be life threatening and require laparotomy. Contributing factors may include high intravesical pressure and infrequent or incomplete bladder emptying.

Some have criticized the staged approach as requiring a greater number of surgical procedures than CPRE.[203] Given the "relative newness" of the CPRE technique, long-term studies will further delineate the number of patients who require hypospadias reconstruction and BNR to achieve urinary continence. As the male children progress through puberty, phallic growth, presence of chordee, erectile function, and ejaculatory function will be outcomes to closely monitor. Given exstrophy is a complex birth defect to reconstruct, no matter which method is chosen, complications will occur,[199,205] most of which require further surgical interventions.[160]

Radical Soft Tissue Mobilization Technique (Kelly Technique)

The RSTM or Kelly technique has been used at some institutions for decades. The initial contribution by Kelly in 1971[206] described a phallic lengthening procedure performed without osteotomies either at the time of or after exstrophy cystectomy with or without epispadias repair. To lengthen the exstrophic phallus, the crus of each corpus cavernosum is released from the ischiopubic ramus by incising the periosteum of the ischiopubic rami. The crus is completely freed from the ramus but still attached to its neurovascular bundle. Each neurovascular bundle in Alcock's canal is mobilized back to the ischial spine, dividing the obturator internis fascia. This greatly increases mobilization of the corpora such that the original sites of crus attachment can be reattached to the fibrous band connecting the pubic bone.

The RSTM technique to repair CBE (Kelly technique), published from Australia in 1995,[185] described a second stage of the exstrophic bladder reconstruction and epispadias repair without the need for osteotomies. RSTM includes complete separation of the urethral plate from the corpora cavernosa and detachment of the levator ani and urethral sphincter striated muscles from the obturator internis fascia. These voluntary and involuntary sphincter muscles are then wrapped around the tubularized

membranous urethra and bladder neck. The tubularized urethra is transferred ventrally under the corpora, and the urethral meatus is placed as a penoscrotal urethrostomy. In 1995, Kelly reported "physiological continence" in 73% of 19 patients.

The theoretical advantages of the RSTM include a tension-free reconstruction and potentially enhanced continent voiding due to the reconfigured sphincteric muscles independent of the initial severity of or the inevitable worsening of the pubic diastasis. Disadvantages include the need for temporary hypospadias necessitating further penile urethroplasty and the risk of vascular damage to the corpora cavernosa, with partial or complete loss of one or both glans and/or corpora. Several series have reported short- and long-term outcomes. In 2009, Jarzebowski et al.[207] reported the Royal Children's Hospital long-term RSTM outcomes from 1980 to 2007, reflecting the Australian experience. Of 106 CBE patients, follow-up data were available on 44, with continence rates at 70% for complete or partial urinary control. More than half did not require bladder augmentation or clean intermittent catheterization. None of the 9 RSTM females had uterine prolapse, which is lower than the 18% in other published series.[27] The lower abdominal wall was felt to appear abnormally sunken in most adults closed with this technique. In 2015, Varma et al. reported on 38 patients with a 4.5-year mean follow-up; 63.5% achieved complete continence, and 82% had functional continence with no bladder augmentations.[208] Others have also reported successful short-term outcomes with the use of this technique. Complications, such as bladder neck cutaneous fistulas and penile loss, have been reported with the use of this technique.[200,209,210]

Complete Penile Disassembly for the Treatment of Isolated Male Epispadias

Mitchell performed his first complete penile disassembly, or Mitchell technique, for epispadias repair in 1989. Mitchell and Bagli first reported their results in 1996.[187] Complete penile disassembly offers several advantages compared with the modified Cantwell–Ransley technique. The planes of dissection extend anatomically to the bladder neck. This facilitates its use with BNR. Complete mobilization of the urethral wedge from the corporal bodies by disassembly also creates a more normal appearance of the penis by allowing ventral placement of the urethra (Figures 62.36 through 62.38). A detailed description of the surgical technique is included in the "Complete Primary Repair for Exstrophy" section. Zaontz and colleagues reported on a multicenter experience using this technique and found that 16/17 boys had straight erections following repair. Three patients developed pinpoint fistulas, of which two closed spontaneously.[211] Hammouda reported on 42 repairs[212]—glans ischemia occurred in 5 cases, with resolution in 3 and loss of hemiglans in 2 cases. A straight phallus was achieved in 81%, and one pinhole coronal urethrocutaneous fistula (2.4% of patients) was successfully closed. He suggested maintaining ventral vascular attachment of the shaft skin to the urethral wedge, the urethral mesentery, which some have suggested may decrease urethral complications. Perovic has described variants of this technique for epispadias that may be used in selected circumstances as well.[213] Modifications of the complete penile disassembly technique include the use of cavernotomies to assist in the correction of chordee and incomplete separation of the urethral wedge and the corporal bodies to avoid the creation of hypospadias.

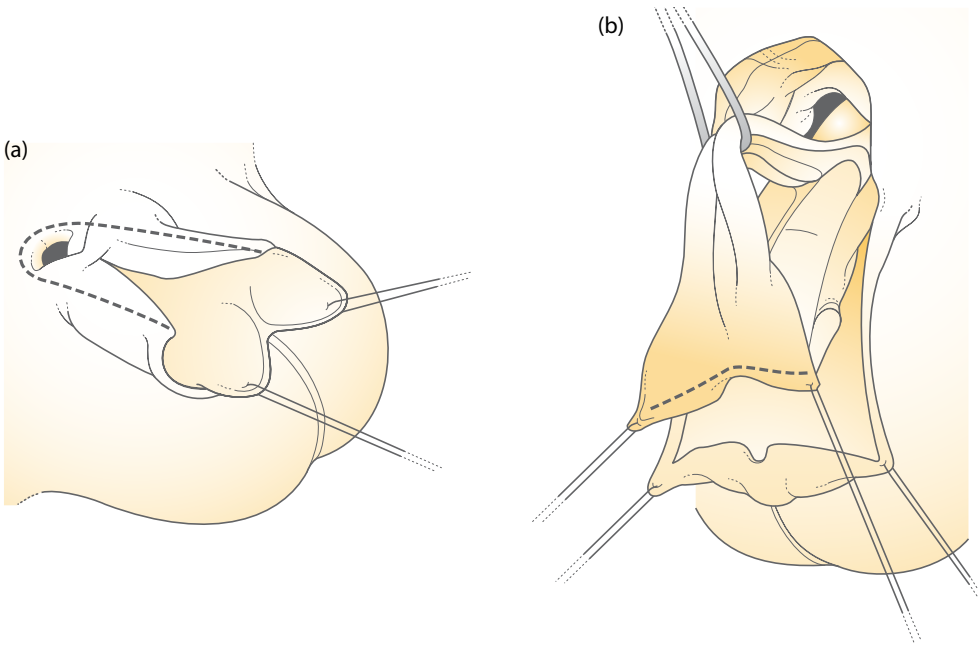

FIGURE 62.36 Complete penile disassembly technique. (a) Lines of initial dissection circumscribing the urethral plate and bladder neck. (b) Careful dissection of the urethra from the underlying corporeal bodies. Dotted line indicates the site of distal incision to free the urethra entirely from the glans. (Adapted from Mitchell ME, Bagli DJ. *J Urol* 1996;155(1):300–4. With permission.)

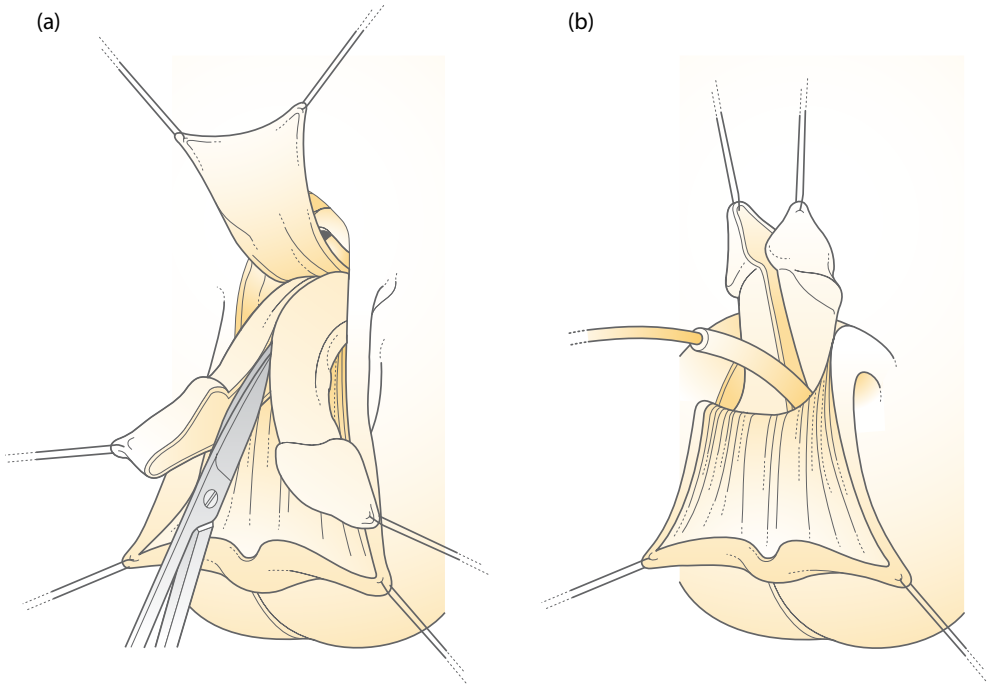

FIGURE 62.37 Complete penile disassembly technique. (a) Corporeal bodies and two hemiglans are separated by a longitudinal midline incision. (b) The urethra is tubularized and brought to the ventrum. The corpora are reapproximated dorsally. They will rotate medially when adequately dissected from each other. (Adapted from Mitchell ME, Bagli DJ. *J Urol* 1996;155(1):300–4. With permission.)

Modern Staged Repair of Exstrophy

The staged reconstruction for exstrophy developed in response to high reported rates of renal damage from single-stage approaches in the 1970s. The initial outline for staged reconstruction as conceived by Jeffs consisted of bladder and posterior urethral closure at birth, BNR at 2–3 years of life, and epispadias repair later.[214] This paradigm was altered when bladder capacity was noted to increase with the added resistance from early epispadias repair.[215,216] Thus, the current MSRE as described by

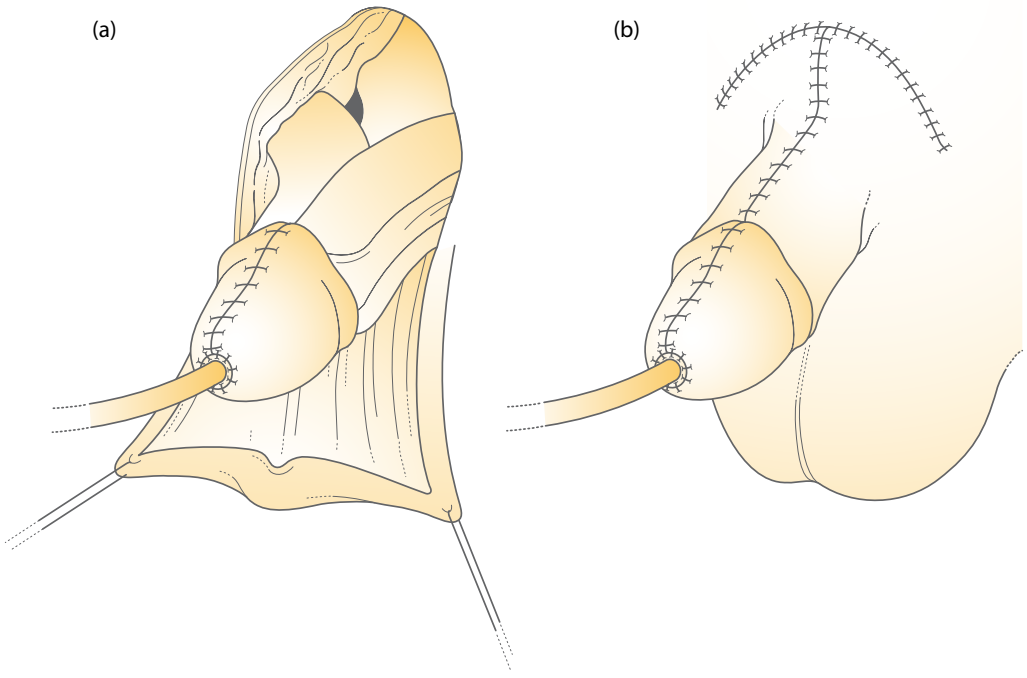

FIGURE 62.38 Complete penile disassembly technique. (a) Completion of urethral meatus; (b) completion of shaft skin coverage. (Adapted from Mitchell ME, Bagli DJ. *J Urol* 1996;155(1):300–4. With permission.)

the Johns Hopkins group consists of bladder and posterior urethral closure at birth or soon thereafter (Stage 1), epispadias repair at 6–12 months of life (Stage 2), and BNR when the bladder capacity is adequate and the child is mentally prepared for toilet training (usually at 4–5 years of life) (Stage 3).[217] In some cases, epispadias repair and BNR ± ureteral reimplantation can be combined.[218,219]

MSRE Stage 1: Initial Early Bladder Exstrophy Closure

At Stage 1 of exstrophy reconstruction, the surgical objectives include (1) closure and repositioning of the bladder and urethra (posterior urethra in males and entire urethra in females) inside the pelvic ring, and (2) approximation of the pelvic ring with closure of the abdominal wall. In male patients, at the end of Stage 1, this closure technique converts the CBE into a male with complete epispadias with incontinence and balanced posterior outlet resistance. This functional state stimulates bladder growth while preserving renal function.

Exstrophy Closure

The initial decision as to whether a bladder template is amenable to closure is currently based on subjective data. Even a small bladder template, if distensible and contractile, can enlarge to a useful size once closed. However, if an examination under anesthesia reveals a small (<5 ccs) acontractile, nondistensible bladder patch, an attempt should not be made to close this bladder.[158] While ureterosigmoidostomy has proven useful in this group of patients,[220] it is preferred to wait and reexamine the child at 4–6 months of age under anesthesia. If at later evaluation the bladder remains inadequate, a nonrefluxing colon conduit is used to divert the urine along with the abdominal wall closure and epispadias repair. This can be converted at a later age to a continent diversion or anastomosed to the rectosigmoid.

If the bladder template is amenable, early exstrophy closure is advantageous for multiple reasons. Socially, for the family, a prompt closure begins the road toward normalcy. In addition, early closure saves the bladder from prolonged exposure, which can lead to such histological changes as acute and chronic inflammation, squamous metaplasia, cystitis glandularis and cystitis cystica, and muscular fibrosis. Functionally, it is likely that this results in a bladder with low capacity and poor compliance.[215] Electron microscopy has shown that the newborn exstrophy bladder is "immature" when compared with control newborns,[221] having fewer small nerve fibers,[14] less smooth muscle, and a threefold increase in type III collagen content.[222] While it is unclear whether these changes are a part of the primary pathology or secondary to the lack of bladder cycling *in utero*, it is conceivable that prompt closure could also "mature" the bladder by restoring bladder cycling. Similarly, clinical data from the Mayo Clinic have verified the importance of immediate postnatal exstrophy closure; infants closed before 7 days of age required fewer bladder augmentations to achieve eventual continence.[223]

Appproximation of the Pelvic Ring

It has become clear that approximation of the open pelvic ring eases abdominal wall closure and diminishes the rate of bladder dehiscence and abdominal wall dehiscence.[224,225] This therefore allows the construction of an intrapelvic urethra and reapproximates the pelvic floor musculature, likely contributing to long-term continence.[36,224] Additionally, in females, osteotomy may reduce the likelihood of uterine prolapse.[224] Therefore, pelvic ring reapproximation is useful at initial bladder closure, as well as at later stages of reconstruction if satisfactory reapproximation was not achieved initially. Pelvic closure in the neonate younger than 48–72 hours old can be achieved without osteotomies due to the effects of maternal relaxin; immobilization is achieved by modified Bryant's traction for 3–4 weeks (Figure 62.15). However, beyond this age or at this time, if the pelvis is not sufficiently malleable, osteotomies are performed at the time of initial closure. An interesting predicament for the surgeon is the situation of the newborn with a large bladder template. In this case, with a bladder having great potential for later continence, the pubic diastasis will be wider and require osteotomy regardless of when closure is attempted. In MSRE with osteotomy, a combined approach of posterior vertical iniac osteotomy with anterior horizontal innominate osteotomy (Figure 62.13) is primarily used with good results.[164,165] Femoral nerve palsy is a possible complication that must be monitored and can be reduced with gradual tightening of the fixator. These osteotomies are secured by intrafragmentary pins, external fixation (4 weeks for newborns, 6–8 weeks for older patients), and light Buck's traction for 2–4 weeks (Figure 62.17).

Male MSRE Bladder and Posterior Urethral Closure Technique

In Stage 1 of MSRE of the male child (Figure 62.39), the bladder and posterior urethral closure technique[1,226] begins as ureteral catheters are placed and secured with a 5-0 or 6-0 chromic suture. These catheters aid ureteral visualization prior to making the initial incision. A traction suture is placed in the glans penis. The posterior urethra is generated by incising a 2 cm wide strip of mucosa from the distal trigone to below the distal verumontanum. Initial dissection begins at the umbilicus and is continued circumferentially, incising around the bladder plate. The entire dissection remains extraperitoneal and is performed with a Colorado tip electrocautery. The two umbilical arteries are ligated and divided. The underlying detrusor muscle is mobilized from the rectus sheath to expose but not enter the peritoneum. The peritoneum is dissected off of the dome of the bladder plate as needed to allow movement deep into the pelvis. Extraperitoneal dissection lateral to the bladder exposes the retroperitoneal space and caudally leads the dissection in the correct plane at the level of the bladder neck. At this level, the rectus fascia meets the pubis and the urogenital diaphragm fibers meet the posterior urethra/bladder neck. The urogenital diaphragm fibers and the intersymphyseal band must be completely taken down from the pubic subperiosteum bilaterally to the pelvic floor, or the posterior urethra and bladder will not be recessed within the deep pelvis.

At this point, the posterior urethra must be assessed. If the urethral groove is adequate in length, no transverse incision is made to transect the urethral plate. If the child has severe chordee and a short urethra that inhibits attempts at penile lengthening, an incision of the

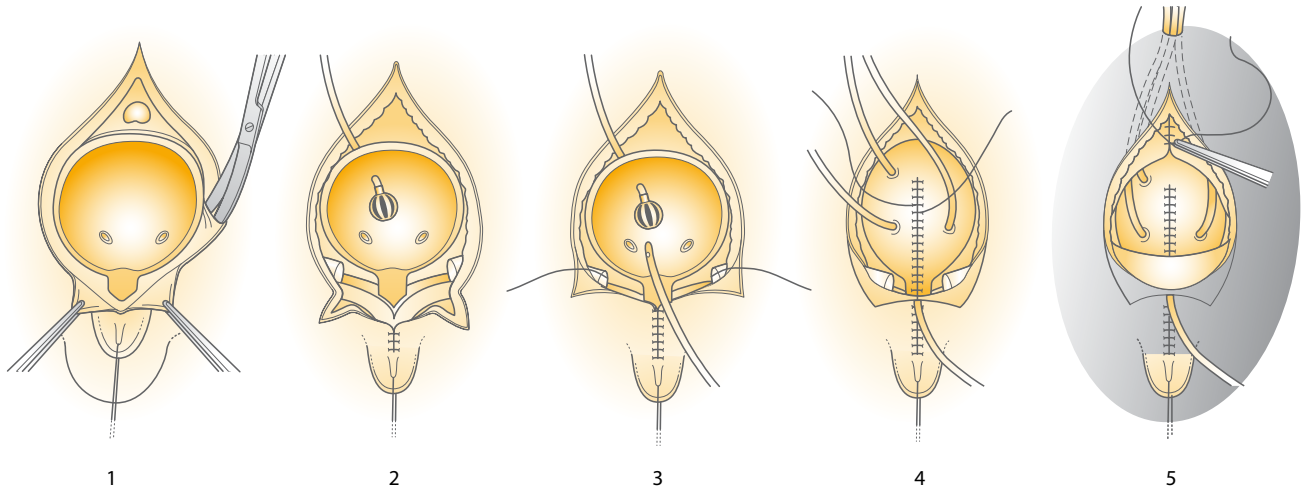

FIGURE 62.39 Primary bladder closure. These diagrams demonstrate the sequence of initial bladder closure in a staged repair for bladder exstrophy in the male patient. From left to right: (1) completion of dissection around the bladder and urethral plate; (2) placement of a suprapubic drainage tube after corporeal reapproximation; (3) tubularization of the urethral plate over the catheter; (4) following two-layer closure of the bladder and urethral plate, the bladder is reduced in the pelvis and fixed with sutures; (5) drainage tubes are brought out superiorly and the fascia, subcutaneous tissue, and skin are reapproximated. (Adapted from Brock III J, O'Neill J. *Pediatric Surgery.* Philadelphia: WB Saunders, 1998, 1709–32. With permission.)

urethral plate may be necessary. Management of this is best assessed after extensive mobilization of the bladder and prostatic plate from the rectus fascia, the pubic bones, and the inferior ramus of the pubis. Once radical division of the urogenital diaphragm fibers from the posterior urethra and bladder neck area is accomplished, the prostatic urethra can be displaced posteriorly into the pelvis. In some cases, division of the anterior attachments of the crura and the suspensory tissue of the penis is needed and displays the gap to be bridged between the prostatic plate and the penile plate. This lack of urethral plate length can be managed by dividing the prostatic plate distal to the verumontanum in a V-shaped fashion. After corporal mobilization and midline reapproximation, the penile urethral plate is fashioned from a lateral rotational flap generated after a single lateral incision into the paraexstrophy skin. Therefore, less tissue redundancy and dissection is necessary. While this has been reconstructed after the manner of Johnston[227] or Duckett,[228] paraexstrophy skin flaps should be used with great caution. The authors have noted a 40% complication rate associated with their use and significant comorbidity.[229]

The corporal bodies are not sewn together at this time, since this will be achieved after the urethra has been transposed beneath the corpora at the time of epispadias closure. Once the dissection appears complete, a sound on the posterior urethra can be compressed and the pelvis manually approximated to roughly assess completeness of mobilization of the posterior urethra and urogenital diaphragm.

After a silicone Malecot suprapubic tube has been placed, the umbilicus is excised and the bladder is closed in the midline in multiple layers with a running 3-0 Vicryl suture. The posterior urethra is also closed onto the base of the penis, sizing it to accept a 12–14 French sound. The intersymphyseal stitch is then placed but initially is not tied. No. 2 nylon suture is recommended. It is key to perform a horizontal mattress closure, planning for the knot to be placed on the anterior surface of the pubis. This technique prevents the suture or knot from eroding into the urethra or bladder neck. Once the suture is in but not tied, three surgical personnel are needed to reapproximate the pubis symphysis. One individual applies pressure over each greater trochanter to push the pubic rami to the midline. A second individual depresses the posterior urethra and bladder neck. The third individual ties the nylon suture. If the rectus fascia is strong, a second No. 2 nylon suture is placed just above the symphysis. The abdominal wall, subcutaneous tissues and skin are then closed in multiple layers. A V-shaped flap of skin is fashioned in the midline for the neoumbilicus at the level of the iliac crests. The neoumbilicus is used as the site to bring the three urinary drainage catheters out to the skin. Inguinal hernias, seen in up to 82% of males, may be surgically repaired at the time of initial exstrophy closure.[40] This can be done through separate incisions or via the midline exstrophy closure incision.

Female MSRE Bladder and Posterior Urethral Closure Technique

In Stage 1 of MSRE of the female child, the surgical technique of bladder, pelvic ring, and abdominal wall closure is identical to that described for the male. However, the closure of the female differs from the male closure in that the female urethra is completely reconstructed at Stage 1.[1,226] The urethral plate mucosal incision is 2 cm wide, traversing from the distal trigone to the vaginal orifice in the female. Paraexstrophy skin flaps are unnecessary in female exstrophy closures.[230] The medial aspect of each hemiclitoris is deepithelialized to permit approximation of the two glans clitori and reconstruction of the mons. The bladder and female urethra are closed in a two-layer Vicryl closure, and the pubic bones, abdominal wall, subcutaneous tissue, and skin are closed as outlined in the male. The monsplasty and genitoplasty are then performed.

Postoperative Care of Stage 1 MSRE

In male and female cases of initial closure, a suprapubic tube and ureteral stents are placed via the neoumbilicus since intubation of the urethra is discouraged. Additional factors that are important to the success of the initial closure include pelvic immobilization and fixation, adequate pain control, prevention of abdominal distention, and postoperative antibiotics.[225,231] The ureteral stents are maintained 2–3 weeks. Adequate urethral caliber and minimal postvoid residuals are ensured prior to removal of the suprapubic tube at 4 weeks. The status of the upper tracts is documented by ultrasound prior to discharge and is followed by ultrasound at 3 months and every 6 months to 1 year. The successfully closed child is continued on prophylactic antibiotics, for essentially all have vesicoureteral reflux. Increasing hydronephrosis, worsening vesicoureteral reflux, retained urine in the bladder, and recurrent UTIs should prompt further evaluation for suture erosion or outlet obstruction. Between the ages of 1 and 3 years, yearly cystograms under anesthesia are performed to assess the degree of reflux and, more importantly, to assess the growth of the bladder. By this age, it is hoped that the capacity will achieve 60–85 ccs.

Delayed Primary Closure

Several recent studies have advocated for the use of delayed primary closure, especially in regard to the use of the complete primary repair technique. Proponents of delayed repair argue that it is safer for the child, and allows a more coordinated surgical effort and time for the most expert team of clinicians to be available to provide surgical care.[232] Others have shown it is feasible to wait months after birth.[233] Zaccara and coworkers used the delay to stimulate the penis with testosterone with the goal to reduce the chance of glans injury and reported good short-term outcomes with this approach in six patients.[234] The successful use of a delayed closure is predicated on adequate protection of the exposed vesical tissue while waiting to coordinate the primary repair. In a series from Mansoura, Hafez showed that delayed use of the primary complete repair technique is also possible in late or initial failed exstrophy closures.[197] A delayed repair does have its disadvantages. Nelson and Gearhart have shown an increased cost, with immediate newborn closure costing roughly two-third that of a delayed repair at their institution.[235]

MSRE Stage 2: Epispadias Repair

Since the initial description by Jeffs of the staged reconstructive approach to exstrophy, the timing of the epispadias repair has undergone change. Originally, Jeffs advocated epispadias repair as the last stage of reconstruction. However, he later recognized that earlier epispadias repair increased the success of later continence procedures by stimulating bladder growth and increasing bladder capacity.[215] In MSRE, epispadias repair (Stage 2) is now typically performed at 12–18 months of age via the modified Cantwell–Ransley technique (Figure 62.40). Epispadias repair can prove challenging. The goals of epispadias repair include a straight penis and urethra, easy urethral catheterization, normal erectile function, and a cosmetically satisfactory phallus. These goals allow the patient to stand while voiding and to have intromission during intercourse.

Preoperative Considerations

In preparation for this repair, the following questions must be addressed: (1) Would preoperative stimulation of penile growth with testosterone benefit the repair? (2) Is penile straightening and lengthening required at this time? (3) Is the current posterior urethral meatus ideal, that is, without and/or not prone to stricture?

Prior to performing the epispadias repair, several surgeons use topical or intramuscular testosterone to increase the size of the phallus and the phallic skin.[213,236,237] Intramuscular testosterone enanthate in oil (2 mg/kg) can be administered at 5 and 2 weeks prior to epispadias closure. The decision as to the need for penile lengthening

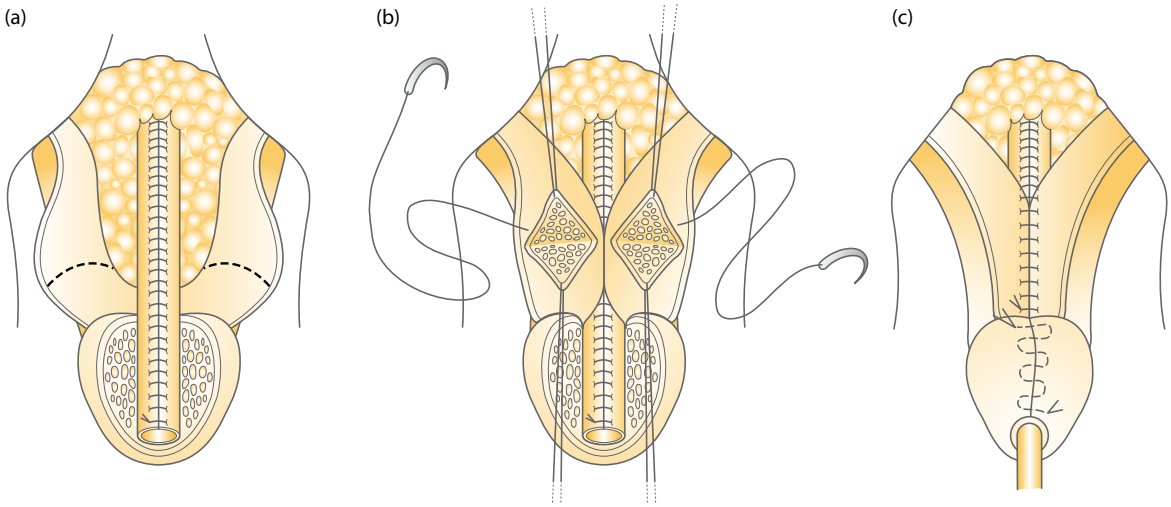

FIGURE 62.40 The steps for the Cantwell–Ransley repair for epispadias. (a) The tubularized urethral plate is placed in a dorsal groove incision in the glans penis. The dotted lines indicate the site of incision for the cavernosa – cavernosotomies; (b) approximation of the corpora cavernosa and performance of cavernosal anastomosis; (c) glans closure over urethra and skin closure. (Adapted from Brock III J, O'Neill J. *Pediatric Surgery*. Philadelphia: WB Saunders, 1998, 1709–32. With permission.)

can then be made after the response to testosterone has been observed. Penile lengthening can be achieved almost always at this time by division of all remnants of the suspensory ligament and scar tissue, as well as further release of the crura from the inferior pubic rami. It is surprising how much of this tissue is intact at the onset of the epispadias repair. In some situations, further urethral lengthening may require free skin grafts, buccal mucosal grafts, ureteral grafts, or pedicle skin flaps. These same maneuvers can be used to repair the scarred or stenosed posterior urethra.

Modified Cantwell–Ransley Technique

Cantwell first described mobilization of the urethra and moving it ventrally for epispadias repair.[238] Ransley subsequently modified this technique and reported on his results in 1988.[239] To begin this procedure, a stay suture is placed into the glans penis (Figure 62.40). A reverse meatal advancement and glanduloplasty (MAGPI) or IPGAM procedure at the distal urethral plate allows advancement of the urethral meatus onto the glans. Following this, skin incisions are made on the lateral edges of the urethral plate and around the epispadic meatus. This plate is dissected from the corporal bodies up to the level of the glans distally and to the prostatic urethra proximally. Glandular wings should be developed distally as well. The corporal bodies are then separated from each other. This allows them to be rotated medially. The urethra is then tubularized over a 6 or 8 French urethral catheter, using a running 6-0 absorbable suture. The corporal bodies are rotated over the urethra and reapproximated using a 5-0 absorbable suture in an interrupted fashion. Cavernocavernosotomies may be performed prior to reapproximating the corporal bodies to help correct persistent chordee. These are performed at the point of maximal angulation. The neurovascular bundles may require mobilization to avoid injuring them if cavernosotomies are performed. The glans wings are then closed over the urethra using interrupted 5-0 absorbable suture. Penile shaft skin can be trimmed and tailored to cover the penis using interrupted 5-0 or 6-0 absorbable sutures. Z-plasties at the level of the pubis may decrease the chance of a dorsal retractile scar at the base of the penis. Postoperative care includes bladder antispasmodics, broad-spectrum antibiotics, and removal of the urethral catheter at 2 weeks.

Outcomes of this technique have revealed urethrocutaneous fistula rates ranging from 5.5% to 42%. In Lottmann and colleagues' series of 40 patients, a successful anatomic and functional result was seen in 90% of the patients at a mean follow-up period of 3 years. These authors also reported complications requiring further procedures in 45%. Complications were more common in those patients who underwent this procedure as part of an exstrophy closure versus isolated epispadias.[240] A recent review of the 10-year Johns Hopkins experience with the modified Cantwell–Ransley procedure[241] found 79 patients with CBE and 14 with complete epispadias: 23% developed early urethrocutaneous fistulas, with a 19% fistula rate at 3 months postoperatively; 7.5% developed urethral stricture proximally, and 83% had a straight urethra by cystoscopy or catheterization; 93.5% had a horizontal or downward-angled penis when standing. Long-term experience with 93 patients with the modified Cantwell–Ransley repair finds a conical glans, a straight penis, and a urethra below the corporal bodies with an acceptable complication rate.[241]

MSRE Stage 1 + 2: Combined Exstrophy and Epispadias Closures

In the event of a significantly delayed primary closure or an initial bladder closure failure, a simultaneous closure of the exstrophy bladder and the epispadias can be performed. The advantages to this approach include one less anesthetic exposure and increasing outlet resistance to stimulate bladder growth. Again, in this scenario, the combined horizontal innominate and the posterior vertical osteotomies are necessary for a secure bladder, abdominal wall, and posterior urethral closure and can allow transposition of the urethra to beneath the corpora with some dissection. This combined approach of simultaneous exstrophy and epispadias closures has been performed in 38 patients at Johns Hopkins with comparable results (i.e., fistula rate, BNR rate, augmentation rate, and continence rate) to age-matched patients who underwent the classic staged approach after failed initial closure.[219]

Bladder Neck Reconstruction: Preoperative Assessment

In incontinent children after CPRE or MSRE, a continence procedure is indicated when (1) the urethra is stricture-free and capable of catheterization if necessary; (2) under anesthesia, the bladder capacity has achieved a minimum volume of 60–85 cc; and (3) the child is mature enough to participate in the postoperative voiding program.[242] This is typically around age 4–5 years. Following a careful history and physical exam, cystourethroscopy and a gravity cystogram under anesthesia are performed for all patients before proceeding to open BNR. Cystoscopy and a gravity cystogram provide information regarding bladder capacity and the status of any previous repairs, including correction of epispadias. Advocates of staged reconstruction emphasize the importance of achieving adequate bladder capacity prior to performing BNR. A bladder capacity of less than 60 mL under anesthesia or during urodynamic evaluation decreases the success of BNR.[32,203] BNR requires adequate bladder capacity because some volume is lost during construction of the bladder neck. Factors that increase the potential for the bladder to achieve adequate capacity prior to BNR include

- Avoidance of urinary tract infections
- Complete bladder emptying with institution of clean intermittent catheterization if bladder emptying is incomplete
- Epispadias repair
- Avoidance of bladder prolapse[43]

Preoperative urodynamic evaluation should be considered because it allows the detection of detrusor hyperactivity or atony, as well as the assessment of functional bladder capacity and leak point pressures. However, the urethra of these patients may be difficult to catheterize. In these situations, a urodynamic catheter can be placed suprapubically

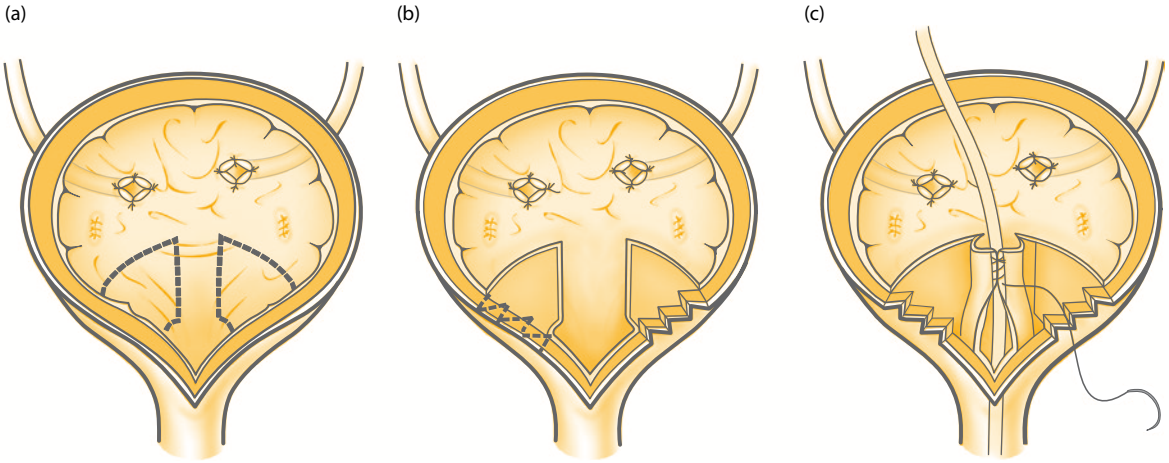

FIGURE 62.41 Principles of the Young–Dees–Leadbetter procedure. This is performed as the third stage of a staged reconstructive approach to exstrophy. The ureters are reimplanted as shown here to prevent vesicoureteral reflux and move them out of the area of the bladder neck reconstruction. The base of the bladder is reconstructed to lengthen the urethra and reinforce the bladder neck. (Adapted from Brock III J, O'Neill J. *Pediatric Surgery*. Philadelphia: WB Saunders, 1998, 1709–32. With permission.)

at the time of the cystourethroscopic examination to be used later that day for the urodynamic evaluation.

Ureteroneocystostomy may be required at the time of BNR to correct vesicoureteral reflux and to move the ureters from the lower bladder where BNR will occur. The Cohen technique is often employed. However, others have described a cephalotrigonal technique that is particularly applicable to exstrophy patients because of the angle of ureteral entry into the bladder.[243] The Marshall–Marchetti–Kranz bladder neck suspension or a bladder neck wrap using rectus muscle or fascia or gracilis may be combined with BNR as well. It is also necessary to reassess whether osteotomy might stabilize the intersymphyseal bar and improve continence at the time of BNR.

The following section describes the most commonly employed BNR techniques, including the modified Young–Dees–Leadbetter (YDL) (Figures 62.41 and 62.42) and the Mitchell (Figure 62.43) repairs.

MSRE Stage 3: Modified Young–Dees–Leadbetter Bladder Neck Reconstruction

The modified YDL bladder neck plasty[244] and the transtrigonal or cephalotrigonal bilateral ureteral reimplantation[243] are the surgical techniques employed in MSRE Stage 3. As evidenced by the name, the combined thoughts of several surgeons spanning over an 82-year period have led to the modern YDL-BNR.[242] To perform a modified YDL procedure (Figures 62.41 and 62.42),[244] the bladder neck is extensively dissected and a vertical cystotomy is made. Occasionally, a portion of the intersymphyseal bar must be resected or the pubic bar divided completely for visual access. After transtrigonal or cephalotrigonal bilateral ureteral reimplantation,[243] a strip of bladder mucosa approximately 1.5–1.8 cm wide and 3–4 cm long is generated and the lateral bladder triangles are demucosalized. Use of an epinephrine-soaked sponge during this dissection aids in hemostasis and visualization. The bladder

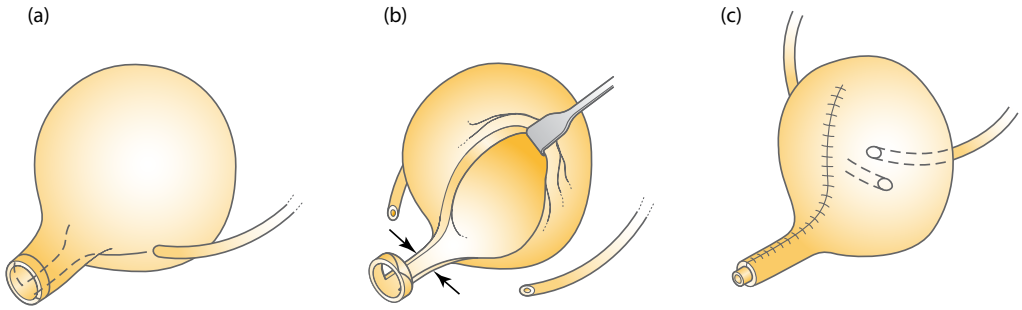

FIGURE 62.43 Mitchell bladder neck reconstruction. (a) Dotted lines represent incisions that will construct posterior bladder strip that will become urethra. (b) Retractor pulling inferior-most portion of the bladder superiorly, effectively enlarging bladder dome. Posterior strip (arrows) is 1.5 cm in width. Ureters detached from bladder. (c) Strip and bladder closed, ureters reimplanted into bladder at high level.

neck may be funneled further with small vertical incisions along the cut edge of the lateral bladder walls. The neourethra is tubularized over an 8 French Firlit stent using interrupted or running polyglycolic acid sutures (4-0 or 5-0). The first of these sutures is a 3-0 PDS, demarcating the bladder neck. The two triangular regions of the demucosalized detrusor muscle are then closed over the mucosal tube in a two-layer "vest over pants" double-breasted technique using 3-0 polyglycolic acid sutures.[43] This reinforces the neobladder neck, decreases the risk of fistula, and augments the outlet resistance.[245] The sutures in the third layer are not cut since they are used in the Marshall–Marchetti–Krantz bladder neck suspension.[242]

In the past, Gearhart has advocated the use of intraoperative urodynamic studies,[246] but now does not routinely perform this. Retrospective studies have shown that intraoperative closure pressures of 70–100 cm H_2O will prevent urinary leakage at 50 cm H_2O intraoperatively.[243] Postoperative management is similar to that following the Mitchell repair. Some surgeons recommend avoidance of a urethral catheter in the postoperative period because of concerns that it may adversely affect later urinary continence. Urinary drainage is achieved by the use of bilateral ureteral catheters and suprapubic tube drainage.[245] Ureteral stents are removed around 2–3 weeks, and voiding trials begin in the third week. The urethra is calibrated with a soft 8 French catheter, and voiding trials are begun with the suprapubic tube in place after the urine has been sterilized. If no urine is passed, cystoscopy and urethral stenting may be required for a short period of time. A bladder readjustment period may span several months before day and subsequently night continence is achieved.

Bladder Neck Reconstruction after CPRE: The Mitchell Repair

This repair employs a modification of the Leadbetter procedure technique described above (Figure 62.43).[244] In this modification, the anterior urethra is incised *transversely and the incision is extended cephalad*. The incision is made full thickness. After cross-trigonal ureteral reimplantation, the urethral strip is tubularized in two layers using a Vicryl or Monocryl suture (4-0 or 5-0) over an 8–10 French urethral catheter, depending on the size of the patient. The bladder may be closed in continuity with the urethral closure. This procedure effectively narrows and lengthens the urethra. It also moves fibrotic tissue at the level of the original bladder neck away from the new bladder neck. Following the closure, dissection around the new bladder neck may be performed if a combined bladder neck wrap or sling will be placed simultaneously.

Postoperatively, urine is drained through a combination of ureteral stents, a suprapubic tube, and a 6 French (Kendall®) urethral catheter. The urethral catheter is removed 7–10 days after the operation. Ureteral stents are removed at 10–14 days after surgery. The suprapubic tube remains for 3 weeks. Voiding trials are performed with measurement postvoid residual urine volumes to assess for urinary retention before removing the suprapubic tube. As with any BNR procedure (without augmentation), several months of adjustment will be required before the patient develops adequate bladder awareness, capacity, and control to achieve prolonged intervals of urinary continence.

Occasionally, trigonal tubularization must be combined with bladder augmentation because of small bladder capacity; most bladder neck repairs decrease bladder capacity since the bladder is used to create the continence mechanism.[247] The stomach offers the best potential to preserve spontaneous volitional voiding in this group, but places these children at risk of hematuria–dysuria syndrome, which can be especially troubling in the face of persistent urinary incontinence and normal sensory innervation.[248] Other intestinal segments may also be used according to surgeon preference. If augmentation is required, appendicovesicostomy or another form of the Mitrofanoff operation can be simultaneously performed if the urethra is difficult to negotiate because of the likelihood that the patient will require intermittent catheterization to empty the bladder after BNR.

BNR Results

After BNR, surgical success is defined as a dry interval of >2–3 hours and spontaneous voiding without catheterization. YDL-BNR and its variants have yielded surgical success with urinary continence rates of 30%–80+% for patients with bladder exstrophy.[244,249–253] Many factors influence the outcome of surgery. For instance, an initial failed bladder closure or prior failed BNR reduces the chance to achieve subsequent urinary continence in these patients.[32] A preoperative bladder capacity of >85 ccs

portends a greater continence rate after YDL-BNR.[254] Use of osteotomies to provide a tension-free anastomosis and patient immobilization through the use of spica casting or Bryant's traction in the postoperative period increases the success of bladder closure and subsequent continence.[218,219] Delayed bladder closure increases the likelihood of eventual need for bladder augmentation due to inadequate bladder capacity that, in turn, reduces the chance for volitional voiding.

Woodhouse and Redgrave have also reported that 8 of 13 patients with initially successful bladder closures and BNR required further surgery in their second decade of life because of poorly compliant, low-capacity bladders that caused urinary incontinence.[255] Surgeons who care for these patients must be committed to the long-term follow-up of this complex group of patients, as late complications may develop. Bauer and Diamond found that only 25% of patients maintained normal detrusor function following YDL-BNR, with compliance and stability being impaired after reconstruction in their series.[256]

Outcomes of MSRE

In contrast to the high rate of renal damage reported by multiple centers employing a single-stage reconstructive effort to bladder exstrophy in the 1970s, results from a staged reconstruction approach appeared significantly better at that time. Jeffs and colleagues reviewed their results with staged reconstruction and noted normal upper urinary tracts in 87%.[257] Later series from Johns Hopkins also achieved low rates of renal damage (12% and 17%, respectively).[224,258]

Urinary continence rates with single-stage efforts in the 1960s and 1970s were also not consistently successful. Continence rates ranged from 0% to 45%, with an average of 17%. In contrast, staged efforts by Jeffs and others demonstrated continence rates of 60%–88% (Figure 62.22).[183,215,225,249,259–262] These results prompted a shift from single-stage reconstruction to planned multiple-stage reconstruction for bladder exstrophy. Accumulation of the data from several series of staged reconstructions reveals that early exstrophy closure, only if in conjunction with pelvic ring approximation, results in a higher rate of continence achieved without augmentation; delayed closure, especially if without osteotomies, resulted in more bladder augmentations.[223,225] Bladder capacity under anesthesia, prior to bladder neck plasty, is the most important single predictor of eventual urinary continence.[21]

Others using the staged approach to exstrophy reconstruction have generally noted lower rates of urinary continence—as low as 9%—with the need for clean intermittent catheterization to achieve urinary continence in as many as 60% of these patients.[244,255,263] These series reflect the variable success of staged reconstruction. Conversion rates in these patients from reconstructive efforts to urinary diversion range from 7.4% to 59.4%.[255,260,264]

Exstrophy Reconstructive Failures

> Errors cannot be avoided. Errors in judgement must occur in the practice of an art which consists largely of balancing probabilities.
>
> *Sir William Osler*

Failed Initial Closure

At the primary closure, failures can manifest as complete bladder dehiscence, bladder prolapse with obstruction, and stricture of the posterior urethra. Failure of the initial closure significantly decreases the chance for eventual continence with volitional voiding.[231,245,265] Gearhart and colleagues reported that only 40% of patients after a failed primary closure attempt will ultimately achieve a bladder capacity adequate for BNR.[243] If more than two closure attempts are required, chances for continence decrease to 20%.[266]

Dehiscence may be largely prevented by approximation of the pelvic ring, adequate pelvic immobilization, prevention of wound infection, abdominal distention, or urinary tube malfunction.[225,231] The child should be given a 6-month recovery period prior to a second attempt at closure. A tension-free closure with osteotomy and immobilization are important factors for both initial and secondary closures.[31] As noted above, the likelihood of obtaining an adequate bladder capacity for bladder neck plasty and eventual continence is markedly diminished following multiple reclosures[31,250,251,267,268]

Bladder prolapse is considered a failure essentially similar to dehiscence and will require bladder reclosure or revision. Prolapse represents dehiscence of the lower end of the closure. It is a consequence of incomplete pelvic ring closure, which is why simple reclosure without osteotomy and pelvic closure is likely to be ineffective.

Bladder outlet obstruction is characterized by postvoid residuals greater than the expected bladder capacity. Outlet obstruction increases the risk of renal damage by raising storage pressures to dangerous levels; this is especially dangerous if unrecognized for several months or more.[41,42] Outlet obstruction also increases the risk of urinary tract infection. The bladder outlet following initial bladder closure may be assessed with sounds or bougies 4–6 weeks after closure to detect stenosis. Ultrasonography of the bladder and upper tracts should be performed 3 months after closure to detect hydronephrosis or bladder distension that might indicate outlet obstruction. Hydronephrosis and high bladder volumes require evaluation with cystoscopy, followed by urethral dilation or the institution of intermittent catheterization as indicated. In a review of 68 patients at Toronto Sick Children's Hospital, 23% developed hydroureteronephrosis following the initial closure, and all were successfully treated with dilation of the bladder outlet or institution of clean intermittent catheterization.[41,42]

Neourethral stricture is often associated with the use of paraexstrophy skin flaps in the posterior urethra;[250,251] pubic suture reaction and erosion or urethral stents have been felt to contribute to this problem. This diagnosis may be somewhat subtle; urinary tract infections, detectable bladder volumes on ultrasound, bladder stones, and prolonged dry periods may be indicators. While nearly all closed exstrophy bladders have vesicoureteral reflux, upper tract deterioration is always due to outlet obstruction. Management options include upper tract diversion (usually diversion into a colon conduit that might be incorporated into augmentation or continent diversion at a later date), urethral dilation and incision, or open urethroplasty

with or without osteotomies, as indicated.[269] Clearly, if renal function is compromised, the therapy must achieve reliable free drainage to allow the upper tracts and the kidneys to fully recover. No additional bladder neck or urethral reconstruction should be performed in the face of an active posterior urethral stricture.

Failed Genital-Urethral Reconstruction

Urethrocutaneous fistula is the most common complication of Cantwell–Ransley epispadias closure, seen in 19% of patients at 3 months postoperatively.[241] Urethral tortuosity with difficult catheterization and strictures are uncommon with this or the Mitchell repair.

At an older age, unsightly penile scars and a short phallus may prompt further surgical intervention. Scar excision can be closed in a plastic fashion if penile skin is available; otherwise, flaps or full-thickness skin grafts can be used. Freeing all scar tissue and suspensory ligament tissue can maximize penile length. A dorsal dermal corporal graft[270] or ventral corporal plication and rotation (Cantwell–Ransley type)[271,272] may additionally help lengthen as well as correct any chordee. However, it must be recognized that the exstrophy penis, when compared with age- and race-matched controls, is congenitally deficient in anterior corporeal tissue as assessed by MRI (Figure 62.3). The posterior corporeal segments, attached to the inferior pubic ramus, are the same length as controls. Therefore, overly aggressive attempts at lengthening the penis may only result in corporeal denervation and devascularization without additional lengthening.[17]

A significantly small phallus can lead to low self-esteem, psychosocial and psychosexual dysfunction, and suicidal ideation. Thus, neophallic reconstruction has been performed, although this procedure is done in a select few centers and with significant risk for complications.[273,274]

Failure to Gain Bladder Capacity

Despite a satisfactory initial closure, some bladders never attain sufficient capacity for normal function. It has become clear that multiple bladder closures, bladder prolapse, dehiscence, bladder calculi, recurrent infections, and vesicostomy have a negative impact on the potential of the exstrophy bladder.[275] Bladder augmentation is recommended in this situation. If the bladder neck and/or urethra is problematic, a catheterizable abdominal stoma with or without bladder neck plasty or transection is performed with the augmentation.[269]

Failed BNR

If urinary continence, defined as a >2- to 3-hour dry interval, is not achieved within 2 years of BNR, this is considered a failure. "Voiding" for an individual with exstrophy is passage of urine against a relatively fixed resistance and thus is not exactly normal.[276,277] Patients who fail to achieve continence after BNR should undergo urodynamic evaluation. Some patients will demonstrate detrusor underactivity,[278] stable detrusor,[279] or uninhibited bladder contractions resulting from increased resistance at the bladder neck after reconstruction. Treatment with anticholinergic agents such as oxybutynin can significantly improve the continence of these patients. If urodynamic evaluation reveals a bladder with adequate capacity but low leak point pressures, the YDL procedure can be performed again. Some success has been seen in repeating a YDL repair if the bladder neck is patulous and the bladder capacity is adequate.[280–282] However, this is an unusual occurrence. The majority of bladder neck failures have inadequate bladder capacity and require eventual augmentation or a continent diversion.[31,32,229] Either the bladder neck is transected proximal to the prostate with a Mitrofanoff substitution or a continence procedure is performed, such as artificial sphincter[283,284] or injection of bulking agents.[230,281,282,285]

Delayed urinary continence has been reported by Kramer and Kelalis at the onset of puberty in some males and has been attributed to prostatic growth.[286] By MRI, the prostate of exstrophy patients is clover shaped and absent anteriorly, while its mean weight, maximal cross-sectional area, and volume are normal.[21] Therefore, it is doubtful that growth of this abnormally configured prostate can impact urinary continence, although the experience of improved continence at puberty is not uncommon.

Recently, autologous myoblasts or muscle-derived cells have been injected in incontinent epispadias–exstrophy patients with mixed success.[287–289]

Management Alternatives after Failed BNR

After failed BNR, several other options are available.

Artificial Urinary Sphincter

An artificial urinary sphincter may be used to achieve urinary continence in patients who have adequate bladder capacity and compliance but an incompetent bladder neck after BNR.[284] This device preserves the ability to volitionally void, but because of the requirements for later revision and the dexterity required to use it, it is not our first choice for younger patients. Others have described its use in combination with bladder augmentation. In one series of 11 patients who underwent sigmoid augmentation with artificial urinary sphincter placement, 9 are continent. However, these patients required multiple operative revisions to achieve this degree of continence.[290] Sphincter erosion into the bladder neck or bowel segment can also occur, possibly due to prior surgeries of the urethra and bladder neck.[291]

Bladder Neck Wraps and Slings

Bladder neck wraps and slings may also be used. However, other series reporting on the use of bladder neck wraps suggest that this procedure does not consistently maintain long-term urinary continence, especially in male patients, who constitute the gender majority in exstrophy.[224,225]

Bladder Neck Bulking Agents

Several authors have used collagen injections[230,292,293] and, more recently, dextranomer (Deflux™)[294–296] at the bladder neck to treat patients with stress incontinence after BNR or primarily in mildly affected epispadiac patients. Ben-Chaim et al. reported an improvement in continence in 53% of patients after collagen therapy, although most required multiple injections.[230] Since this injection

is placed into a previously operated field, overall success rates for bladder neck bulking agents are significantly less than the success rates achieved for vesicoureteral reflux (in children without exstrophy).[297] Bulking agents can be used as an adjunctive procedure for those patients who demonstrate slight leakage due to stress incontinence after BNR.

Bladder Neck Closure

Bladder neck closure in conjunction with appendicovesicostomy is also an option in those patients who have failed multiple attempts at BNR. This option eliminates the chance to void per urethra and commits the patient to intermittent catheterization. It is difficult, if not impossible, to reverse.

Urinary Diversion

Proponents of urinary diversion for the treatment of exstrophy argue that the varying continence rates achieved with functional reconstruction demonstrate the unreliability of this approach.[298] The use of the native bladder will often require later bladder augmentation with intestinal segments to achieve a functional bladder storage capacity. Certainly, some centers report poor rates of continence after primary reconstruction, and some urodynamic studies do demonstrate low urine flow rates and poor contractility in patients following primary bladder reconstruction.[299,300]

Primary urinary diversion avoids the complications associated with functional reconstruction, including urinary retention and subsequent kidney damage, a predisposition to urinary tract infection, and later dependence on clean intermittent catheterization to empty the bladder with its own possible complications of urethral stricture formation, epididymitis, and urinary tract infection.[301] Advocates of early urinary diversion also cite a decreased risk of epididymitis and obstruction of the vas deferens by the creation of a seminal receptacle with a suprapubic window at the level of the prostatic urethra.[301] Diversion can be combined with cosmetic operative procedures for the external genitalia.

Urinary diversion is used to provide urinary continence in patients who have failed multiple attempts at functional reconstruction.[302] Some also advocate primary urinary diversion for patients with bladder plates deemed too small to close. However, because it is impossible to *accurately predict* which bladder plates will increase significantly in size after primary closure, we *do not* divert the urine primarily in exstrophy patients. Arap has described preserving the very small bladder by using it as the continence mechanism rather than a storage vessel after anastamosing the ureters to a sigmoid conduit in an antireflux manner.[359] Final reconstruction involves attachment of the sigmoid conduit to the neourethra and reconstruction of the abdominal wall.

Advocates of early urinary diversion argue that it achieves the primary goals of surgical intervention for bladder exstrophy with fewer operations and higher success rates than are achieved with bladder closure and urethral reconstruction. Prior to the popularization of staged reconstruction, ureterosigmoidostomy was the treatment of choice for exstrophy reconstruction. The long-term complications of ureterosigmoidostomy, including hyperchloremic metabolic acidosis, chronic pyelonephritis, and a 250- to 500-fold increased risk of colonic adenocarcinoma formation at the site of anastomosis dampened enthusiasm for this procedure despite improvements in ureteroenteral anastomoses.[303–306] Ureterosigmoidostomy was subsequently replaced by incontinent urinary diversions, such as the colonic and ileal conduits, which have the disadvantage of an external appliance. The introduction of clean intermittent catheterization allowed the development of continent urinary diversions, which are now the preferred method of urinary diversion to the abdomen in this population.

Rectal Reservoirs

Various investigators have made significant improvements on the use of the rectum as a urinary reservoir, including the Mainz II pouch and the sigma pouch.[298,301] Use of a rectal reservoir permits urinary continence without reliance on clean intermittent catheterization. Hohenfellner and Stein report a 92% rate of renal preservation in their series of children treated primarily with a urinary rectal reservoir (Mainz II pouch since 1991). Continence rates of 97% in school-aged children are reported in using this technique.[301] The Heitz–Boyer–Hovelaque procedure involves isolation of a rectal segment for ureteral implantation, followed by posterior sagittal pull-through of the sigmoid colon through the anal sphincter to achieve both urinary and fecal continence with separate anal openings for each. A small series using this procedure reported continence rates of 95% with acceptable complication rates.[307] The modified Heitz–Boyer–Hovelacque rectal bladder at 5–10 years' follow-up showed continence, except minor urine loss at night; few to no UTIs, and excellent renal function in 14 children[308] and in 19 children.[309]

Complications of rectal diversion include fecal–urinary incontinence in patients with impaired anorectal sphincter control.[245] Metabolic electrolyte imbalances can be treated with complete frequent emptying of the rectal reservoir, reducing the contact time between urine and the absorptive mucosa, along with oral bicarbonate replacement. Oral bicarbonate replacement is recommended for all patients who have a base deficit of 2.5 mmol/L or greater.[301] The risk of malignant degeneration still remains with use of a rectal urinary reservoir. If the increased risk of adenocarcinoma is due to conversion of urinary nitrates into carcinogenic nitrites by fecal bacteria, modifications of the rectal reservoir to prevent admixture of feces and urine may theoretically decrease the incidence.[310] Long-term results are not yet available.

Approaches to Urinary Diversion

Methods to construct urinary diversions include the following.

Continent Diversions

External diversions (continent urinary reservoir)

- Indiana pouch
- Mainz pouch
- Penn pouch

- Kock pouch
- Others

Internal diversions (rectal sphincter-based continence)

- Ureterosigmoidostomy
- Sigma pouch
- Ghoneim reservoir
- Gersuny
- Heitz–Boyer–Hovelacque procedure
- Rectal bladder with proximal colostomy
- Ileocecal ureterosigmoidostomy

Incontinent Diversions

- Ileal conduit
- Colon conduit
- Ileocecal conduit

Management of Cloacal Exstrophy

Introduction

Although CE has been recognized for at least several hundred years, Spencer was the first surgeon to report the successful repair and survival of an infant with this anomaly in 1965.[311] Mortality rates of infants with CE remained high for years following this initial success. In 1979, the mortality rate of a contemporary series stood at 50%.[312] Affected infants routinely died of malnutrition and sepsis. With continuing improvement in total parenteral nutrition and neonatal management, mortality rates currently are less than 10%.[313] Issues of quality of life are now paramount in this patient group.

Perioperative Management

CE patients are best cared for by a team of experienced physicians, including a pediatric urologist, surgeon, orthopedist, gastroenterologist, endocrinologist, and neurosurgeon. Given many are diagnosed prenatally by ultrasound, this multiorgan system care can often be coordinated prior to the infant's birth. Advances in neonatal care, intravenous nutrition, and the surgical management of these children have markedly reduced the mortality and morbidity of this disease. Nonetheless, the management of these children remains challenging.

In the neonatal period, the bladder and hindgut plate should be covered (Saran Wrap or Vigilon) to protect these structures. The umbilical cord should be ligated with a silk suture to prevent an umbilical clamp from abrading the bladder or hindgut plate. Antibiotic prophylaxis should be given to these patients because of the high incidence of renal abnormalities.

Preoperative studies include ultrasonography, abdominal x-ray, and karyotyping. Sonographic examination allows the evaluation of the upper urinary tracts, internal genital structures, and spinal cord. Because the genital anomalies associated with CE may make it difficult to accurately identify the sex of the baby (Figures 62.8 and 62.44), karyotyping is indicated to define the chromosomal sex in situations where the gender of the infant is unclear.

FIGURE 62.44 Female cloacal exstrophy. When compared with male cloacal exstrophy in Figure 61.8, each hemiclitoris is not much smaller than each hemipenis. However, closer inspection reveals labia majora instead of bilateral rugated hemiscrotum. The vaginal orifices cannot be seen in this view, but are present.

Cloacal Exstrophy Closure Techniques

Each CE patient is unique, requiring an individualized surgical plan. As indicated above, closure of a CE should involve a team of pediatric specialists experienced in the care of these children. If the baby is medically stable, the initial reconstructive procedures should be performed within the first 48 hours of life, thus taking advantage of the pliable bony pelvis if closure of the entire defect is possible. However, in 29%–75% of these children, spina bifida is present and may need surgical intervention, delaying the ventral abdominal wall closure. In addition, the omphalocele, seen in 88% of CE patients,[314] may require immediate care to prevent rupture. The size of the omphalocele, the size of the hindgut plate and bladder plates, the extent of the pubic diastasis, and the extent of comorbidities largely dictate the timing and staging of the initial closure. A large omphalocele containing liver may preclude any attempt at complete closure.[26] If the large omphalocele is not closed because of increased abdominal pressure or tension, a silastic silo closure may be used as a delayed closure of the abdominal hernia, or an alloderm graft can be used to complete the closure.

Gastrointestinal issues are paramount. Although in the past a terminal ileostomy was routinely performed, the metabolic consequences can be significant. Currently, management decisions focus on the use of the exstrophic cecal plate and the terminal blind-ending hindgut. Options for the cecal plate include retaining it in the bladder closure as a bladder augmentation versus separating it and reconstructing it for the fecal stream. To improve bowel length and water resorption, most recommend that the cecal

plate be tubularized, making the terminal ileum, cecum, and blind-ending hindgut segment all in line for the fecal stream. The hindgut segment can be anastomosed in either an isoperistaltic or antiperistaltic fashion and brought out as the terminal colostomy. In some cases, there are hindgut duplications. No segment of bowel should be discarded unless absolutely unusable, since it could be used in reconstruction of the bowel, bladder, or vagina. Similarly, appendiceal segments should be preserved in these patients for possible use in later reconstruction of the urinary tract. Few patients with CE are candidates for an anal pull-through procedure. The best candidates are children with anal fistula and preserved innervation.

Before the dissection begins for bladder closure, ureteral catheters are placed in the ureteral orifices and secured in place with a 5.0 chromic suture. The omphalocele repair is begun with the initial dissection beginning superiorly. The umbilical vessels are ligated and the bladder plates separated from the adjacent skin, as described in the CPRE and MSRE techniques. The medial cecal hindgut plate is separated from the paired, separated bladder plates and tubularized. After the hindgut has been reconstructed, the bladder halves are reapproximated in the midline. Inguinal hernias should be repaired if detected. Primary bladder closure may be performed at this time if the intra-abdominal pressure remains low after omphalocele closure. This can be determined clinically by assessing ventilatory effort. A one-stage closure of CE, including closure of the omphalocele, cecal plate tubularization and hindgut terminal colostomy, bladder and urethral closure, reconstruction of the external genitalia, and osteotomies, should be performed only under optimal anatomical conditions. The decision to proceed with one-stage closure versus staged reconstruction spanning a period of months must be weighed carefully. Following forced closure, increased abdominal pressure may result in organ ischemia, excessive tension to the midline closure, or compromised lower extremity blood flow. The importance of including surgeons experienced in the care of these patients cannot be overemphasized. Thus, the reconstruction can be staged at this point by converting the CE (Figures 62.6 and 62.44) into a CBE (Figure 62.45). A colostomy is created with the previously described caveats in mind.

If staging was required, once the baby has recovered sufficiently to tolerate another surgical procedure, the remaining steps of reconstruction of the bladder, bladder neck, and genitalia using the CPRE technique[315,316] or MSRE technique[317] are performed as previously described. Deep pelvic diaphragm dissection with division of the intersymphyseal band is crucial to allow for appropriate posterior positioning of the bladder and urethra. After the bladder and urethra are positioned within the pelvis, reconstruction of the bladder, genitalia, abdomen, and pelvis is anatomic.

Osteotomies are almost always necessary to assist in closure and posterior positioning of the urinary tract, given that the pubic diastasis is usually more severe than in CBE. Prior to incision, the need for osteotomies is assessed under anesthesia by watching for ischemia of the lower extremities and external genitalia during pubic reapproximation. The Hopkins group recommends bilateral combined anterior innominate and vertical iliac osteotomy

FIGURE 62.45 Staged closure of male cloacal exstrophy. The omphalocele has been reduced. The cecal plate had been tubularized and the terminal hindgut has been brought out as an end colostomy. The hemibladders have been united in the midline but remain exstrophic.

with gradual approximation of the bones over 1–2 weeks via the external fixture and interfragmentary pins.[37,318] The Seattle group prefers iliac osteotomies. Other authors prefer to avoid the use of osteotomies because they believe that osteotomies make the abdominal closure more difficult.[319] This has not been our experience. Fewer wound dehiscences and ventral abdominal wall hernias have been noted with osteotomies.[37]

Late procedures may be required on the urinary tract to achieve continence, including BNR; bladder neck closure; bladder augmentation with stomach, ileum, or hindgut; and creation of a continent catheterizable stoma.[50,267,268,320,321] Given that nearly all these children will be dependent on clean intermittent catheterization to achieve dryness, surgical reconstruction must be individualized to meet the needs of their limitations.

Genital Reconstruction and Sex of Rearing

Sex assignment for patients with CE is currently under scrutiny both by the medical profession and by the lay public. Traditionally, male patients underwent sex conversion in infancy because of concerns that the small, paired male hemiphalluses in these patients were inadequate for reconstruction. This approach was supported by anecdotal data of unsatisfied patients following reconstruction of the male phallus.[50] These observations, in conjunction with the prevailing notion that humans were gender neutral at birth and could undergo sex conversion safely in infancy, have recently come into question.[186,322,323] Recent evidence suggests that gender imprinting may occur during fetal development.[324] Gender identity now appears to be a much more complex issue than previously thought.

Currently, males with CE are routinely reconstructed as males whenever technically possible. Many gender reassigned individuals will later identify themselves in a male gender role in adolescence and adulthood.[186,322,325] Technically, however, reconstruction of external male genitalia in the CE population can be quite difficult. The wide

pubic diastasis and small phallic size add to the technical complexity because these findings make it more difficult to bring the two phallic halves together in the midline. In some cases, if one phallic half is diminutive, the small one can be removed and the reconstruction performed using only the larger phallic half.

Female genital reconstruction is complex as well. In genetic females, complete Müllerian and vaginal duplication often leads to attempted midline reapproximation. However, if one system appears more substantial, excision of the lesser unit may be prudent. In genetic males raised female, neovaginal reconstruction is typically delayed and may require use of hindgut segment or perineal skin.

Gastrointestinal Reconstruction

Short-gut syndrome is usually present in patients with CE at birth, even in those with normal length of bowel. The effects of malabsorption and fluid loss from this entity appear to be clinically most significant early in life.[326] Many such children require parenteral nutritional support in early infancy.[327,328] Because of this, we share the belief that the hindgut should be constructed and placed in continuity with the intestine during initial reconstruction. This will perhaps improve nutrition and also preserve intestinal tissue that may be used in later reconstruction of the urinary tract or to form a vagina, if this is eventually needed. It is interesting that Rickham noted the importance of preservation of the hindgut in the intestine in his report of the first surviving neonate with CE.[329]

Long-Term Concerns in Exstrophy

Psychosocial Concerns

Children with exstrophy face significant challenges in the development of their psychosocial identity.[330] Unfortunately, this area of development has been poorly studied but is drawing attention.[331] Reiner and coworkers have noted that "in children with exstrophy, psychosocial and psychosexual hurdles are the rule" rather than the exception. A preliminary study of 135 children and adolescents with bladder exstrophy revealed that a detailed sexual and social history was rarely part of the routine evaluation of these children. Other studies have shown that adolescent males with exstrophy were psychosexually delayed 2–4 years compared with their peers and delayed 4–6 years in their activity. Data on teenage girls with exstrophy are incomplete, but Reiner has noted that these girls struggle with sexual self-esteem issues, such as body image, genital perception, and genital appearance. Current recommendations include regular assessment of social development. These may include child psychiatric evaluation at birth, with parental education about concerns. Child assessment can begin as early as 12–18 months of age and then periodically after that. Evaluation and intervention are also useful prior to operative procedures. Reiner has found that anxiety and psychosexual disorders are universal in the patients he has evaluated to date. Further, a higher percentage of patients with exstrophy experience suicidal ideation.[332] Routine patient and parental education should be considered.[333] A recent German study found affected females to have better psychosocial and developmental outcomes than affected males.[331] Adolescents with exstrophy are resilient, however, and have been shown to develop creative coping strategies to deal with the chronic aspects of their condition.[330] Most adolescents with exstrophy express a strong desire to be normal and resent arrangements that emphasize their differences (such as the use of faculty or nursing facility bathrooms).[334]

Sexual Function

While sexual function is of little relevance to the newborn or prepubertal child born with exstrophy, it is an issue of considerable importance to the parents of the child, who wonder what future sexual function will be possible for their child, and for adolescents with exstrophy, for whom sexual function or the potential for sexual function is an area of focus.

For male patients, erectile function and sensation are usually intact.[335,336] Variable degrees of chordee can create difficulty in achieving intercourse for some patients.[336] Libido for patients with exstrophy is characteristically present with or without surgical correction. However, penile size and curvature can impact the ability to engage in sexual intercourse. Several studies of adult men with exstrophy have demonstrated that approximately a third choose not to or cannot engage in sexual intercourse.[306] Woodhouse noted in his series of patients with exstrophy that many of them do develop stable partnerships. He found 33 of 43 patients married or living with a partner. However, sexual counseling in these patients is paramount because of the difficulties they face. In these situations, a female superior position provides closer apposition of the genitalia for intercourse.

For some men, exceedingly small penile size deters them. Several groups have published the successful use of a radial forearm flap to construct a penis analogue in five men with diminuitive penises.[274,337] All described improved quality of life following the operation.[273,338–343]

Ejaculation is often present as well despite the extensive reconstructive procedures that are done for these patients. The seminal emission may be slow and continue several hours after orgasm. Further, sperm quality and quantity are often impaired. This may be due to partial obstruction from surgery or epididymitis or recurrent urinary tract infections. In the Hopkins series, only 63% had antegrade ejaculation.[25] However, long-term studies in adults with exstrophy found that a minority of them were able to conceive without ARTs, while others used ARTs to have children.[306,344,345]

For women with exstrophy, ~80% will require genital surgery,[27] including vaginoplasty, to permit intercourse, or clitoroplasty or labioplasty.[346] Diminished clitoral sensation and partial clitoral atrophy have been reported.[346,347] Sexual intercourse is possible, and sexual function is often intact.[335] Of 38 bladder exstrophy females who had tried to conceive, 66% had been successful.[348] In Woodhouse's series, 14 of 23 patients had normal intercourse,[349] while 18% reported dyspareunia in the Hopkins series.[27] Narrowing at the vaginal introitus can be problematic in up to 32% of patients.[350] This can be addressed with serial calibration and dilation as a first option or with vaginal cutback or advancement skin flaps as surgical options. Some recommend the use of vaginal dilation postoperatively,

but it is not mandatory. Fertility is unimpaired in female patients with exstrophy, although prolapse occurs in 38% secondary to the lack of pelvic floor support structures and can be unmasked with vaginoplasty or pregnancy.[28] This can make bed rest necessary in the later stages of pregnancy. Pregnancy in a patient with exstrophy is considered a high-risk event,[97,351] and many pregnancies have been reported with deliveries vaginally or by Caesarian section.[27,352] Hydronephrosis and bacteriuria are common during pregnancy and may necessitate antimicrobial prophylaxis.[353] Caesarian section is the recommended path of delivery (with urologic presence) versus vaginal delivery, which can occasionally be problematic.[348,354] Vaginal and cervicouterine prolapse surgery may be necessary in women with exstrophy, as prolapse occurs at a younger age than in the general population.[28,352,355] Several surgical methods (colposuspension, mesh sacrocolpopexy, uterine antefixation, and Gore-Tex uterine wrap) have been reported in exceedingly small numbers; however, the best method of repair has not emerged.[356] For recurrent prolapse cases, simultaneous osteotomy with external fixation has been successfully employed.[30]

CONCLUSIONS

Whereas it was once deemed "impossible to restore the bladder" (H. J. Jewett, patient communication, 1957) in patients with exstrophy, modern management can successfully preserve renal function, provide urinary continence, and maintain the health of children and adults with bladder exstrophy and CE. The progress made over the past few decades makes us optimistic in anticipating the future of therapy for these interesting and vital patients.

CHAPTER
63

Unusual Conditions of the Bladder, Including Bladder Trauma, Urachal Anomalies, and Bladder Diverticula

Pablo Gomez III and Marc Cendron

INTRODUCTION

Other than the notable embryological pathologies of the bladder, which include bladder exstrophy and cloacal anomalies, anomalies of the bladder in children are relatively rare. In this chapter, a brief review of the embryology and function of the bladder is presented, followed by a review of bladder trauma, bladder diverticula, and urachal and other unusual bladder entities, such as bladder agenesis or hypoplasia, bladder duplication and septation, and megacystis, as well as tumors and inflammatory conditions seen in children.

The embryology of the bladder is a complex, three-dimensional process that encompasses the formation of the cloaca (or primitive hindgut), as well as the elaboration of an anteriorly located muscular reservoir connected to the ureters posteriorly and to the urethra inferiorly.[1] At about 28 days of gestation, the cloaca undergoes partitioning by ingrowth of the mesoderm from the point of confluence between the allantois and the hindgut to form the urorectal septum, which will separate the genitourinary tract from the gastrointestinal tract. The urogenital sinus thus formed will divide by further ingrowth of the mesoderm to form the bladder precursor anteriorly and superiorly during the fifth and seventh weeks of gestation. The bladder is connected to the allantois and the mesonephric ducts. Growth of the anterior abdominal wall will allow expansion of the bladder. The allantois, which later will become the urachus, remains attached to the bladder dome and extends to the base of the umbilical cord. The lumen of the urachus will obliterate early in human fetal development.[2]

Structural organization of the bladder occurs at 16 weeks of gestation, with histological appearance of urothelium by 20 weeks of gestation concomitant with organization of smooth muscle cells into three layers. Organization of the bladder therefore depends on the carefully orchestrated differentiation and growth of the mesodermal mesenchyme. While the exact molecular events involved have not been clearly and precisely elucidated, functional organization of the bladder has been well identified on a histological basis. The bladder begins to provide storage and expulsion functions as the kidneys start to produce urine at 9–10 weeks of gestation. The muscular and urothelial units are submitted to sequential stretching and contraction as documented by prenatal ultrasonography.[3] Developmental alterations in the structural organization of the bladder may allow for anomalies such as bladder diverticula to occur. In this case, normal muscular organization of the paraureteral area is altered to the extent that a muscular defect occurs, allowing for the urothelium to herniate through it and into the perivesical space.

Bladder agenesis in viable newborns is exceedingly rare and mostly observed in females.[4,5] The exact cause of bladder agenesis has not been determined. In general, the gastrointestinal tract is intact, implying normal division of the cloaca with atrophy or failure of the bladder to develop, resulting in the incorporation of the distal ureter into the urethra, vestibule, or Gartner's duct in the female and the prostatic urethra in the male.[6] The ureters may display distal obstruction due to their ectopic location, causing upper urinary tract dilatation and possibly poorly functioning, dysplastic kidneys. The outcome for these patients depends largely on their renal and pulmonary function. Most infants born with bladder agenesis are stillborn, and rare survivors are usually females.[7,8] Initial urinary diversion followed by major reconstruction of the lower urinary tract may be required should renal and pulmonary function be sufficient for survival. Other congenital anomalies are frequently seen in association with bladder agenesis.[9]

Conditions associated with under- or overfilling of the bladder with urine (cycling) early in development may lead to either underdevelopment of the bladder (hypoplasia) or overdistention (megacystis). Bladder hypoplasia occurs in disorders in which either low urine output causes the bladder not to cycle adequately (seen in bilateral renal agenesis or severe bilateral renal dysplasia), low outlet resistance (as seen in epispadias with incontinence), or if the bladder is bypassed altogether (bilateral ureteral ectopia). Children who experience chronic low urine output due to renal failure or due to bilateral nephrectomies may develop acquired hypoplasia of the bladder. This condition is usually

reversible once the child has undergone renal transplantation, increased urine output and bladder cycling. A pretransplant voiding cystourethrogram (VCUG) will show small bladder capacity, and very often filling of the bladder will be associated with benign, self-limited extravasation of contrast (Figure 63.1).[10]

Congenital megacystis, or enlarged bladder, can be seen in association with refluxing, massively dilated ureters, a syndrome known as megacystis–megaureter (Figure 63.2).[11] The dynamics of the dilated bladder and refluxing urine cause a constant cycling and concomitant overdistention (yo-yo effect between the upper and lower urinary tract). Prenatal diagnosis of this rare condition has been reported.[12] Congenital enlargement of the bladder is also reported in association with microcolon intestinal hypoperistalsis syndrome and Ehlers–Danlos syndrome, and it can also be secondary to bladder outlet obstruction.[13,14] Initial management of patients with megacystis is directed toward improving bladder emptying and often requires clean intermittent catheterization and antibiotic prophylaxis in order to prevent infections. Surgical treatment of the vesicoureteral reflux should, in general, be delayed until 6 months of life. Reimplantation of the ureters (with or without tapering) may be helpful in improving bladder dynamics and emptying of the upper urinary tract. Reduction cystoplasty is not recommended.

Bladder duplication and septation are also rare. In complete duplication, two functional bladders are found and are felt to possibly be the result of partial twining.[15] Various types of bladder duplication and septation have been described (Figure 63.3).[16] In 90% of bladder duplications, two separate urethras are found. In males duplication of the penis and in females duplication of the vagina and uterus are usually present. Management of this condition is aimed at maintaining normal lower urinary tract function and is tailored to the individual situation.

BLADDER TRAUMA IN CHILDREN

Given its location early in development, the bladder is an intra-abdominal organ until 4–5 years of age, at which point, with somatic growth, the bladder becomes a pelvic organ. Trauma to the bladder is a rare occurrence in children. It is usually associated with blunt trauma to a full bladder.[17] As in adults, the most common causes of blunt trauma to the bladder include motor vehicle accidents, falls, and sport injuries.[18] *In young children, the full bladder typically extends above the pelvic ring, allowing for bladder injuries to occur with blunt trauma to the abdomen without associated pelvic fracture.*[19] A classification of bladder injuries has been published by Sandler et al.[20] (Table 63.1).

FIGURE 63.1 Bladder hypoplasia in patient with chronic renal failure. Urine extravasation is noted after partial bladder emptying.

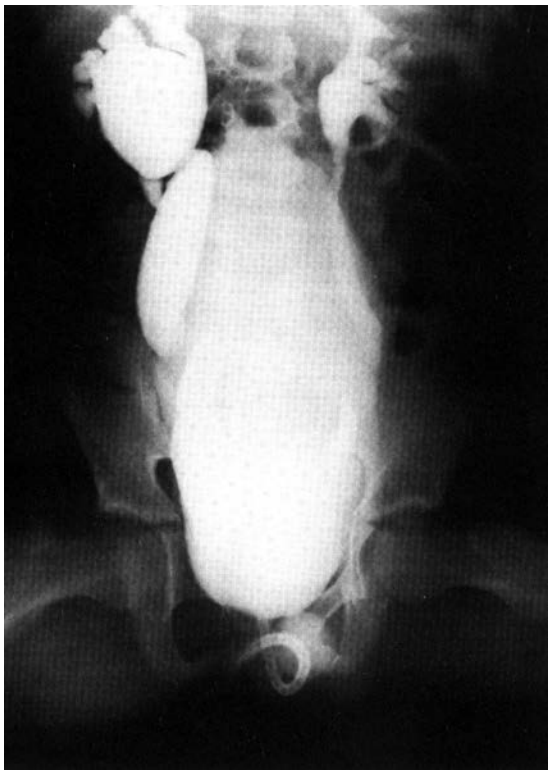

FIGURE 63.2 VCUG of a patient with megacystis–megaureter. Note the massive elongation and distention of the bladder with dilatation of the ureters associated with vesicoureteral reflux.

Bladder contusion involves damage to the bladder muscle and mucosa without disruption of the integrity of the bladder. In general, bladder contusion presents with gross hematuria. Imaging by either ultrasound or computed tomography (CT) scan will reveal a thickened, irregular bladder wall (Figure 63.4). Bladder contusion is present in one-third of all bladder injuries. The management of bladder contusion is usually expectant or with catheter drainage.

Rupture of the bladder can be classified as either intraperitoneal or extraperitoneal. The treatment is drastically different based on the above dichotomous findings and should be specific to the diagnosis and anatomy of the injury. Adequate radiological imaging is particularly important to differentiate between the two.

Intraperitoneal rupture is seen more commonly in children because of the anatomic location of the bladder. The mechanism of injury involves blunt trauma to the bladder, with an abrupt rise in intravesical pressure causing disruption of the bladder wall at the level of the dome, the weakest

portion of the bladder wall. In general, urine will extravasate into the peritoneal cavity due to disruption of the peritoneal lining of the bladder. Extravasation of the urine into the abdominal cavity will cause urinary ascites, peritoneal signs, and in the majority of cases, abnormal serum chemistries.[21] This helps to distinguish patients with extraperitoneal rupture who, in general, will display normal serum chemistries in the acute setting. Patients presenting early

with intraperitoneal bladder rupture will display increased serum creatinine and potassium, whereas those presenting later will exhibit increased serum levels of blood urea nitrogen, creatinine, and potassium, and lower levels of serum sodium. Acidosis can also be occasionally observed.

Standard imaging techniques in patients suspected of having a bladder injury should include a CT scan of the abdomen and pelvis.[22] If this modality is not available, then a VCUG should be obtained.[23] The diagnosis of a bladder rupture can be difficult, and it must be accomplished with retrograde filling of the bladder through a urethral catheter. The contrast material should be instilled by gravity until the bladder is fully distended and post-drainage images, anteroposterior and oblique, must also be obtained. Retrograde bladder filling should be performed during CT scan imaging (CT cystogram) because simple administration of intravenous contrast may not allow full bladder distention.[24]

Imaging of intraperitoneal bladder rupture by either CT scan or cystography will demonstrate outlining of the large and small bowel loops by contrast material and evidence of dilute contrast extending from the pelvis up into the abdominal cavity, usually along the paracolic gutter (Figure 63.5). Unless the bladder is well filled and then emptied completely, evidence of contrast material extravasation may be easily overlooked. Careful instillation (by gravity) of contrast material during the cystogram and then emptying will reveal diffuse extravasation of the contrast in the abdominal cavity with extension on the posterior aspect in the supine patient. Forceful injection of contrast into the bladder is contraindicated because it may worsen the injury and potentially allow for bacterial seeding of the retroperitoneum and/or abdomen.

Extraperitoneal bladder rupture occurs in cases of blunt pelvic trauma, usually associated with a pelvic fracture. Various mechanisms of injury have been described, and the lower half of the bladder is usually involved.[25] Sandler et al. described four types of bladder injury due to blunt trauma and divided extraperitoneal rupture into simple

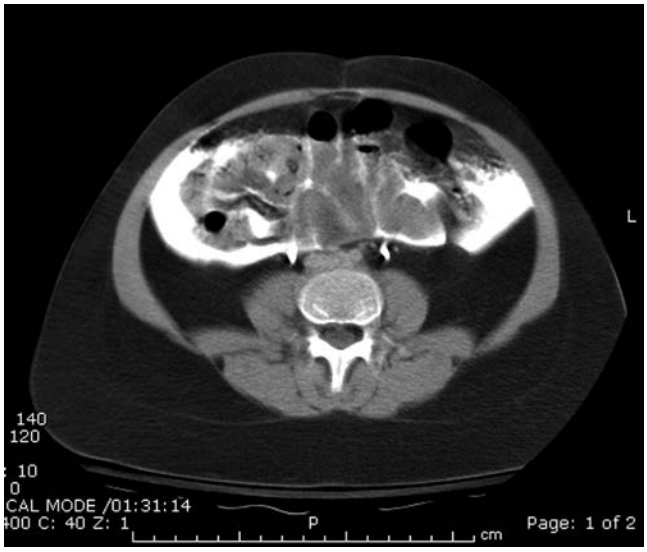

FIGURE 63.5 CT scan of patient with extravesical bladder rupture showing contrast extravasation extending into the abdomen along the paracolic gutters.

and complex.[20] This classification is based on the appearance of contrast extravasation during the cystogram. A simple extraperitoneal rupture will display contrast material extravasation limited to the pelvic extraperitoneal space. Complex extraperitoneal extravasation will show contrast material outlining the muscle groups in the thigh and diffusely throughout the pelvis. It may extend into the scrotum and perineum. Bony spicules, which can be the result of a fractured pelvis, may also contribute to the mechanism of injury. It is important to carefully assess the bladder and the surrounding structures for fragments of bone, which may contribute to further laceration of the bladder if left in place. CT scan is the best modality for detecting osseous fragments.

Management of bladder injuries is dependent on the type of injury diagnosed. In general, bladder contusion is either managed expectantly or treated with catheter drainage while gross hematuria is present. In general, the catheter can be removed once the urine has cleared and there is no evidence of passage of blood clots. Reimaging of the bladder is not necessary, although a pelvic ultrasound can be used to ascertain resolution of the intramural hematoma, rule out any extravesical collections, and assess the presence or absence of hydroureteronephrosis.

The standard management of intraperitoneal bladder rupture is open surgical exploration with repair of the bladder defect. This is usually carried out on an emergent or urgent basis, with concomitant exploration and irrigation of the peritoneal cavity. Once the bladder injury has been repaired, bladder drainage is accomplished by either suprapubic tube or a urethral catheter.[26] Urethral catheters appear to be as effective in draining the bladder as suprapubic catheters, and will usually ensure a shorter period of diversion.[27] Prior to removal of the drainage catheter, a cystogram should be carried out to ensure that the integrity of the bladder has been restored.

Simple extraperitoneal bladder ruptures can be treated nonoperatively with urethral catheter drainage for 7–10 days. However, if a patient has experienced more complicated injuries involving the pelvis with the presence of bony spicules or fragments within the bladder, then surgical exploration can be considered to remove the fragments of bone and carry out bladder repair and drainage. Again, follow-up cystogram is warranted to ensure that bladder healing has occurred and that there is no evidence of persistent extravasation. There are, in general, no long-term consequences of bladder injury or rupture in simple cases.[28] However, in the more complicated cases involving pelvic fracture and multiorgan injuries, and in those with evidence of a urethral disruption, the complication rate rises significantly.

BLADDER DIVERTICULA

F. Douglas Stephens published the first series of bladder diverticula in children in 1960.[29] The advent of cystography had allowed the evaluation of children who presented with urinary tract infections. A number of these patients were found to have smooth bladders and what was then described as saccules at the ureterovesical junction. Saccules had been previously reported in trabeculated bladders secondary to bladder outlet obstruction in adults. Douglas Stephens and subsequently John Hutch proposed that there would be two possible etiologies to bladder saccules or diverticula: (1) those secondary to bladder outlet obstruction and (2) those that may be congenital and seen in association with a smooth bladder wall.[30] Classification of bladder diverticula in children can therefore be based on their etiology: (1) those associated with bladder outlet obstruction, including posterior urethral valves, urethral strictures, large prolapsing ureterocele, and neurogenic dysfunction; (2) those occurring after bladder surgery, specifically after ureteral reimplantation when the hiatus is not reinforced, causing iatrogenic weakening of the paraureteral detrusor layer; (3) those associated with specific syndromes, more frequently prune belly, Menkes, Williams, and Ehlers–Danlos syndromes; and (4) those felt to be primary, congenital, or idiopathic diverticula with or without vesicoureteral reflux.[31,32] Bladder diverticula in children may be single or multiple. They may be found in up to 1.7% of children evaluated by cystogram.[31]

A bladder diverticulum represents a herniation of the bladder mucosa between fibers of the detrusor muscle, resulting in outpouching into the perivesical space. The exact etiology of congenital bladder diverticula is not known but is thought to represent an intrinsic weakness in the muscle wall of the bladder. They are most commonly seen adjacent to the ureteral orifice, as described by John Hutch in 1961.[30] The discussion in this chapter is limited to congenital bladder diverticula and diverticula associated with various congenital syndromes. Not discussed are diverticula associated with bladder outlet obstruction and neurogenic bladder. Congenital syndromes in which bladder diverticula are seen include Menkes kinky hair syndrome (a connective tissue disorder characterized by increases in tissue copper and metallothionine contents);[33] Ehlers–Danlos syndrome (a syndrome characterized by defective collagen synthesis, resulting in joint hypermobility, skin extensibility, and tissue fragility), which is usually

inherited as an autosomal dominant condition;[34] cutis laxa (a syndrome characterized by decreased or absent elastic tissue); and finally, Williams syndrome (a disorder characterized by mental retardation, growth abnormalities, facial anomalies, and aortic stenosis).[35] Williams syndrome is associated with gene deletion on chromosome 7q, a region in which the *ELN* gene is located (a gene coding for elastin synthesis).[36] Patients with Williams syndrome have also been found to have a higher rate of renal abnormalities, suggesting the need for screening of the upper urinary tract by ultrasound.[37]

Bladder diverticula associated with chromosomal abnormalities are usually multiple and may cause bladder dysfunction. The patient has the ability to store urine but is unable to completely empty the bladder. Urinary stasis, with resultant urinary tract infections, may be the only manifestation of the bladder diverticula (Figure 63.6). Frequent, complete bladder emptying, potentially using clean intermittent catheterization, will help prevent stasis and possibly infection. *Surgical excision of bladder diverticula in patients with chromosomal abnormalities must be considered with caution, as the diverticula are multiple and may recur once surgical excision has been carried out.*

Congenital bladder diverticula are discovered, in general, in the course of the evaluation for urinary tract infection when a cystogram is carried out. Equal male-to-female distribution is noted. Bladder diverticula are usually asymptomatic, but bladder obstruction or ureterovesical junction obstruction symptoms have been reported.[38,39] Bladder outlet obstruction may be caused by an enlarging bladder diverticulum that extends inferiorly to compress the bladder neck or proximal urethra. Also, and depending on the size and location of the diverticulum, the ureteral hiatus may be incorporated in the diverticulum (Figure 63.7).

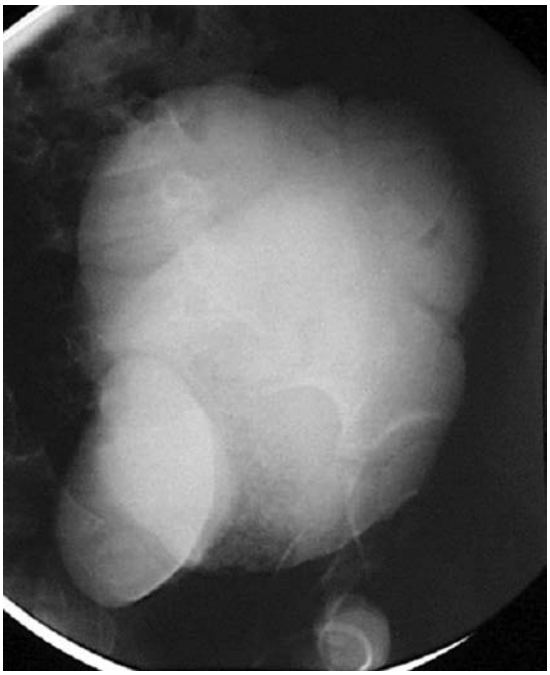

FIGURE 63.6 Cystogram of a 6-year-old patient who presents with recurrent urinary tract infection and incontinence. A large bladder diverticulum is seen on the right side of the bladder.

FIGURE 63.7 Cystogram view demonstrating a bladder diverticulum associated with vesicoureteral reflux. Note the contrast in the ureter, which inserts into the diverticulum.

Periureteral diverticula can, in effect, distort the normal ureterovesical junction and cause an abnormal intramural tunnel, thus altering the normal antireflux mechanism. As a result, vesicoureteral reflux may then occur.[40] Vesicoureteral reflux is associated with bladder diverticula but may not always be apparent on a VCUG and has been reported with a wide variability.[41] In addition to reflux, bladder diverticula may also be associated with distal ureteral obstruction in up to 5% of cases.[42]

Although bladder diverticula are often diagnosed incidentally during radiological evaluation for a urinary tract infection, the relationship between urinary tract infection and bladder diverticula remains unclear. It has been postulated that large bladder diverticula may predispose to urinary stasis, which, in turn, will provide a nidus for bacterial growth.[43,44]

Urinary tract infections in children with abnormal voiding patterns warrant close evaluation by ultrasound of the bladder and kidneys and a VCUG. These children may be found to have detrusor sphincter dyssynergia, hyperreflexia, or hypertonia. Specifically, patients with Hinman–Allen syndrome (nonneurogenic neurogenic bladder) have been reported to have associated periureteral diverticula.[45] A VCUG is the usual diagnostic modality, which allows bladder diverticula to be found; however, they can also be noted on bladder ultrasound and CT scan of the pelvis. Intravenous urogram will usually not allow the detection of bladder diverticula because the bladder will overlie the diverticulum and the diverticulum may be filled with dilute contrast material. Larger diverticula can also be confused with other bladder lesions, such as urachal cysts, bladder ears seen in very young children, bladder herniation, ectopic ureteral insertion at the bladder neck, bladder duplication, everting ureteroceles, and ureteral stump resulting from excision of the upper part of the ureter and kidney (Table 63.2).

TABLE 63.2 Differential diagnosis of bladder outpouching in the pediatric age group

- Urachal cyst (dome of bladder)
- Bladder ears (seen in young babies)
- Bladder herniation (seen in large inguinal hernias)
- Ectopic ureteral insertion (usually at or around the bladder neck)
- Bladder duplication
- Everting ureterocele
- Refluxing ureteral stump

The relationship between bladder diverticula and voiding dysfunction has not been thoroughly clarified. Very few studies have used urodynamic evaluation to assess bladder physiology in the face of bladder diverticulum. Interestingly enough, Douglas Stephens, as early as 1960, attempted to evaluate bladder pressures in 4 patients of his series of 23 patients with bladder diverticula.[29] The main issue shrouding the urodynamic assessment of bladders associated with bladder diverticula is the fact that pressure recordings are difficult to interpret given the compliant nature of the bladder diverticulum. Thus, cystometrogram may be notoriously unreliable. However, detrusor sphincter dyssynergia, if present, may be diagnosed by doing a videourodynamic study.

The upper urinary tract may also be abnormal in the face of a bladder diverticulum. As noted, there is a variable rate of vesicoureteral reflux associated with bladder diverticulum. In addition to vesicoureteral reflux, 16%–30% of patients with bladder diverticula have been reported to have renal abnormalities in early studies, although this is likely to be a gross overestimate based on modern imaging.[46,47] These abnormalities range from focal dysplasia to multicystic dysplastic kidney. Renal lesions have also been reported in patients with vesicoureteral reflux and a history of febrile urinary tract infection. Upper tract dilatation may also be observed in cases where the bladder diverticulum causes obstruction by extrinsic compression of the distal ureter.[38] An early report from France documented 7 of 43 cases of patients with bladder diverticula having evidence of renal dysplasia or multicystic dysplastic findings.[46] In a later study by Tokunaka et al. out of Japan, 17 patients were evaluated, 13 of whom showed dilatation of the upper collecting system associated with renal scarring, and 4 had small nonfunctioning kidneys.[47] The authors correlated the severity of the renal abnormalities with the position of the ureteral orifice in relationship to the diverticulum and postulated that abnormalities in ureteral bud formation may have impacted normal nephrogenesis. When the ureter inserted directly into the diverticulum, the likelihood of cystic dysplastic changes in the kidney increased. In light of the fact that a significant number of patients with bladder diverticula have upper tract changes, further functional evaluation of the kidney may be warranted in the form of a dimercaptosuccinic acid (DMSA) renal scan. On the other hand, most of these patients likely presented with symptoms related to their renal pathology, and were subsequently found to have bladder diverticula, so the overall likelihood of renal anomalies associated with diverticula is much smaller.

The management of patients with congenital bladder diverticula depends on the presentation and symptoms. As noted, most patients present with urinary tract infection. Evaluation and treatment of any bladder dysfunction should be considered prior to any attempts to treat the diverticulum surgically. It should be noted that some children with small bladder diverticula and lower grades of vesicoureteral reflux may outgrow the reflux and have the diverticula disappear.[41] *The indication for surgical treatment of bladder diverticula is dictated by the presence of persistent high-grade vesicoureteral reflux and recurrent urinary tract infections, or documented obstruction of either the distal ureter or the bladder neck*. In cases of functional bladder outlet obstruction due to a very large diverticulum extending underneath the bladder neck, excision of the diverticulum is recommended. In patients with recurrent urinary tract infection and persistent vesicoureteral reflux, diverticulectomy is recommended and should be accompanied by reimplantation of the ureter.

The surgical approach can be either intravesical or extravesical. The key surgical principle is to reinforce the muscular hiatus of the bladder to prevent reformation of the bladder diverticulum. Should the upper tract evaluation reveal a nonfunctioning kidney, consideration should be given to nephroureterectomy with diverticulectomy. Extravesical approaches and laparoscopic or robotic techniques can be used in these cases.[48–50]

URACHAL ANOMALIES

The urachus is an embryologic remnant derived from both the allantois and a part of the bladder.[51] Early in fetal development, the bladder descends toward the pelvis, retaining its attachment to the umbilicus through the urachus. The urachus has a lumen early in gestation that spontaneously closes, but may remain patent in cases of bladder outlet obstruction, such as posterior urethral valves.[2] However, in humans the urachus appears to close very early in gestation and rarely remains patent. Closure of the urachus is thought to occur between the fourth and fifth month of gestation by progressive accumulation of desquamated epithelium within the lumen. Anatomically, the urachus is identified between the umbilicus and the dome of the bladder. It is 3–10 cm in length and 8–10 mm in diameter. It is surrounded by the umbilical sheath, which extends on either side to the umbilical arteries and down to the bladder dome. The urachus is composed of three histological layers, and a central lumen is usually hard to identify. Congenital anomalies of the urachus result from abnormal involution of the urachus. They are rare and usually are asymptomatic until adulthood. Typical presenting symptoms in children are periumbilical discharge (42%), umbilical mass (30%), abdominal or periumbilical pain (22%), and rarely dysuria (2%).[52] In a series of 26 patients, McCollum et al. 11 (42%) presented with infection, 7 (21%) with clear drainage from the umbilicus, 3 (12%) with polypoid granulation of the umbilicus, 3 (12%) with pain, 1 (4%) with recurrent urinary tract infections, and 1 (4%) with an asymptomatic sinus.[53]

Urachal anomalies can be divided into urachal sinus, urachal cyst, patent urachus, and vesicourachal diverticulum (Figure 63.8). They are isolated defects and are not associated with specific syndromes or conditions, with the exception of bladder outlet obstruction (rare) or prune

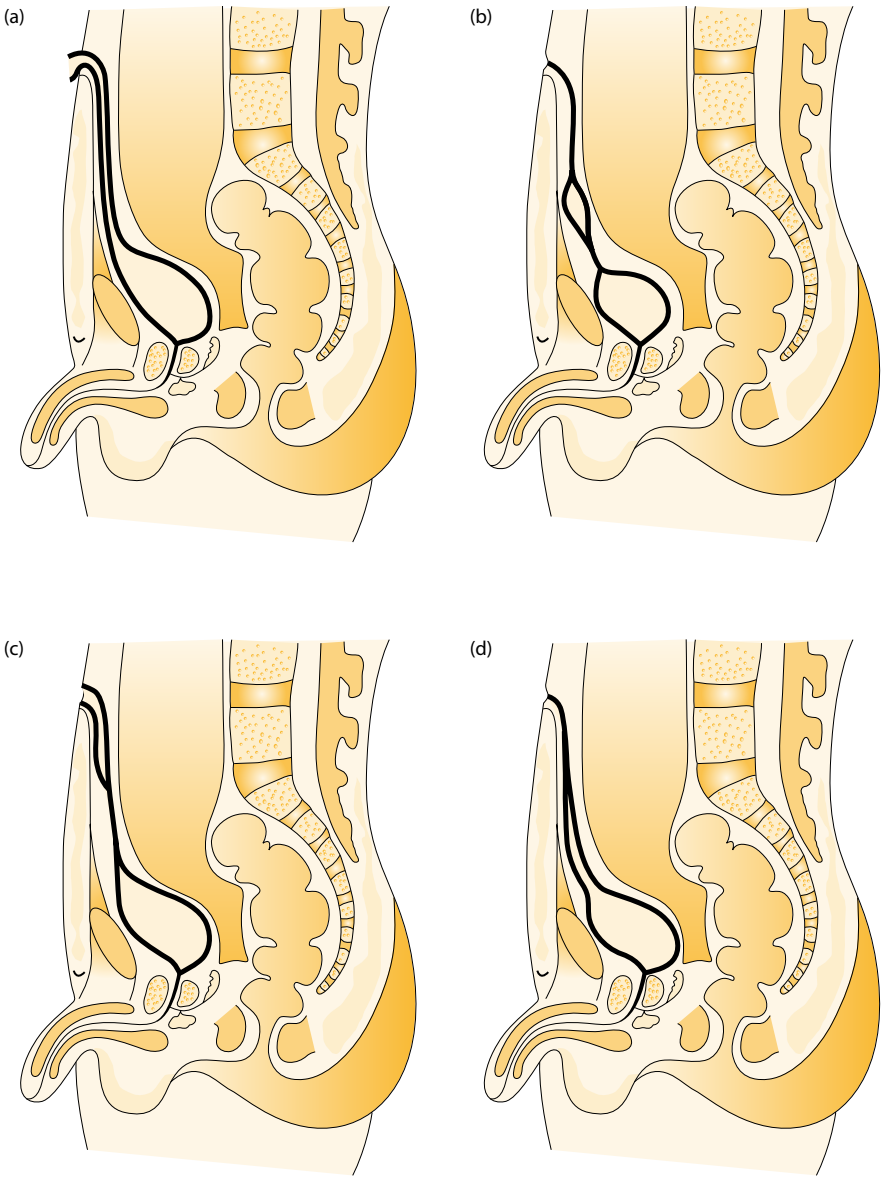

FIGURE 63.8 Congenital urachal anomalies: (a) patent urachus, (b) urachal cyst, (c) urachal sinus, and (d) vesicourachal diverticulum. (From Schnyder PA, Candardjis G. *AJR Am J Roentgenol* 1981;137(5):1063–5. Copyright American Roentgen Ray Society.)

belly syndrome.[54] Diagnosis of urachal anomalies is made either by careful physical examination or by radiographic evaluation. Children with a draining umbilicus should undergo an injection of the draining sinus with contrast.[55] Alternatively, a cystogram may reveal a patent urachus. A child presenting with a periumbilical mass should be evaluated with ultrasonography or, alternatively, with a CT scan.[56]

A urachal sinus occurs when the lumen of the urachus fails to completely obliterate. Children will present with intermittent or persistent drainage from the umbilicus. Occasionally, granulation tissue can be seen at the site of the lumen. A urachal sinus can become infected and inflamed, causing lower abdominal pain with fever. Very occasionally, patients will present with lower abdominal pain occurring at the end of voiding. This is due to tension on the inflamed urachal remnant. Dimpling of the umbilicus may also be reported. A sinogram is the diagnostic test of choice in this situation. Complete surgical excision of the sinus tract and resection of the omphalomesenteric duct remnant should be carried out. If an inflammatory process has been present, injury to the intraperitoneal structures is more likely, as adhesions may have formed around the urachal remnant.[57]

Urachal cysts are quite rare clinically, but reported in up to 1 in 5000 in autopsy series.[58] Urachal cysts are usually found in the distal third of the urachus. Urachal cysts will present during late childhood and early adulthood either as an asymptomatic suprapubic mass or with suprapubic pain and/or irritative voiding symptoms. Bacterial colonization and infection (usually caused by *Staphylococcus aureus*) can occur.[59,60] The infection is usually confined to the space of Retzius, but rupture of the infected cyst may cause peritoneal contamination and intraperitoneal involvement.[61,62] Severe sepsis associated with a urachal abscess has also been reported.[63]

The diagnosis of a urachal cyst is achieved by either ultrasound or CT scan. Ultrasonography allows for accurate delineation of the cystic structure and its position relative to the bladder and the peritoneum.[56] CT scan may be helpful in cases of infected urachal cyst to determine the extent of the cyst and inflammatory process, which may be quite large and involve adjacent structures, such as bowel (Figure 63.9).[64] Bladder involvement can also occur and be better defined by a VCUG or cystoscopy.

Treatment of urachal cysts is usually tailored to the presentation. Small asymptomatic cysts may be observed. Symptomatic cysts may be excised by either open or laparoscopic and robotic techniques.[65,66] Infected cysts should be treated with a staged approach: first, incision and drainage with antibiotic coverage, followed by surgical excision once the inflammatory process has subsided, as documented by follow-up imaging.[67]

Patent urachus is a rare anomaly due to failure of obliteration of the lumen of the urachus. Such a situation may be seen in prune belly syndrome and rarely in posterior urethral valves. A patent urachus may be identified incidentally in the newborn when clear drainage is noted from the umbilicus. Symptoms can include intermittent drainage, and periumbilical swelling in association with an umbilical hernia. Granulation tissue may be seen and can mimic other umbilical lesions, such as a healing umbilical stump, a patent vitelline or omphalomesenteric duct, or an infected umbilical vessel. The diagnosis of patent urachus can be made by collecting fluid and analyzing its creatinine level. Injection of the lumen with contrast or a voiding cystogram will confirm the diagnosis. The fistulous tract should be seen extending from the dome of the bladder to the umbilicus (Figure 63.10).

Management of a patent urachus can be expectant, as a number of children will experience spontaneous closure in the first month of life.[68] In children with bladder outlet obstruction, treatment of the obstructive process will, in general, allow for spontaneous closure. Excision of the urachal tract is reserved for those patients in whom drainage persists. Surgical removal of a bladder cuff is usually recommended to ensure that all remnants of the urachus are removed.

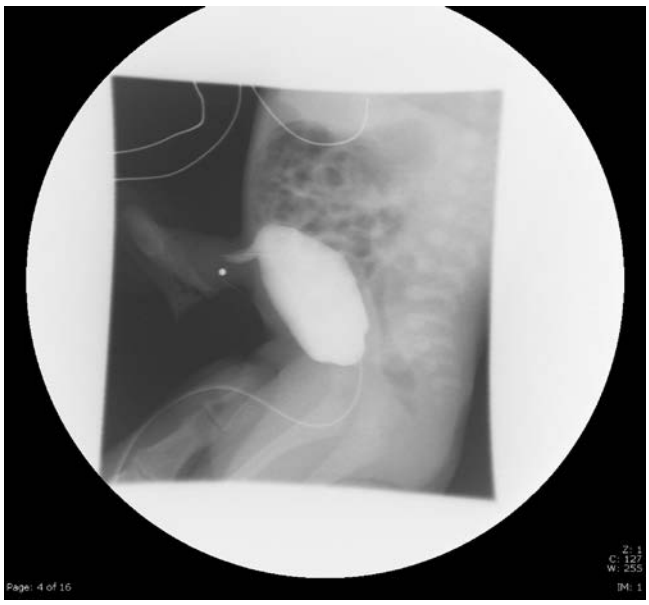

FIGURE 63.10 Patent urachus in a 3-month-old boy who presented with persistent clear drainage from his umbilicus. Note the small lead ball placed at the umbilical site of drainage to help with three-dimensional localization. Contrast extends from the dome of the bladder to the base of the umbilicus, with the feeding tube in the urachus.

FIGURE 63.9 CT scan image of a patient with a pyourachus. Note the large inhomogeneous area anterior to the bladder corresponding to the abscessed urachal cyst. The patient underwent percutaneous drainage and subsequent excision of the urachal cyst.

Vesicourachal diverticula are usually found incidentally on a VCUG. Failure of closure of the lumen at the level of the bladder dome allows for the formation of a fusiform outpouching (Figure 63.8). In general, these lesions are of little or no clinical significance. Surgical excision is required if the diverticulum does not drain well or is symptomatic.

Urachal anomalies are known to be associated with malignant degeneration in the adult population, usually in the form of urachal carcinoma (adenocarcinoma). Other forms of malignancy have also been reported, such as transitional cell carcinoma, neuroblastoma, rhabdomyosarcoma, teratoma, and yolk cell sarcoma.[69,70] While malignant degeneration is rare and accounts for 0.34% of all bladder cancers, management of urachal anomalies may be skewed toward surgical excision. Observation in children is certainly reasonable using yearly ultrasound as a monitoring technique. However, parents and patients should be educated as to the malignant potential of these lesions.

INFLAMMATORY CONDITIONS OF THE BLADDER IN CHILDREN

Inflammatory conditions of the bladder include eosinophilic cystitis and interstitial cystitis (IC). Fewer than 25 cases of eosinophilic cystitis have been reported in children.[71] Eosinophilic cystitis may be diffuse or localized

and present as an intravesical mass. Symptomatology will usually be irritative voiding symptoms with frequency or urgency, suprapubic pain, and hematuria. Ultrasound imaging of the bladder may reveal diffuse thickening of the bladder, and the diagnosis will be made by cystoscopy and biopsy of the lesion. The disorder is felt to be caused by an antigenic stimulus (infection or foreign body) that triggers an immunoglobulin E–mediated eosinophilic invasion of the bladder wall. Degranulation of the eosinophils then promotes release of inflammatory mediators. The process is felt to be self-limited with little or no consequences on the lower urinary tract.[72] Various therapeutic modalities have been reported to alleviate symptoms. These modalities include antibiotics, antihistamines, corticosteroids, cyclosporine A, surgical resection of the lesion, and even partial cystectomy.[73] The condition is occasionally seen in association with chronic granulomatous disease.[74]

Myofibroblastic tumor of the bladder is another rare inflammatory condition seen in children. Symptoms are similar to those of eosinophilic cystitis. A distinct mass is seen on ultrasound, and histologically these lesions are characterized by spindle cells with myofibroblastic and fibroblastic proliferation associated with a prominent inflammatory process.[71] Etiology of this condition has not been elucidated. The lesions may be fairly aggressive and may reoccur. Transurethral resection may be curative, but large tumors may require more extensive (open) resection. These tumors are benign but should be differentiated from sarcomas or lymphomas. Immunohistochemical staining is the best way to evaluate these lesions.[73] As noted previously, eosinophilic cystitis may also present as a discrete mass, but histologically the lesion appears less invasive than myofibroblastic tumors.

IC has been reported in children and in adolescents.[75,76] However, its incidence is hard to ascertain, as it is a difficult diagnosis to make and thus may go underreported. Held et al. note that adult women with IC are 10–12 times more likely to report childhood bladder problems than a group of matched controls.[77] In the face of irritative voiding symptoms associated with painful bladder, cystoscopic and histological findings are needed to make the diagnosis of IC in children and adolescents. In a relatively small cohort of patients, Close et al. documented IC in 16 children under 16 years old.[76] All were treated by hydrodistention, and half of them responded, while the rest required further therapy. Bladder compliance was reduced in only three cases.

IC should be considered a possible diagnosis in children with severe irritative symptoms associated with painful bladder who do not respond to first-line therapy. However, the diagnosis of IC may be elusive.[78]

CHAPTER 64

Posterior Urethral Valves

Stephen A. Zderic and Douglas A. Canning

BACKGROUND

Hugh Hampton Young initially described posterior urethral valves and proposed the current classification scheme.[1] Dewan et al. argued for an alternative to Young's system and proposed the term *congenital posterior urethral membrane*.[2] Regardless of the classification, it is clear that this anomaly presents with great variability.[3] *Posterior urethral valves occur in 1 in 5000 live births, which would mean that some 400 to 500 new cases occur in the United States every year.* While this might seem to be a small number of cases, one must consider that within this annual patient cohort, approximately 150 will develop end-stage renal disease (ESRD) and require either dialysis or transplantation within their first 18 years. Given today's advances in dialysis and transplantation, and life expectancies that will approach 70–80 years, this small number of patients places a substantial financial burden on the healthcare system. Clearly anything that can be done to lower the incidence of ESRD in this population will have a substantial societal impact, in addition to a profound effect on the lifestyle of the boy and his family.

EMBRYOLOGY AND CLASSIFICATION

In Young's original classification, *type 1 posterior urethral valves begin as leaflets that originate at the distal aspect of the verumontanum and then fan out to fuse in the midline just proximal to the external striated sphincter. Type 1 valves are a hypertrophied variant of the inferior urethral crest, which is formed by the insertion of the distal ends of the Wolffian ducts into the anterolateral walls of the cloaca*.[4] Stephens believed that the remnants of the normal urethral crest are visible as nonobstructing ridges that sweep inward from the lateral walls of the prostatic urethra and converge in the midline at the verumontanum (Figure 64.1). Cranial to this fusion at the veru, the Wolffian ducts and associated ureteral buds are absorbed into the bladder neck and trigone. If, however, the Wolffian ducts should insert into the anterior wall of the cloaca, these folds would become more prominent with a propensity to fuse in the midline. Depending on the degree to which this occurs, the valve leaflets will then become obstructive in nature. Type 1 valves account for 90%–95% of all cases. *Type 2 valves in Young's original classification are not obstructing, and reflect mucosal folds extending from the verumontanum superiorly to the bladder neck.*

Type 3 valves represent a circumferential annulus that resembles a stricture. These account for 5%–10% of all cases of posterior urethral valves. Their embryologic origin is different and probably arises from a persisting urogenital membrane.[4] The urogenital membrane is the anterior portion of the cloacal membrane that the urorectal septum divides.

The exact embryologic origins of posterior urethral valves remain unclear, and await further study, with modern molecular techniques being applied to fetal and neonatal postmortem specimens.[5] While there are numerous knockout mice described with abnormalities of ureteral budding, none develop posterior urethral valves. Thus far, the only models of posterior urethral valves involve the surgical creation of partial or complete fetal bladder outlet obstruction in several species.

SPECTRUM AND CONSEQUENCES OF POSTERIOR URETHRAL VALVES

Mild cases of posterior urethral valves may remain asymptomatic until adolescence or even adulthood. Severe cases usually present in utero with abnormal fetal sonography. Alternatively, they may present in the neonatal unit with a palpable bladder and urinary retention. In the most severe cases, as shown in Figure 64.1, the bladder outlet obstruction from the valve results in severe hydroureteronephrosis and cystic dysplasia within the kidney. In these boys, pulmonary hypoplasia is the cause of death in the neonatal period. However, the primary pathophysiology begins with the onset of partial bladder outlet obstruction.

PATHOPHYSIOLOGY OF BLADDER OUTLET OBSTRUCTION

The varied spectrum of outcomes noted in boys born with valves may represent differences among patients in the degree of obstruction, the timing of the obstruction, and underlying genotypic risk factors. To better understand these diverse outcomes, a brief discussion of the pathophysiology of bladder outlet obstruction is important. In

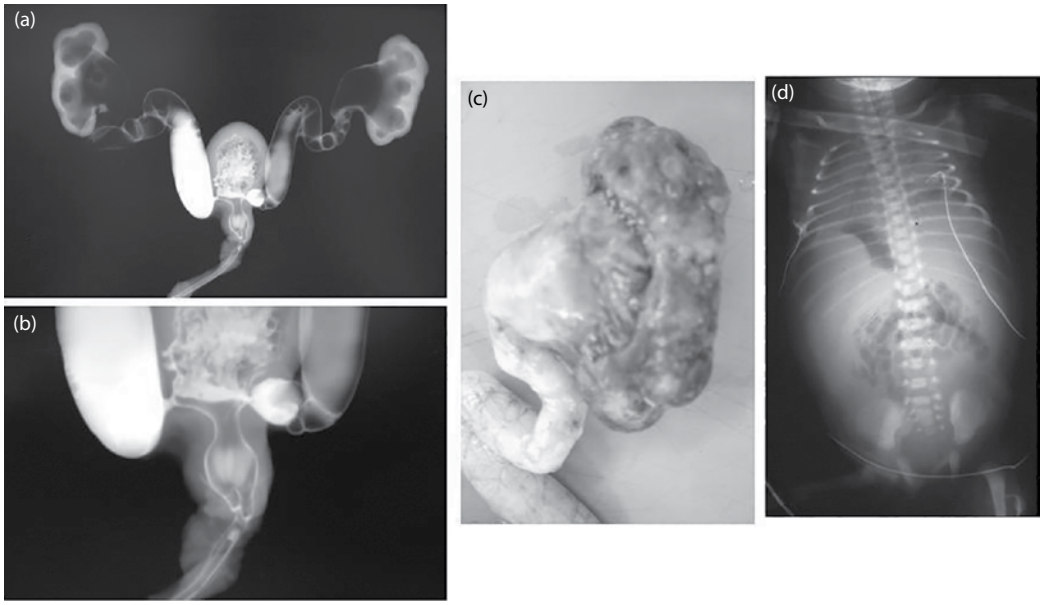

FIGURE 64.1 The consequences of severe type 1 posterior urethral valves. (a) Severe bladder wall thickening was associated with bilateral reflux in this postmortem retrograde study performed ex vivo. (b) The hallmark of type 1 valves is the origin of the cusps at the verumontanum, which fan out laterally and fuse in the midline. (c) Associated with this is severe cystic dysplasia. (d) Because of the oligohydramnios in utero, severe pulmonary hypoplasia developed in the neonatal period that was the cause of death. (Panels a–c courtesy of Dale Huff, MD, and Christopher Austin, MD.)

a simplified scheme, partial bladder outlet obstruction begins with the onset of bladder wall hypertrophy that enables the bladder to adapt to its new workload. During this compensated phase, the bladder is capable of generating a high voiding pressure, and may empty nearly completely. Over time, however, these compensatory mechanisms fail to keep pace with the demands, and the volume of the postvoid residuals begins to increase. The rising storage pressures within the bladder are transmitted to the renal pelvis, calyces, and ultimately, the glomerulus, resulting in renal damage. The pathophysiology of this process is complex, and incompletely understood. It is, however, clinically important given that long-term bladder dysfunction may plague these patients in their daily lives despite successful valve ablation.

Effects on Bladder Function

The impact of partial outlet obstruction on subsequent bladder function has been the subject of ample investigation. A review of the literature reveals myriad studies using human tissues taken at the time of surgery, as well as a large number of fetal and adult animal models. In this brief overview, we hope to summarize the steps that lead to bladder dysfunction in the face of partial outlet obstruction. There is evidence to support the following tenets: *the presence of partial outlet obstruction leads to an increase in smooth muscle size (hypertrophy) and a hyperplasia of interstitial cells (fibroblasts and myofibroblasts) that increase their deposition of extracellular matrix. The pathophysiological changes in the bladder wall lead to an alteration in blood flow to the detrusor that ultimately results in ischemia, a shift to anaerobic metabolism, and damage to the nerves within the bladder wall.*

If one characterizes disorders of voiding into failures of bladder storage or bladder emptying, one can understand how partial bladder outlet obstruction interrupts this cycle. Mitchell summarized this concept nicely in a diagram (Figure 64.2) that illustrates that mild hypertrophy follows outlet obstruction, which results in higher voiding pressures that initially preserve near-complete bladder emptying. However, as this filling and emptying cycle repeats, further remodeling of the bladder wall occurs, and gradually the postvoid residual begins to increase. In the developing fetus with posterior urethral valves, the rise in urine output that accompanies normal growth and development further stresses this system. *Ultimately, the*

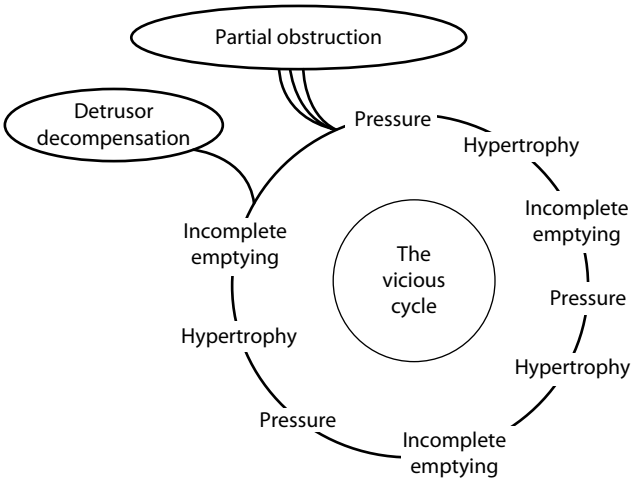

FIGURE 64.2 Mitchell's schematic concept of how partial outlet obstruction affects the bladder cycle and over time alters the bladder.

bladder's ability to adapt cannot keep pace with the functional demands, and the detrusor decompensates. In this setting, the bladder continues to produce elevated voiding pressures, but it does so inefficiently, at the expense of an elevated resting pressure before voiding, and a markedly increased postvoid residual.

Does the bladder have a functional reserve upon which additional demands may be imposed without penalty? Sullivan and Yalla[6] offered evidence in favor of the detrusor functional reserve, which they defined as the peak *isometric* pressure (measured by balloon occlusion of the outlet) minus the peak *voiding* pressure (measured with the balloon deflated). With mild obstruction and a minimal postvoid residual, this number was always in excess of 40 cm H_2O. However, as the detrusor reserve dropped, the postvoid residual began to rise. As a result of this rise in the residual urine, the patient's bladder spends more time "living on the right side" of the cystometry curve, where the storage pressures will be higher. These studies were done in adults and, for technical reasons, have not been replicated in the fetus, but it is logical to assume that a similar concept would apply in the fetal setting.

Experimental models of fetal partial bladder outlet obstruction have provided some insight into this pathophysiology.[7] Cystometry following partial outlet obstruction in the fetal sheep revealed a spectrum of curves similar to that noted in other models. Kirsch et al.[8] noted a remarkable increase in bladder compliance ($\Delta V/\Delta P$) following partial outlet obstruction. In fact, the more compliant bladders were associated with upper tract dilatation. Because these cystometrograms were performed in the operating room, the ureters could be occluded, which means that these measures were a true reflection of isolated bladder compliance. These data would suggest that as the bladder underwent decompensation, the upper urinary tract was placed at risk.[9] Using the fetal sheep model of partial outlet obstruction, several groups have described a large distended bladder with poor contractile performance of selected muscle strips in vitro.[10,11] Similar findings were noted in a rabbit model of fetal bladder outlet obstruction by Rohrmann et al.,[12,13] who performed in vitro cystometry and noted an increased bladder capacity with low intravesical pressures. The common theme across all these models was the marked deposition of extracellular matrix elements between the muscle bundles, which is very similar to what is described in specimens from patients with posterior urethral valves.[14]

Basic research has succeeded in answering some of the following fundamental questions about the bladder's response to outlet obstruction.

What are the molecular pathways that account for the less efficient bladder function seen following outlet obstruction? Understanding these steps is critical if one tries to prevent damage to the bladder during the course of gestation using pharmacologic intervention. This approach is important in the fetus because surgical intervention for valves in the fetus has been shown to carry as high as a 50% fetal mortality rate.[15] In order to realize this goal, we need to understand the molecular pathways that lead to bladder dysfunction in the face of partial outlet obstruction. A simplified scheme of this complex pathophysiology is suggested in Figure 64.3.

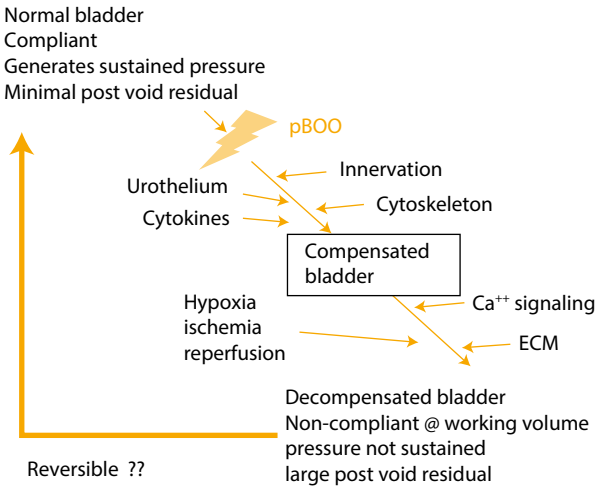

FIGURE 64.3 Schematic representation of the proposed sequence of events that result when a bladder is subjected to partial outlet obstruction. Early changes take place that allow for a bladder to *develop compensated function and generate higher pressures with minimal increases in postvoid residuals.* However, over a prolonged period of time, *additional changes take place and the postvoid residuals begin to rise, reaching the stage termed decompensated.* Although there is experimental evidence to support a role for each of these proposed contributing factors, the exact sequence of these events remains poorly understood. (Concept and figure developed by Bagli DJ, Wilcoxon DT, Kogan B, Zderic SA.)

Does the bladder respond to the rise in intraluminal pressure or to stretch? Numerous studies suggest that the progressive stretch resulting from outlet obstruction is the key factor mediating these molecular changes. Park et al. demonstrated this concept in a rat model of complete outlet obstruction in which the upper half of the bladder was constrained within a tube that allowed it to "sense" pressure, but prevented distention.[16] Park noted changes in cyclooxygenase 2 (COX-2) expression only in those bladder segments that were able to stretch, and not in those segments in which the restricting collar inhibited stretch. Furthermore, these changes in COX-2 expression were recapitulated in cultured cells subjected to mechanical deformation.[17] With an in vitro rat whole bladder model subjected to distention, Bagli and coworkers showed an increase in mRNA expression for collagen types I and III, as well as an increase in integrin expression.[18] Using human bladder smooth muscle cells subjected to mechanical stretch in vitro, Adam et al. showed changes in expression of some 20 genes (out of almost 12,000 analyzed) using microarray technology.[19]

Is Partial Outlet Obstruction Associated with Bladder Wall Hypoxia?

Hossler and Monson demonstrated using vascular resin casting, followed by tissue digestion and microscopy, that a rich capillary plexus exists within the bladder wall (it is especially prominent within the lamina propria region) (Figure 64.4).[20] Thus, it is not surprising that with overdistention, the perfusion of the detrusor is diminished, resulting in hypoxia. Using a porcine model of partial

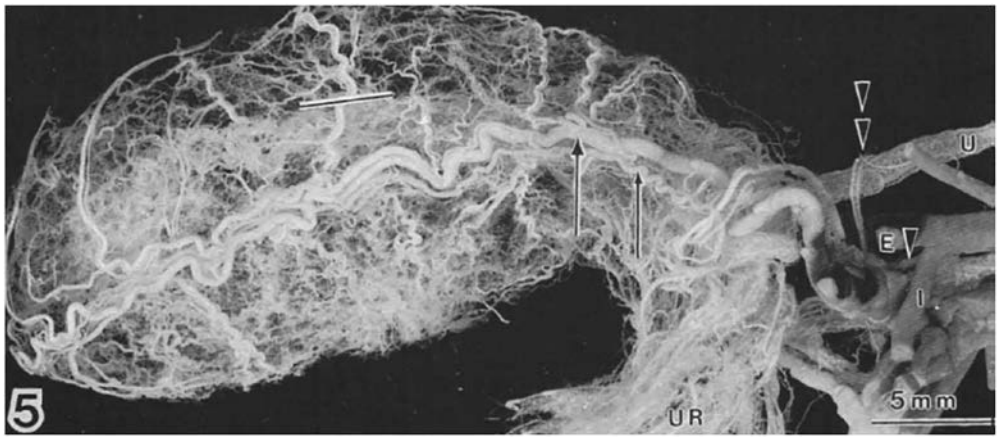

FIGURE 64.4 This resin cast of the rabbit urinary bladder shows a rich vascular architecture within the bladder wall that can be compressed to alter resistance with overdistention. (From Hossler FE, Monson FC. *Anat Rec* 1995;243(4):438–48. Reproduced with permission.)

outlet obstruction, Greenland and Brading demonstrated a marked drop in wall oxygen tension that was more pronounced with voiding.[21] Similar findings have been noted by other groups.[22] Levin and coworkers have observed increases in the expression of hypoxia-inducible factor (HIF), a transcription factor activated in the presence of lowered oxygen tension.[23] Stephany et al., using an acute preparation of bladder distention at constant pressures, showed an increase in HIF gene expression.[24] Azadzoi et al. documented alterations in bladder wall perfusion in atherosclerotic rabbits, and even in the absence of outlet obstruction, bladder wall hypoxia was associated with a marked deposition of extracellular matrix.[25] This is significant, as there is evidence to connect hypoxia with the profibrotic cytokine connective tissue growth factor (*ctgf*),[26] in part because the promoter site for *ctgf* contains a consensus binding sequence for HIF.[27] Growing evidence suggests that much of the hypoxic damage is the result of free radical toxicity,[28] and that the reperfusion phase is even more damaging than the hypoxia.[29] This hypoxic injury is especially damaging to the neural structures within the bladder wall and is substantiated with in vivo studies using the fetal sheep model of partial outlet obstruction.[10,11]

Which components of the bladder wall are affected by outlet obstruction, and where does the DNA synthesis take place? Following outlet obstruction, several changes in bladder morphology have been documented. There is an increase in smooth muscle size[30] (i.e., hypertrophy), and there is a prominent deposition of extracellular matrix components within the bladder wall. This has been shown in both human fetal specimens[14] and numerous fetal models of partial outlet obstruction.[8] It has been known for some time that bladder wall DNA synthesis takes place following outlet obstruction. Monson et al. showed this to take place within the lamina propia using pulsed tritiated thymidine and autoradiography,[31] which limited the labeling to one time point. Using continuous bromodeoxyuridine (BrDU) labeling and dual-immunofluorescence detection, Lassman et al.[32] showed that the DNA synthesis is prominent in the urothelium, lamina propria, and interstitial cell population, and is almost never seen within the smooth muscle bundles (Figure 64.5). This prominent

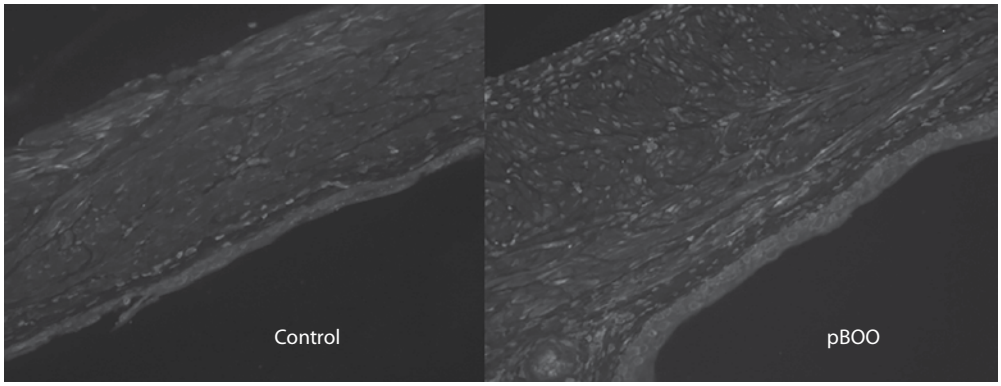

FIGURE 64.5 The sites of DNA synthesis in the bladder wall were determined in control mice and following partial bladder outlet obstruction using continuous BrDU uptake. Dual-immunofluorescence microscopy showed the sites of DNA synthesis (pink nuclei) to be predominantly contained within the interstitial cell population, and *not* within the smooth muscle population, as defined by staining against smooth muscle myosin heavy chain (green). This would suggest that DNA synthesis is occurring within the interstitial cells, and hence provide a means for increased collagen synthesis and matrix deposition. (From Lassmann J et al. *Am J Physiol Regul Integr Comp Physiol* 2008;294(1):R58–65. With permission.)

DNA synthesis within the areas of the bladder that are rich in fibroblasts ties in well with the impressive deposition of extracellular matrix elements that have been described in humans and experimental models. Experimentally, there is an increase in collagen synthesis in cultured bladder "smooth muscle" cells subjected to biaxial mechanical strain,[33] and this is mediated at the transcriptional level as shown by increased mRNA expression.[34] The caveat in these experiments done with cultured bladder cells in culture is that the cell type more likely represents a myofibroblast. The benefits of such a system are its simplicity and the ability to manipulate the variables more readily. Changes have also been described in the complex regulatory system that breaks down collagen. The matrix metalloproteinase enzymes may break down the extracellular matrix, and the tissue inhibitors of the matrix metalloproteinases (TIMPs) may in turn regulate them as a feedback mechanism. Peters et al. have shown TIMP expression to be increased within the bladder wall in a fetal sheep model of partial outlet obstruction, thus providing another mechanism for the dramatic increase in bladder wall fibrosis.[35] The clinical relevance of these observations is that this prominent deposition of extracellular matrix alters both the active and passive properties of the bladder wall.

Are there specific signaling pathways that are activated following outlet obstruction that lead to hypertrophy, and how might these be used for therapeutic benefit? The calcineurin–nuclear factor of activated T cells (NFAT) pathway represents one potential pathway to bladder hypertrophy, as demonstrated in a murine model of outlet obstruction.[32,36] Of the four existing NFAT isoforms, $NFATc_4$ has been shown by a CHIP on CHIP (chromatin immunoprecipitation ["ChIP"] with DNA microarray ["chip"]) analysis to bind to the *ctgf* promoter,[36] thus providing a second link to this profibrotic cytokine, which is upregulated following pBOO. Clearly, other pathways contribute to this remodeling, as shown by Schroder et al., who have shown that the mammalian target of rapamycin (mTOR) pathway is also mediating this hypertrophy.[37] These findings are of clinical relevance because cyclosporine A (a calcineurin inhibitor) and rapamycin (an inhibitor of mTOR) have been shown to protect the bladder in experimental pBOO models.[36,37] In time, it is hoped that this work will have clinical translational relevance in improving bladder function in this patient population.

Effects on the Upper Ureter, Renal Pelvis, and Kidney

Ultimately, as the bladder fails to adapt to its imposed workload (compensate), a sequence of molecular events results in which the bladder begins to retain larger volumes of urine. Because of this, the resting pressure in the bladder before voiding becomes significantly elevated, and this increased resting pressure is transmitted to the upper urinary tract over prolonged periods. *It is clear that elevated voiding pressures by themselves do not cause harm to the upper urinary tract*. Sillen et al. have documented extremely high voiding pressures in normal male infants or those with reflux and normal renal function.[38] *Thus, damage to the upper urinary tract occurs because of elevated intravesical storage pressures over prolonged time intervals*. The results of this are manifested in the resulting ureteral dilatation and rise in intrarenal pelvic pressures. Elevated bladder pressures are transmitted back to the renal pelvis under conditions of *high bladder volumes, noncompliant bladders, and a high urinary diuresis;*[39–41] *these conditions are met in patients with posterior urethral valves*.

Elevated renal pelvic pressures ultimately have a profound effect on renal morphology and function. A complete review of obstructive nephropathy is beyond the scope of this chapter; however, some basic concepts deserve mention. Obstruction impacts renal concentrating ability, glomerular filtration rate (GFR), and renal morphology. Numerous human and experimental observations support the notion that renal concentrating ability is diminished in the presence of obstruction.[42,43] This might occur as a result of damage to the luminal cells within the tubules, as shown in a study in which mechanical deformation of renal epithelial cells in culture was associated with apoptosis.[44] This might also reflect changes in blood flow to the medulla,[45] and a subsequent loss of the medullary concentrating gradient.[46,47] While these changes are probably of lesser significance in the fetal kidney that has poor concentrating ability, they have a profound impact in the older patient with posterior urethral valves who is left with pronounced polyuria and a compensatory polydipsia.[48] These changes also can account for the occasional patient who has a postobstructive diuresis following initial catheter placement in the neonatal intensive care unit (NICU).

Most boys with valves experience a drop in their GFR, although this is variable. Some anatomic variants dampen the pressure transmitted by the upper tracts to the kidney and thereby lessen renal damage. *When the full effects of high resting pressures are transmitted to the kidneys, fibrosis has been observed clinically and experimentally* [49] *both within the renal pelvis and within the renal parenchyma*. The cytokine transforming growth factor β (TGF-β) is associated with this fibrosis and is also secreted into the urine, providing a biological marker for the presence of obstruction.[50,51] There is also therapeutic potential in this observation, for in an experimental study, treatment with antibodies to TGF-β alone or in combination with an angiotensin-converting enzyme (ACE) inhibitor resulted in diminished renal fibrosis.[52,53] The deposition of the fibrosis is not necessarily uniform throughout the kidneys, which might reflect regional alterations in perfusion.

Genotypes and ESRD

Researchers have tried to determine if ESRD seen in boys with valves is solely a consequence of the obstructive uropathy or the result of delay in treatment in the fetal period. *Harrison et al. found that fetal surgical intervention for the infant with posterior urethral valves did not lead to improved renal outcomes, although it was associated with better pulmonary outcomes*.[54] However, these interventions were reserved for the most severe cases, and the authors concluded that by the time of intervention, the damage from obstructive uropathy may have become irreversible. An alternative explanation might be that obstruction alone is not the sole etiology of the ESRD, but that anomalies in the ureteral bud and nephrogenesis may

also contribute. The role of the angiotensin II receptor in ureteral and renal development is well established, and its targeted gene deletion may be associated with ureteral ectopia and associated renal hypoplasia.[55]

Given the central importance of the angiotensin receptor (ATR) in ureteral budding, branching, and renal development, several investigators have sought to study how the renin–angiotensin system (RAS) is altered in patients with posterior urethral valves. Components of the RAS where such genetic variability arises include ACE, angiotensinogen (AGT), and the ATR. Insertions and/or deletions within a fragment of intron 16 of the ACE gene account for up to 50% of the variability of the serum enzyme activity.[56] If all cases of ESRD associated with posterior urethral valves were attributable to obstructive uropathy alone, there should be no clustering of genotypes according to clinical outcomes. However, the distribution of the ACE I allele, which is associated with lower enzymatic activity, was much more likely to be seen in children with posterior urethral valves and renal insufficiency than it was in a normal population. Despite this observation, higher peripheral renin activity is observed in patients with posterior urethral valves than normal age-matched children.[57] This seeming discrepancy may arise because of the difference between the role of the RAS in development and renal branching, and its response in the postnatal period in the face of renal injury.

DIAGNOSIS

With the widespread use of screening antenatal sonography, the majority of patients with posterior urethral valves are being diagnosed in utero. It was initially hoped that this increase in diagnostic ability would lead to fetal intervention and better renal outcomes. Despite the widespread use of fetal sonography, there continues to be a high incidence of long-term renal failure in these patients. This suggests that by the time current imaging technology detects renal damage, it is already irreversible, or that the patient may have an at-risk genotype, or some combination of the two. Even with the widespread use of prenatal sonography, several series report that up to 10%–20% of boys present with symptoms such as urosepsis or urinary incontinence. In our own recent review of cases, 40% of patients presented beyond the neonatal period because of either a urinary tract infection or incontinence.[58] Possible explanations for this include a lack of access to prenatal care, a single screening ultrasound being performed at 19–20 weeks, and a lesion whose effects of the upper urinary tract may be progressive over time. One such example of a male fetus is shown in Figure 64.6, whose antenatal imaging was normal and yet who presented with incontinence and a rise in serum creatinine (Cr) as he failed to successfully toilet train.

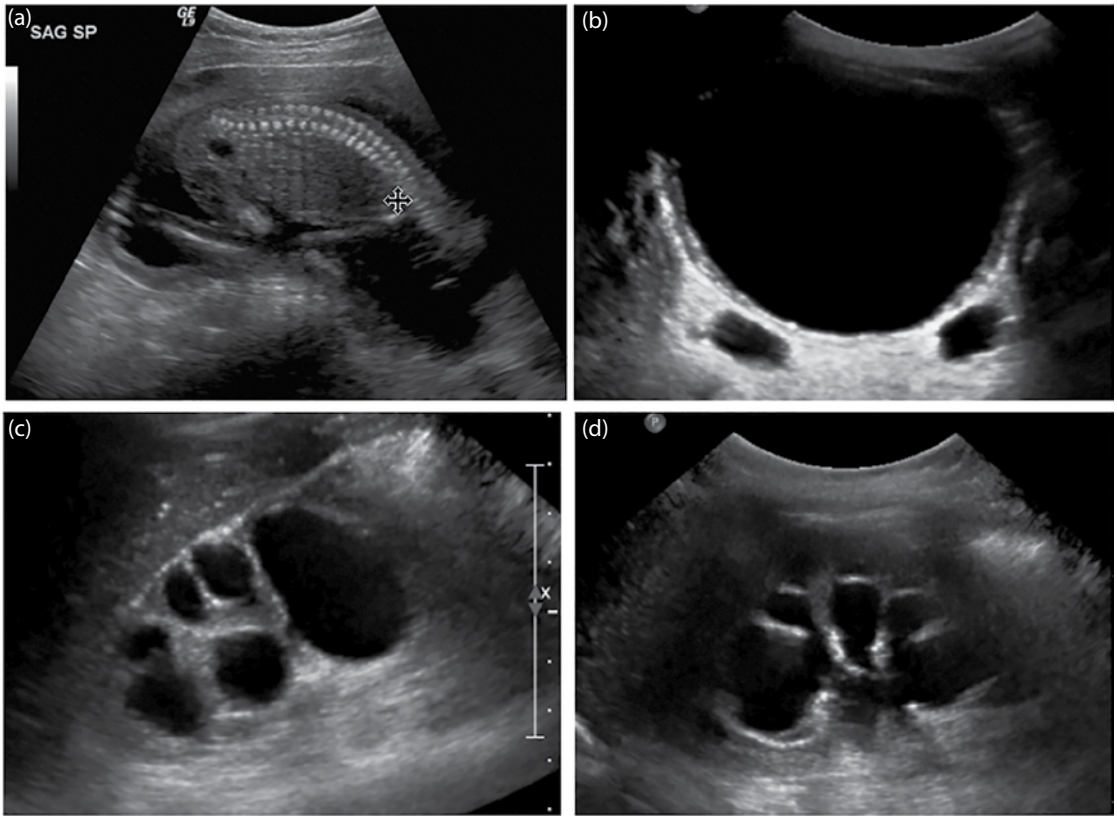

FIGURE 64.6 (a) The fetal sonogram of a boy showed no hydronephrosis and a normal bladder at the 23-week mark of gestation. However, at 5 years of age, this patient presented with urinary incontinence and a rising Cr. (b–d) His renal and bladder ultrasound demonstrated a thick-walled bladder and bilateral hydroureters (b). Severe hydronephrosis was noted in both kidneys, with cortical thinning worse on the right (c) than the left (d). He proved to have posterior urethral valves, after which his Cr declined to within a normal range. Such presentations are not uncommon.

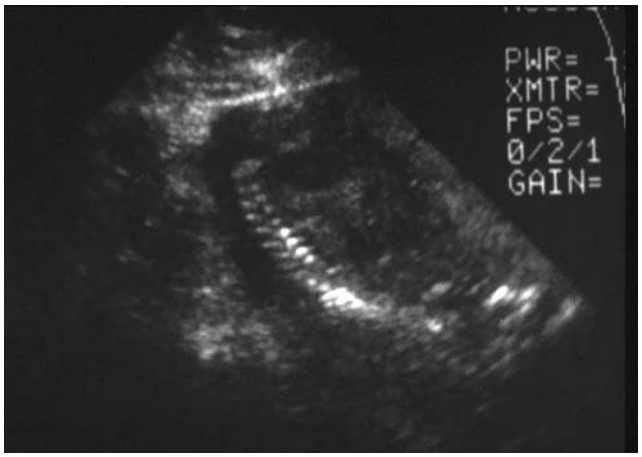

FIGURE 64.7 Fetal sonogram showing severe oligohydramnios. Note the lack of amniotic fluid between the spine and the uterine wall. Death occurred in the neonatal period from pulmonary hypoplasia.

Fetal Imaging

Screening sonography will usually detect a major obstructive uropathy at 18–19 weeks of gestation, and lead to further study with a higher-resolution ultrasound. The finding of a thick-walled bladder and bilateral hydroureteronephrosis in a male fetus suggests posterior urethral valves. However, ultrasonographers also see these changes in boys with the prune belly syndrome. One study suggests that sonography is accurate in making a diagnosis of posterior urethral valves in 50% of cases.[59] In addition to a determination of how much renal parenchyma is present, a critical factor in assessing the sonogram is the presence or absence of amniotic fluid. Oligohydramnios (Figure 64.7) is an ominous sign of advanced and severe obstruction. *In recent years, the role of sonography has been supplemented with the use of fetal MRI in highly selected cases* (Figure 64.8).[60] *The indications for fetal MRI in such a setting include bilateral hydroureteronephrosis, bladder wall thickening, and oligohydramnios*. In one study of early third-trimester gestations, the addition of the fetal MRI altered the initial diagnosis made by sonography in 30% of the cases.[61] Another study revealed MRI to be highly accurate in the assessment of total lung volumes (TLVs) in patients with genitourinary anomalies after 26 weeks of gestation, but similar predictability was seen using a determination of whether oligohydramnios was present or absent.[62] Further work will clarify the precise benefits this imaging can offer over conventional sonography.

IN UTERO MANAGEMENT: INTERVENTIONAL

Harrison's pioneering work in fetal intervention began with extensive experimental work in the fetal sheep model in 1978,[63,64] and the first clinical interventions took place in the early 1980s[65] with the hope of improving the renal prognosis. Open fetal surgical intervention using either a vesicostomy or ureterostomies was performed and shown to be technically feasible.[54] However, despite technical success in a majority of these cases, the incidence of renal insufficiency remained high.[15] However, intervention improved pulmonary function and the restoration of amniotic volume due to the internal stenting of the aspirated amniotic fluid.[66,67]

It was clear that not all boys with posterior urethral valves benefit from in utero intervention, because the severity of the obstruction from the valve is so variable. If one performs aggressive intervention in a population skewed toward advanced disease, as shown in Figure 64.1, the results are uniformly disappointing. Most boys have a good prognosis if they complete a normal gestation and have a neonatal valve incision. *Attempts to better stratify the at-risk group, in whom fetal intervention for obstructive uropathy would be helpful, led to the development of urinary sampling as a means of predicting which patient might benefit from this approach*. The ability to sample urine from the fetal bladder allows for analysis of

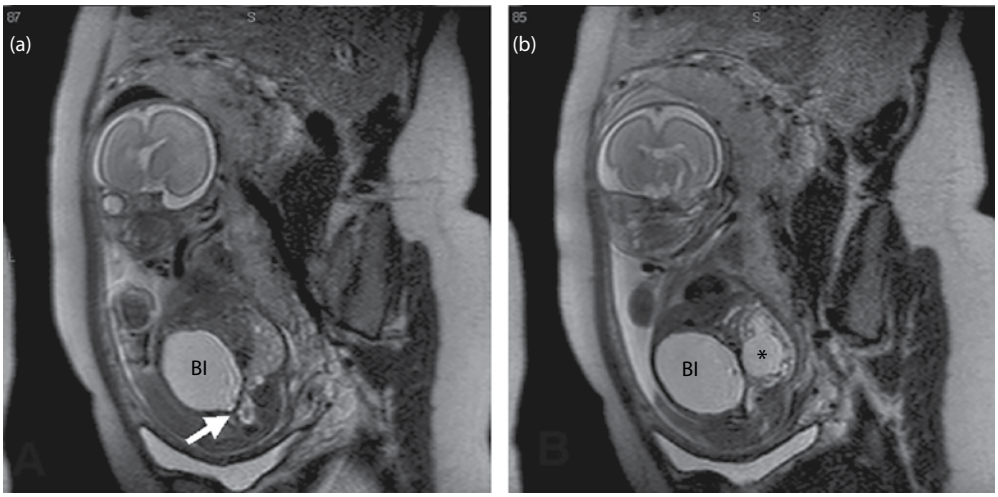

FIGURE 64.8 Maternal–fetal MRI showing moderate amniotic fluid levels and evidence of a dilated bladder (Bl), dilated posterior urethra (arrow) (a), and hydroureteronephrosis (*) (b).

electrolyte composition and testing for the expression of markers such as β_2-microglobulin. Under ordinary conditions, the fetal urine is hypotonic, which reflects the fetal kidney's poor ability to concentrate the urine. This is because proximal tubular function develops and active sodium transport results in a hypotonic filtrate. This hypotonic filtrate then passes on through the distal tubules with minimal reabsorption of free water. In contrast, in the older child, this hypotonic filtrate is concentrated by the absorption of free water via the aquaporin channels.[68] Glick et al. demonstrated that in the fetus with severe obstructive uropathy and renal dysplasia, a nearly isotonic urine was observed, which suggested significant problems with proximal tubular function, which mediates sodium reabsorption.[69] In contrast, with mild renal impairment, urine sodium, chloride, and osmolarity are hypotonic. There was initial optimism that urinary aspiration from the bladder with electrolyte and osmolarity analysis might predict long-term renal outcomes. *Favorable urinary electrolytes were deemed as follows: $Na^+ < 100$ mEq/L, $Cl^- < 90$ mEq/L, and an osmolarity below 210 mOsm/L. In the long term, fetal urinary electrolyte analysis still fails to separate those with a favorable renal prognosis from those in whom ESRD develops.*[15] The use of additional urinary markers, such as β_2-microglobulin, has also been investigated,[70] but none offer the perfect predictive test. Freedman et al. offered evidence that sequential bladder taps on 3 successive days might increase the predictive power of this method.[71] Despite this, in a recent review, even among those patients with favorable electrolyte patterns, the incidence of ESRD remained increased at nearly 30%.[72,73] In summary, *urinary electrolytes, if unfavorable, can predict the most severe cases of fetal obstructive uropathy seen with dysplasia. However, even patients with a favorable electrolyte pattern may progress to ESRD.* The pitfalls of this diagnostic dilemma have been reviewed by Elder,[74] and it remains an area for further research. Perhaps with the application of proteomics to urine samples collected from patients with known postnatal outcomes, a better marker of irreversible renal injury may be identified.[75]

Neonatal demise in patients with severe posterior urethral valves does not result from ESRD, but rather from pulmonary hypoplasia.[76] The etiology of this appears secondary to the loss of the mechanical distending forces provided by the aspiration of the amniotic fluid.[66,67] This experimental work formed the basis for clinical trials of amniotic fluid replenishment, which have resulted in improved neonatal pulmonary function.[77,78] In another smaller review of fetal intervention, Coplen et al. reported a high incidence of ESRD in shunted patients, but no evidence of respiratory compromise. However respiratory compromise was seen in those patients who were not shunted.[79] To summarize, *the hopes of fetal intervention for the prevention of renal failure have not been realized, but pulmonary function has improved in the most severe cases. Improved criteria might allow for the promise of fetal intervention to a small and highly selected population of patients with obstructive uropathy.*[71] Such efforts should be limited to those centers with expertise in this complex procedure and the antepartum care.

IN UTERO MANAGEMENT: OBSERVATIONAL

We recommend observing most patients with an in utero diagnosis of posterior urethral valves with serial sonograms to monitor the degree of urinary tract dilatation and the amount of amniotic fluid. Allowing these gestations to progress as close to term as possible optimizes pulmonary development. Communication between the obstetrical team and the pediatric urologist is always helpful to establish a clear plan of action for the family, and the healthcare team. The potential for good renal function and a near-normal lifestyle should be emphasized, as well as the small but real potential for long-term renal failure.[80] In severe cases where ESRD is likely, families may opt for termination of pregnancy.[81] The need for antibiotic prophylaxis, a renal bladder ultrasound, and voiding cystourethrogram (VCUG) in the neonatal period must be communicated to the family and referring physicians.

DIAGNOSIS IN THE OLDER CHILD

Although less common in this era of prenatal sonography, boys with valves still present with a history of either urinary tract infection, retention, or incontinence (Figure 64.6).[2,82–84] Not surprisingly for so diverse a condition, there is a case report of a boy presenting with valves despite a normal prenatal sonogram at 30 weeks' gestation.[85] *Boys with a urinary tract infection should have a renal and bladder ultrasound to exclude major underlying structural problems. If the boy has a febrile urinary tract infection or retention, we add a VCUG.*

Some older boys with valves have only urinary incontinence. In some cases, it is hard to single out the one boy who has a valve from the many with dysfunctional voiding and wetting from volitional urinary retention. While isolated nocturnal enuresis or an occasional daytime episode of wetting associated with delays in voiding is not cause for alarm, *the boy who presents with regular day- and nighttime wetting should trigger a suspicion of bladder outlet obstruction.* A screening renal bladder ultrasound should be done to exclude associated bladder wall thickening and assess the upper tracts, followed by a uroflow study and determination of postvoid residual. *The presence of a thick-walled bladder and obstructive uroflow pattern should lead to a VCUG being performed to rule out the presence of posterior urethral valves or a stricture.* Once these studies have ruled out any anatomic blockages, treatment of the dysfunctional voiding may proceed. Rarely, boys with valves have been treated for dysfunctional voiding for several years with growing frustration at the lack of progress—hence the importance of maintaining a high index of suspicion for this diagnosis in the setting of a clinic filled with incontinent children, the vast majority of whom do not carry this diagnosis.

Postnatal Imaging

We prescribe antibiotic prophylaxis for the neonate we suspect may have posterior urethral valves prior to

postnatal imaging. Imaging begins with a renal and bladder ultrasound, which may be diagnostic. We order a VCUG as soon as possible if the ultrasound has any features that suggest a possibility of posterior urethral valves, such as a thick-walled bladder or hydroureteronephrosis.

Ultrasound

The presence of a dilated posterior urethra, thickened bladder wall, bilateral hydroureteronephrosis, and cortical thinning in a newborn boy is suggestive of valves (Figure 64.9). In some cases, the hydroureteronephrosis is limited to one side and with an associated cystic- or dysplastic-appearing kidney. This represents the valves, unilateral reflux, and renal dysplasia (VURD) syndrome,[86] in which one renal unit absorbs the brunt of the high pressure and loses function, while the opposite side is spared and undergoes compensatory hypertrophy (Figure 64.10). Ultrasound examination may also detect the presence of urinary ascites. In addition to a thick-walled bladder, there may also be an associated diverticulum (demonstrated on the VCUG in Figure 64.10). *These pressure pop-off mechanisms are associated with better long-term renal*[86,87] *and bladder*[88] *function*.

In addition to noting the degree of upper tract dilatation, the intrarenal echogenicity can also serve as a valuable clue to the renal prognosis. Within the normal kidney, there are substantial differences in the echogenicity observed between the renal medulla and cortex (Figure 64.11). *In contrast, with substantial renal damage, there is a loss of this corticomedullary differentiation* (Figure 64.11). The loss of this corticomedullary differentiation suggests a more ominous renal prognosis.[89,90]

VCUG

The VCUG remains the cornerstone of achieving an accurate diagnosis of posterior urethral valves. Sometimes it is difficult to pass an 8 French feeding tube (Figure 64.12), which may coil within the dilated prostatic fossa. Using a coudé-tip catheter allows for the passage of the catheter over the hypertrophied bladder neck. Once the radiologist fills the bladder and the bladder begins to contract, the catheter is withdrawn to allow fluoroscopic observation of the entire urethra. The characteristic valve cusp appears at the inferior aspect of the dilated prostatic urethra and appears identical to the leaflets seen at the time of cystoscopy (Figure 64.13). Although the diagnosis of valves is

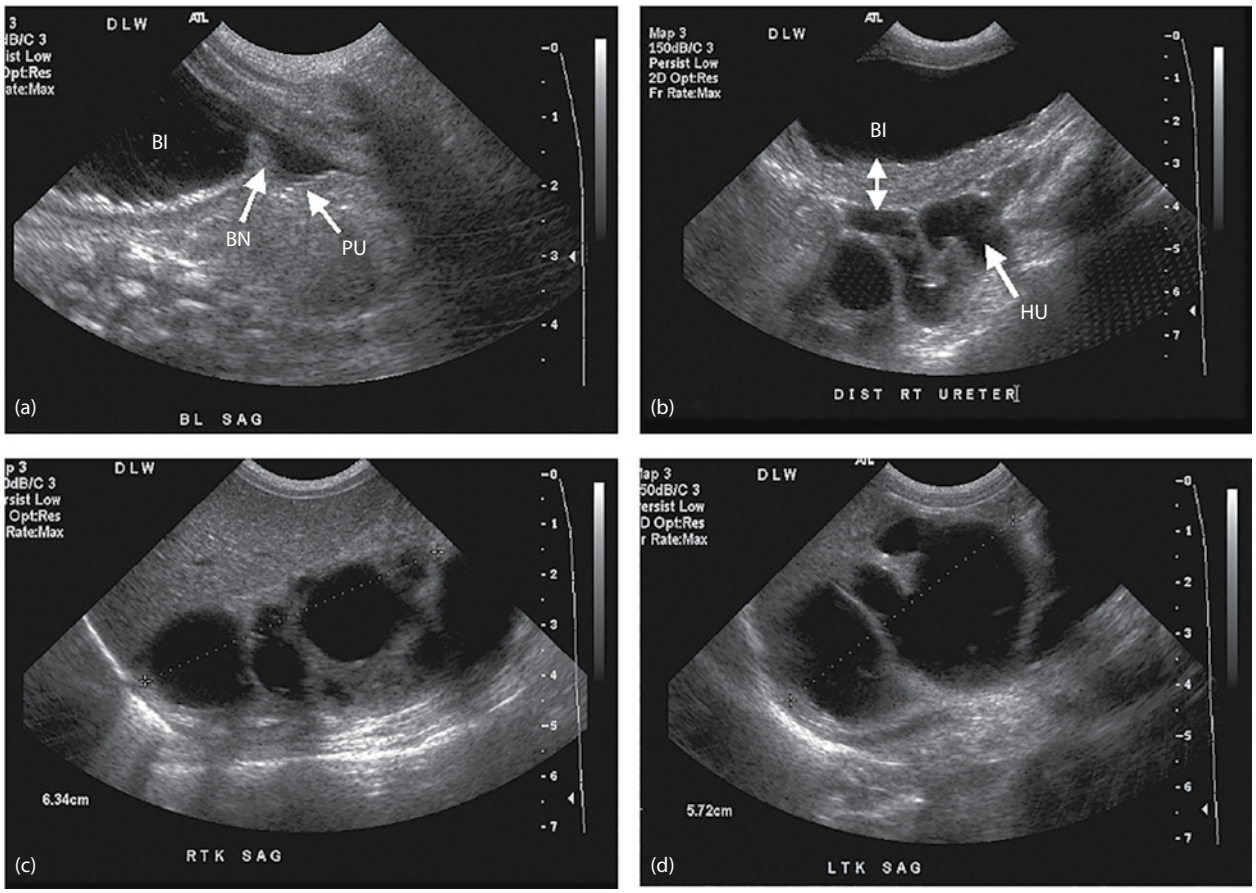

FIGURE 64.9 This postnatal ultrasound demonstrates the classic findings of severe posterior urethral valves. (a) The distended bladder (Bl) can be traced in this sagittal view down to the level of a dilated bladder neck (BN) and dilated posterior urethra (PU). (b) The dilated bladder has a very thick wall (arrows) and associated severe hydroureteronephrosis (HU). (c and d) Both kidneys show severe cortical atrophy.

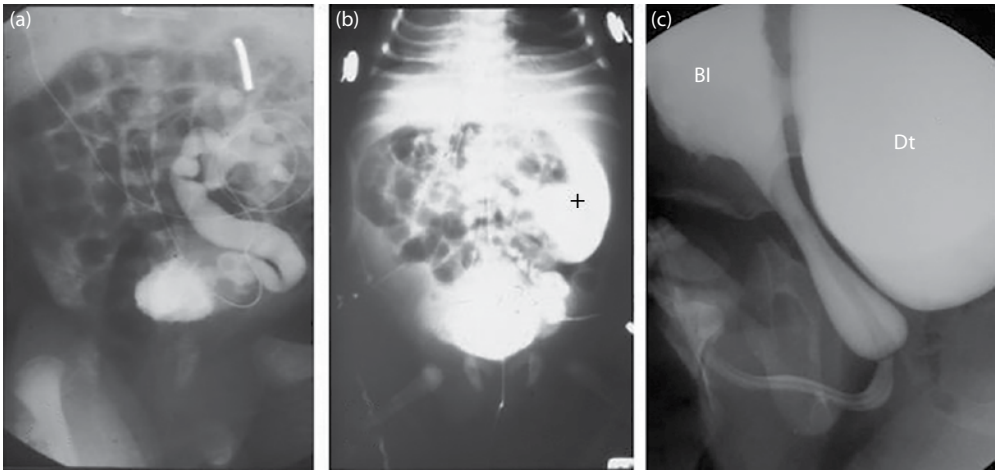

FIGURE 64.10 Pressure pop-off mechanisms that serve to vent elevated intravesical pressure and preserve renal function have been well described. (a) Example of the VURD syndrome in which the left renal unit has high-grade reflux and dysplasia; this spared the right kidney. (b) Extravasation into the perinephric space (+) following a forniceal rupture may also occur. (c) The large bladder diverticulum spared this patient's renal function. Bl, bladder; Dt, diverticulum.

not affected by having the catheter in place during micturition (Figure 64.10c), it is best to have fluoroscopic voiding views free of any interference.

Sometimes it is not clear from the VCUG whether one is seeing a posterior urethral valve or contraction of the striated external sphincter. It is critical to view each image provided to find a view that demonstrates a relaxed external sphincter. In this case, "real-time" fluoroscopy is useful by personally observing the VCUG, if possible, or asking for a video recording. If any doubts remain as to whether the narrowing is physiologic or anatomic, we perform cystoscopy to exclude the presence of a valve leaflet. Similar concerns may arise on a postoperative VCUG following valve incision. In one illustrative case, initial views showed a narrowing of the distal aspect of the prostatic urethra (Figure 64.14b) that opened widely on subsequent views (Figure 64.14c).

The VCUG may also reveal the presence of unilateral or bilateral reflux. *Unilateral reflux may occur in a dysplastic and nonfunctioning kidney, and serve as a pressure pop-off mechanism.*[86,91] *Similarly, a large diverticulum may also serve as a venting mechanism and confer a better renal prognosis. We do not excise these diverticula. We believe that they provide low-pressure storage capacity unless urinary retention or infection intervenes.* We have illustrated these concepts with the cases in Figure 64.10.

Nuclear Medicine

If high-grade reflux into one kidney is associated with a thinned renal parenchyma, a mercaptoacetyltriglycine (MAGIII) renal scan will allow for quantification of function. However, the automatic removal of such kidneys is unwise unless infection forces the issue. Such dilated systems serve as low-pressure pop-off mechanisms and should be preserved if possible. Scans are often ordered to rule out ureterovesical junction obstruction, but in such highly dilated systems, the washout times will always be

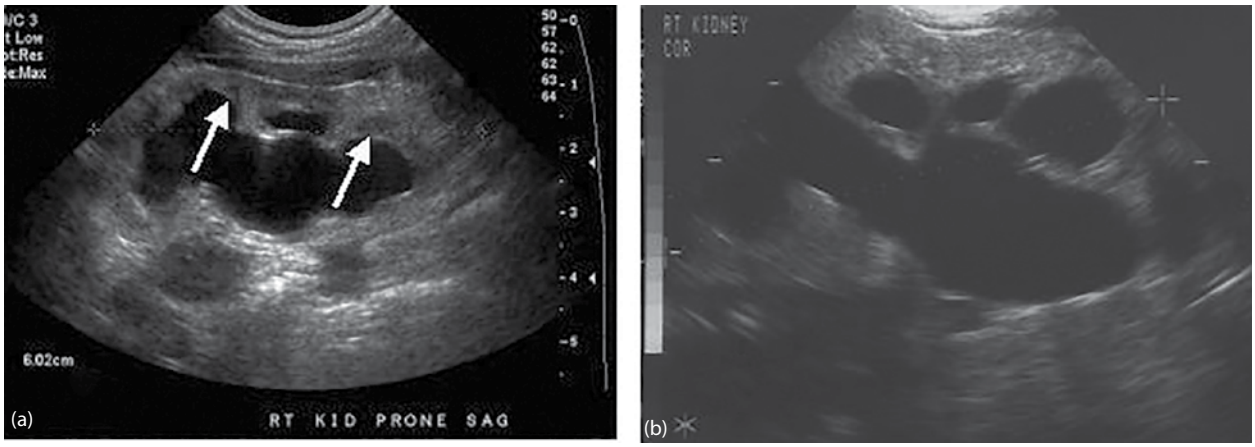

FIGURE 64.11 (a) Differences in renal corticomedullary echo density or differentiation are a favorable prognostic sign. The arrows point to areas within the medullary region that are of distinctly lower density than the surrounding cortical regions. Sometimes these areas are mistaken for a fluid-filled calyx. (b) In contrast, a renal sonogram shows severe hydronephrosis and a renal parenchyma that is uniformly dense and shows no corticomedullary differentiation. Fifteen years later, this patient is in renal failure.

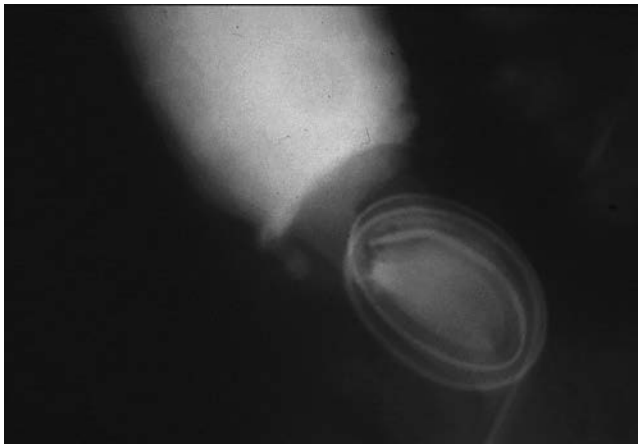

FIGURE 64.12 The challenge of placing a catheter in a dilated posterior urethra is usually circumvented by using a coudé-tip catheter. Occasionally, even a coudé-tip catheter will coil in the posterior urethra, and require fluoroscopic placement. This is useful for the older boy with valves who is going to initiate CIC.

prolonged, which makes the test less useful. For this reason, renal MAGIII scans need not be ordered routinely, but should be restricted to a small subset of patients.

Management Options

Initial Management in NICU

Following delivery, a healthy neonate with good pulmonary function can safely bond with his mother and father. Within hours, as the neonate is transferred to the NICU, we obtain an ultrasound, and if the findings are consistent with valves, we place a feeding tube in preparation for the VCUG. We then start antimicrobial prophylaxis with amoxicillin. *A child who is stable from a pulmonary standpoint can then be prepared for valve ablation often within 48–72 hours of life.*

If the boy has pulmonary hypoplasia and complex ventilatory requirements, prematurity precluding endoscopic manipulation, or significant postobstructive diuresis, we delay the valve incision and opt for a period of urethral catheterization. Sometimes in these settings, the infant's serum Cr rises above the maternal Cr as the degree of renal impairment becomes manifest. Usually, the diuresis is physiologic, but rarely, the rise in Cr may reflect prerenal dehydration that follows postobstructive diuresis. In these situations, we recommend maintaining catheter drainage and allowing the medical condition to stabilize.

Surgical Aspects

With the major advances that have taken place in fiberoptic technology, it is now possible to incise posterior urethral valves in all but the smallest premature neonates. Many approaches to valve incision have been described.[92] A bugbee electrode can be passed through a 7.5 or 9 French neonatal cystoscope to apply cutting current to the valve leaflets at the five, seven, and twelve o'clock positions (Figure 64.15) or at the twelve o'clock position alone. Valve incision requires only that the surgeon disrupt the integrity of the valve; overzealous attempts to fully excise the valve raise the risk of stricture formation.

We consider performing a vesicostomy as the initial surgical intervention in the very premature neonate whose urethra will not accommodate an endoscope; trauma from a large cystoscope can induce a urethral stricture. We also consider this approach in a neonate whose Cr has risen despite successful catheterization. In this setting, the vesicostomy minimizes lower urinary tract storage pressures and optimizes GFR.[93,94] We believe that a vesicostomy does not place the bladder at total rest; in fact, the bladder does fill, and undergoes partial cycling, albeit at much lower pressure. A vesicostomy allows for venting of high intravesical pressures as they develop, thus minimizing any transmission of pressure back toward the kidneys.

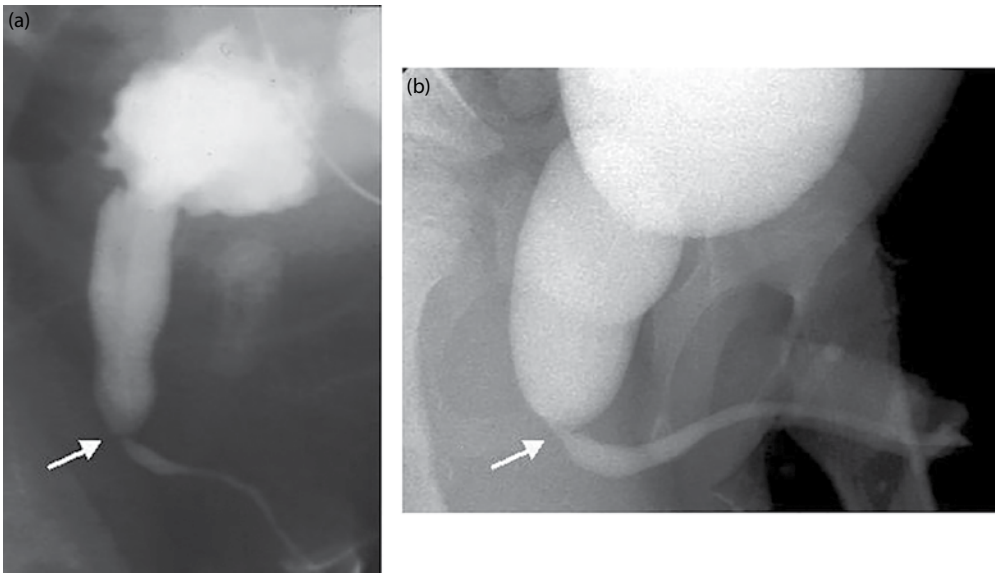

FIGURE 64.13 (a and b) The classic valve cusps associated with type 1 posterior urethral valves (arrows) are demonstrated in these two VCUGs.

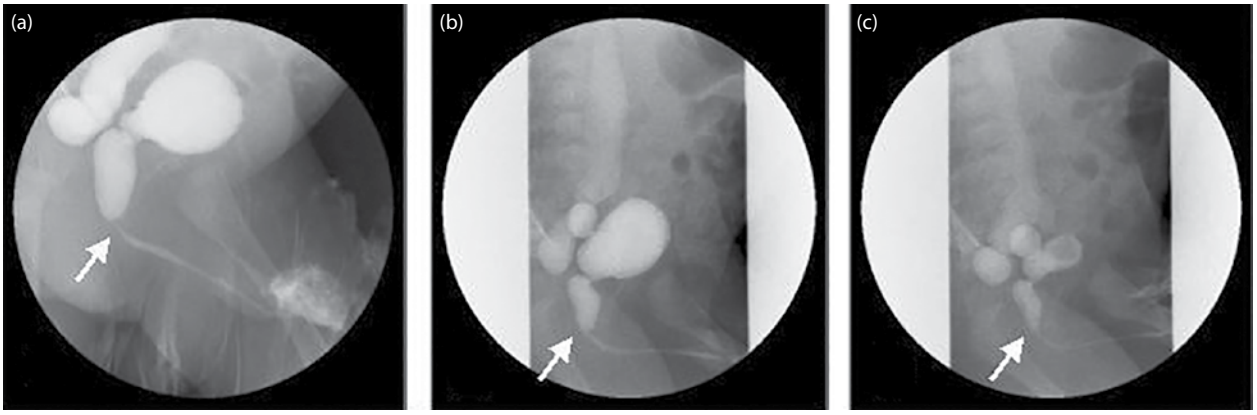

FIGURE 64.14 (a) The classic type 1 posterior valve is shown preoperatively (arrow). (b) The postoperative appearance of a VCUG for a patient 3 months following valve resection demonstrates what might appear to be a residual valve leaflet (see arrow). (c) However, full review of all the fluoroscopic images reveals that this narrowed area opens up when the striated external sphincter is relaxed.

One long-standing controversy in the management of patients with posterior urethral valves revolves around the use of high urinary diversion. Historically, a child whose renal function failed to improve, or even worsened, following valve ablation might undergo bilateral ureterostomy or pyelostomy. Following the surgery, the Cr level often decreased, and thus high diversion has had its advocates.[94,95] Some believe that boys with severe outlet obstruction develop a secondary obstruction at the ureterovesical junction due to potential obstruction of the dilated ureter as it passes through the severely thickened bladder wall. If this were true, then high diversion would potentially reduce risk of renal damage from ongoing high pressure despite valve incision. If, in such a setting, a nephrostogram is performed, it is possible to demonstrate an "obstruction" at the ureterovesical junction (Figure 64.16). *Although there are still centers where persisting dilatation of the upper urinary tract following successful valve ablation leads to consideration for upper urinary diversion, most pediatric urologists do not recommend high diversion despite some clinical evidence that resulting bladder function is good following undiversion.*[94] The

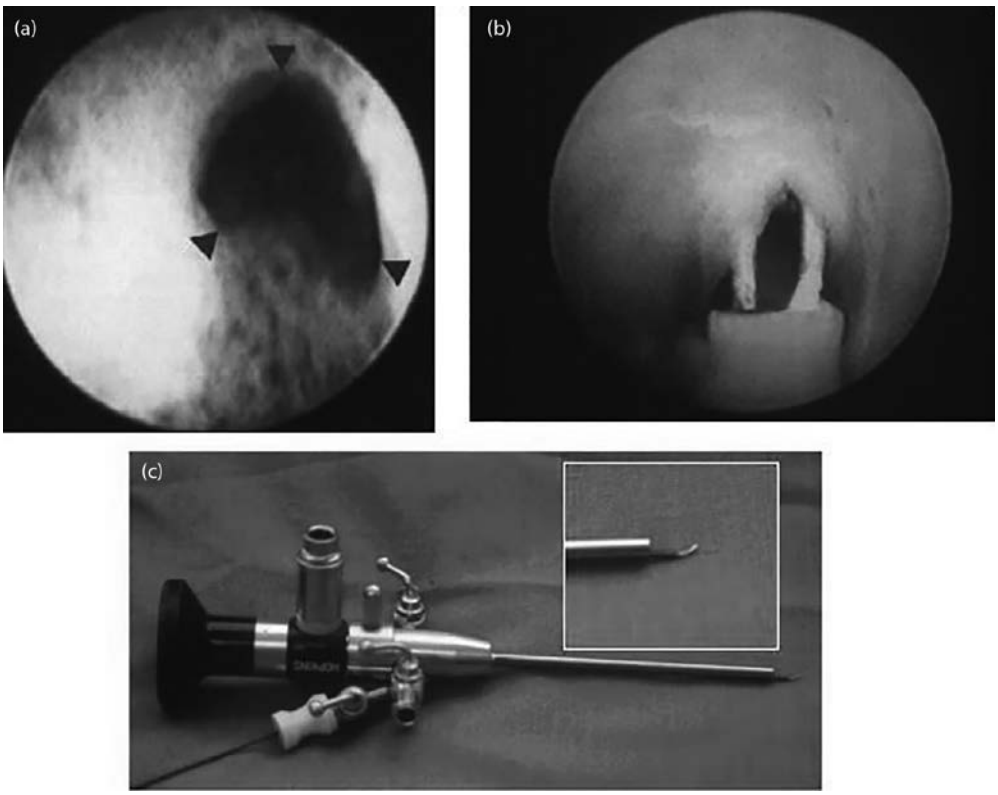

FIGURE 64.15 Incisions may be made at the twelve, five, and seven o'clock positions (a) using either a resectoscope (b) in an older child or a bugbee electrode delivered by a 9 French cystoscope in the neonate (c).

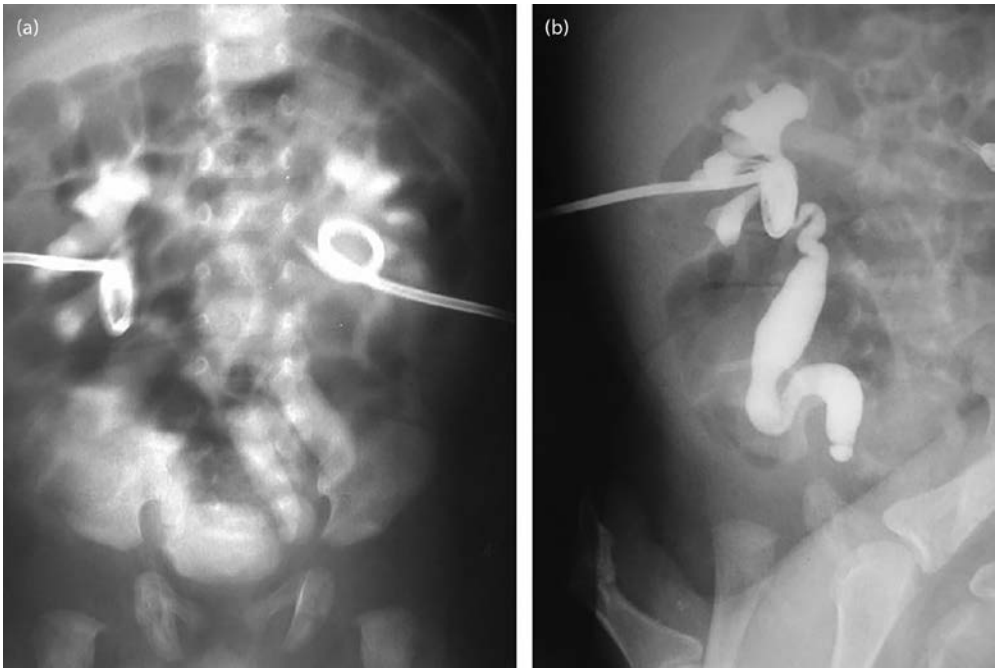

FIGURE 64.16 Upper tract imaging was ordered in this boy because the hydronephrosis failed to respond to primary endoscopic valve ablation. (a) The intravenous pyelogram reveals bilateral hydroureteronephrosis with delayed washout on the left. (b) An antegrade nephrostogram revealed a distal ureteral narrowing with impedance of flow into the bladder. At the time of these studies, this patient was 2 months old and had a serum Cr of 0.7. Advocates for high urinary diversion to maximize GFR would note that the increased resistance to drainage shown in panel B supports their approach. Advocates of the watchful waiting approach would counter with the following arguments: (1) If the nephrostomy tube were clamped, and one waited, contrast would flow into the bladder over time, because this is not a complete obstruction. (2) As the bladder experiences repeated filling and emptying cycles, it will heal, and as the wall thickness diminishes, the resistance to antegrade flow will diminish. Our recommendation in this case was for the maintenance of antibiotic prophylaxis, circumcision, and serial imaging of the upper tracts at increasing intervals as the upper tracts decompressed.

alternative point of view is that high diversion interrupts the normal bladder cycle of filling and emptying,[96] resulting in a stiff fibrotic bladder that is more difficult to rehabilitate later on prior to transplantation.[97–99] This view is supported in part by experimental evidence in a dog model of urinary diversion and undiversion, which demonstrated detrimental physiologic and pharmacologic changes that take place when the bladder was prevented from cycling.[100] Similar findings were noted in a fetal sheep model with increased expression of extracellular matrix elements[101] and increased apoptosis[102] following high diversion.

Circumcision

We recommend circumcision in boys with valves. Wiswell's data suggest that febrile urinary tract infections are more commonly seen in uncircumcised males.[103,104] The consequences of urinary tract infection superimposed on a dilated urinary tract with stasis and renal insufficiency should be enough to give every urologist ample cause to encourage circumcision in this setting.

Nephroureterectomy

The traditional approach to the management of patients with unilateral high-grade reflux and associated dysplasia (the VURD syndrome)[86] called for an initial valve incision, followed by a nephroureterectomy. However, we no longer remove poorly functioning kidneys unless recurrent urinary tract infections are definitively localized to the poorly functioning unit. In our experience, this is very rare. We believe the low-pressure venting into the nonfunctional system places less stress on the compromised valve bladder. For boys in renal failure, the native kidneys maintain fluid balance; renal failure with moderate polyuria is easier to manage than anuria. *It has been our experience that native nephrectomy is rarely required in these boys. If a nephrectomy is required, the ureters should be left behind for use in subsequent reconstructions.*[105]

Ureteral Reimplantation

While up to 50% of patients presenting with valves show signs of vesicoureteral reflux on their initial VCUG,[93] successful valve ablation and bladder cycling lead to resolution in the majority of cases. Glassberg and coworkers have argued for management based on urodynamic data. He notes that treating residual voiding dysfunction often leads to reflux resolution in this population.[106] If bladder function is optimal, then reimplantation can be performed succesfully.[107] It is well established that reimplantation of dilated ureters into thick-walled bladders with associated voiding dysfunction carries a higher complication rate.[108] Thus, if correction of reflux in this patient population is desired, some consideration should be given to endoscopic injection.[109] *In our own experience, ureteral*

reimplantations are almost never required in circumcised boys with successfully incised valves and may compromise bladder compliance or, worse, potentially further compromise a failing kidney.

Surgical Complications

Surgical complications from endoscopic valve ablation are rare with the current generation of smaller high-resolution fiber-optic endoscopes. The feared complication of past years was a stricture induced by passing too large an instrument through a tiny urethra. We almost never see this complication now that we have pediatric cystoscopes as small as 7.5 French with a side port for a bugbee electrode. This is preferable to using the resectoscope, which is a larger instrument. *In the very small infant, in the rare event that available endoscopes cannot pass through the urethra, we consider a vesicostomy with a plan for delayed valve incision.*[92]

Short- and Long-Term Outcomes of Posterior Urethral Valves

Short-term complications seen following valve incision may include urinary retention and renal failure.[93,110] If voiding is not complete and urinary tract infection ensues following valve incision, short-term use of clean intermittent catheterization (CIC) may become necessary. In general, if urinary retention is noted postoperatively, catheterization for 24 hours, followed by a repeat voiding trial, is nearly always successful. The number of valve patients who have true myogenic failure is small.[111]

In some boys, the neonatal course is complicated by renal failure. In many of these cases, the more immediate life-threatening problem is respiratory failure brought from hypoplastic lungs (Figure 64.1). Fetal sonography allows for an opportunity to minimize pulmonary complications by either shunting or amniotic fluid infusions. Extracorporeal membrane oxygenation (ECMO) has been used for these boys until they can be managed with conventional ventilatory support,[112] but the majority of these patients will develop ESRD and require renal transplantation later. Transplantation in the first year of life is rarely needed and should be a last resort. *While technically feasible, the discrepancy between the organ size and the total body volume of the recipient makes such procedures more challenging and higher risk than for older patients.* For this reason, as well as the desire to minimize the years of immunosuppression, *every effort is made to optimize renal function, avert dialysis, and let the child develop without the transplant as long as possible.*

Approximately 15%–30% of patients with posterior urethral valves go on to develop ESRD, depending on the series.[113] Studies suggest that if by 1 year of age the serum Cr has reached a nadir value of 0.8 or less, ESRD will be avoided.[93] Despite severe cortical thinning on sonography, many patients will see their Cr drop below 1.0 only to return with ESRD later in life. What can predict such a transition to ESRD? Some have suggested serial Cr measurements and a derivation of velocity with which the Cr drops.[114] Pulido et al. measured the renal parenchymal area from the initial ultrasound and demonstrated that for those patients with severe cortical thinning, a total parenchymal area of less than 12.4 cm^2 defined the cutoff for progression to ESRD by 6 years of age.[58] For the patients whose Cr at 1–4 weeks of age ranged from 0.8 to 1.1, the cohort whose renal parenchymal volume fell below 12.4 cm^2 was at far greater risk of ESRD by 6 years of age.[58] These findings must be validated in a larger multicenter study. The ability to identify the high-risk cohort for progression to renal failure would allow for the design of trials of medical intervention in the neonatal period with the goal of preventing or delaying the onset of ESRD. We suspect that the patients with low renal parenchymal volumes whose Cr values drop have no renal reserve, as they are perfusing all the limited number of glomeruli their kidneys possess.

If renal insufficiency is present in the neonatal period, there is usually enough GFR to support growth and development. Both the pediatric urologist and nephrologist must work together to closely follow boys whose Cr approaches these values. On occasion, these boys suffer from tubular acidosis and require bicarbonate replenishment. For those with more advanced renal insufficiency, growth hormone may be required. As the renal failure advances, calcium, parathyroid hormone, and bone development must be closely monitored. Long before the time for transplantation approaches, the urology and nephrology team must begin to address the function of the lower urinary tract, and its ability to safely sustain an allograft with low storage pressures.

Most series report a substantial delay in the acquisition of daytime and nighttime continence for all patients with valves.[93,110] For patients with less severe valves, the bladder and renal functions combined allow for continence usually around 6–7 years of age. However persistent urinary incontinence is an ominous sign in patients with a diagnosis of posterior urethral valves.[115] Given the pathophysiology of upper and lower urinary tract obstruction outlined at the beginning of this chapter, this incontinence is more readily understood. Because of the bladder wall fibrosis and poor storage capabilities, an increasing volume of urine is stored at higher pressures within the upper urinary tract. The severe polyuria that these patients exhibit due to distal tubular injury in utero worsens this problem. Ironically, the boy himself may also unwittingly aggravate the condition in his desire to be dry. As he struggles to achieve dryness by suppressing the desire to void, and retains urine, he contributes to upper tract dilatation and increasing storage pressures. For many boys, a regimen of timed voiding is effective. In others with upper tract dilatation, double voiding will safely result in dryness. Instructing the boy to void in the ultrasound suite, while assessing his bladder with pre- and postvoid views of the kidneys, ureters, and bladder, provides a powerful teaching tool for the boy, who will benefit from double voiding.

It has become clear in recent years that for many of these patients, overnight catheter drainage[116,117] and CIC will provide continence, lower storage pressures, and preserve renal function. For all these reasons, *a critical time to follow a boy with valves closely is around the time the child begins to express an interest in potty training.*

Videourodynamics

For the valves patient who has persistent urinary incontinence, or is approaching ESRD, videourodynamics offer an invaluable tool to optimize the chances for achieving dryness[106,118] *and for successful transplantation*. Prior to performing videourodynamics, it is essential to have the patient and family complete a thorough diary that includes not only the urinary output, but also the fluid intake. This helps to determine the average urinary volume produced on an hourly basis by day and night, and what voiding frequency will be required. *In contrast to conventional urodynamics, a videourodynamics study will help to determine what part of storage capacity is provided by the bladder and compare that with what is contributed by the upper tracts*.

We have demonstrated this concept with the study shown in Figure 64.17. This study, if done conventionally, would suggest that the boy has a very compliant bladder. In fact, when the video images are considered, it is clear that the bladder has poor compliance and there is high-grade reflux early in filling. The high-grade reflux into his native kidneys augmented this boy's storage capacity and masked poor bladder compliance. Despite attempts at double and triple voiding, his diurnal urinary incontinence persisted in part due to his polyuria. He resisted our attempts to teach him urethral CIC, which is typical in this population of boys with a sensate perineum and a dilated posterior urethra (Figure 64.12). Based on this study, we recommended an appendicovesicostomy to allow intermittent catheterization every 2–3 hours by day, and overnight catheter drainage. As long as this boy was compliant with his daytime catheterization schedule, he remained dry. Following transplantation, he remains continent due in large part to the improved concentrating ability of his allograft. In this case, the videourodynamics study altered this boy's care in two ways. First, the study made it clear that native nephroureterectomy would compromise his ability to achieve safe storage pressures. Second, the large residual urine measured by the study reflected storage in his upper tracts that would not respond to double-voiding regimens. Given these findings, clean catheterization via an appendicovesicostomy offered him the optimal management for achieving dryness in the short term, while preparing for the inevitable renal transplant that followed.

Postobstructive Diuresis

Boys with a history of posterior urethral valves often have persistent dilatation of the upper urinary tract that worsens as they begin to toilet train. For some boys, the imposition of daytime dryness achieved by delaying voiding and conscious use of the external sphincter places additional burden on the upper tracts. This worsens during sleep. What produces a reward for the child in terms of dry sheets in the morning and clean underwear at the end of the day may contribute to worsening of renal function. For some boys, this leads to a cycle (Figure 64.18) in which increasing bladder storage pressures result in higher renal pelvic pressures. This in turn aggravates renal medullary concentrating ability, which is already compromised,[48] and thus results in additional diuresis.

Clinical and experimental evidence support these concepts. In a videourodynamics assessment of partial bladder outlet obstruction, decompensated rabbit bladders had good compliance, defined as $\Delta V/\Delta P$. They also required much larger volumes (with a higher prevoid baseline pressure) to initiate their voids, which were small and associated with high residuals. Within this group, the postvoid residual urine recorded exceeded the infused volume.[119]

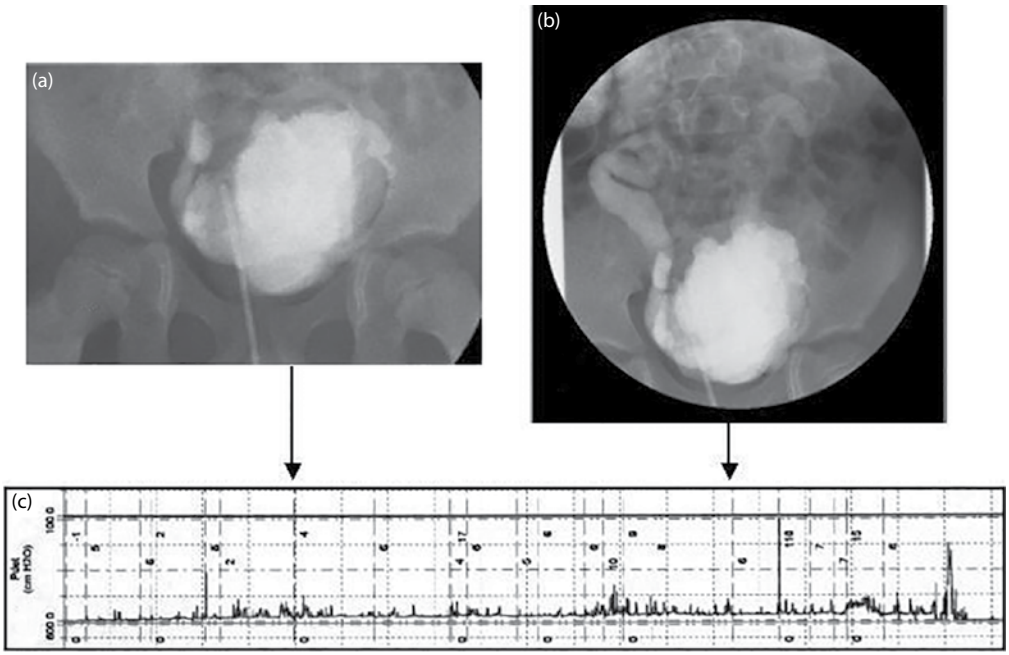

FIGURE 64.17 (a and b) This videourodynamics study demonstrates the benefit of the fluoroscopic examination. (c) This appears at first glance to be a very compliant cystometrogram; however, close examination reveals that compliance is augmented by the reflux into the upper tracts (b).

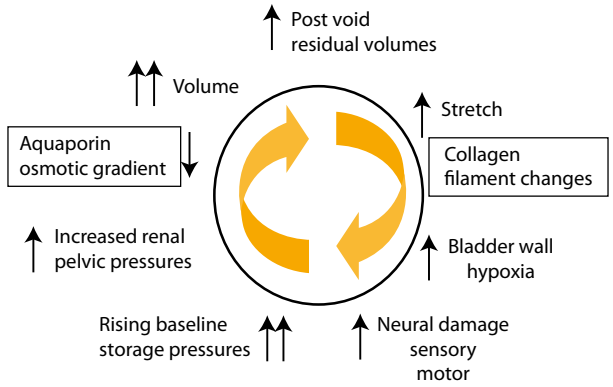

FIGURE 64.18 Schematic representation showing the integration of upper and lower urinary tract dysfunction in boys with posterior urethral valves. The cycle of gradual increasing postvoid residual volumes leads to increased resting prevoid pressures, which in turn lead to increasing renal medullary pressures. The resulting loss of concentrating ability results in increasing diuresis that aggravates the cycle by subjecting the bladder to increasing stretch.

This led us to consider these cystometrograms on an individual basis, and to classify them according to their baseline pressure before voiding. For the subset of obstructed bladders (30%) in which the baseline pressure exceeded 10 cm H_2O, the postvoid residual urine exceeded the infused volume by an average of 30 cc (Figure 64.19). How could the residual volume exceed the infused volume by nearly 40%? In performing these experiments, we emptied the bladder under fluoroscopic control before initiating slow-fill cystometry at 1–2 cc/minute. During the filling period, the diuresis from the upper tracts was pronounced in those bladders with an elevated baseline pressure before voiding. Although the majority of these bladders demonstrated "good compliance," these rabbits were spending most of their time at the far right of their cystometry curves, and thus subjecting their upper tracts to the same higher baseline pressure. This postobstructive diuresis was also observed in 30% of the rabbits following reversal of outlet obstruction in a subsequent group of experiments.[120]

We have observed similar findings in boys with posterior urethral valves. During a videourodynamics study of a boy with urinary incontinence following valve ablation, we noted that despite having initiated the study by aspirating all urine from the system, the postvoid residual urine exceeded the volume infused. We also observed this phenomenon in another boy with valves in whom we had created a unilateral end-cutaneous ureterostomy. We recorded this boy's ureterostomy output and correlated it with the catheterization status of the bladder. When this boy slept without an indwelling catheter, we recorded larger volumes of urine from the ureterostomy. In contrast, when sleeping with an indwelling catheter, the overnight volumes recorded from the ureterostomy dropped by almost 40%. This finding supports our conclusion[116] and that of others[117,121,122] who feel that *overnight catheter drainage can eliminate a substantial volume, and hence pressure burden, on the upper tract* (Figure 64.20). Taken over a period of time, and with recovery of some concentrating ability, the total 24-hour urine volumes often drop, both offering the benefits of improved daytime continence and optimizing renal function.

Pretransplant Evaluation

The pediatric urologist caring for these boys must continue to remain actively involved with the nephrology transplant

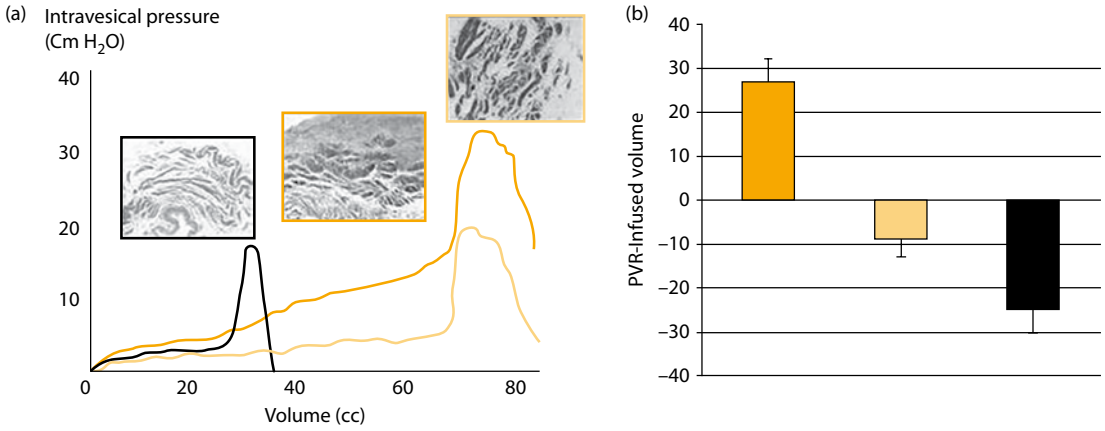

FIGURE 64.19 Experimental work demonstrates the relationship between a noncompliant bladder and postobstructive diuresis. (a) Following partial bladder outlet obstruction in rabbits, we performed videourodynamics free of any sedation 24 hours after placement of bladder and peritoneal catheters. For the sham control (▬), we recorded a normal slow fill cystometrogram (CMG) terminating in a voluntary void to completion. For decompensated bladders, we observed two populations of curves. In one group of bladders, compliance was preserved if expressed as ΔP/ΔV; however, the resting pressure just before voiding was higher (▬). However, for a second group of decompensated bladders, a noncompliant pattern was observed with a much higher resting pressure before void (▬). In each instance, we recorded an accurate postvoid residual with fluoroscopic confirmation. Note the increased deposition of extracellular matrix elements in the two decompensated bladders. (b) If one subtracts the infused volume from the postvoid residual, and exceeds zero, this is evidence of a diuresis that occurs during bladder filling. We observed the presence of a postobstructive diuresis only in those noncompliant decompensated bladders whose resting pressure before voiding exceeded 10 cm H_2O. (Adapted from Stein R et al. *J Urol* 2001;166(2):651–7.)

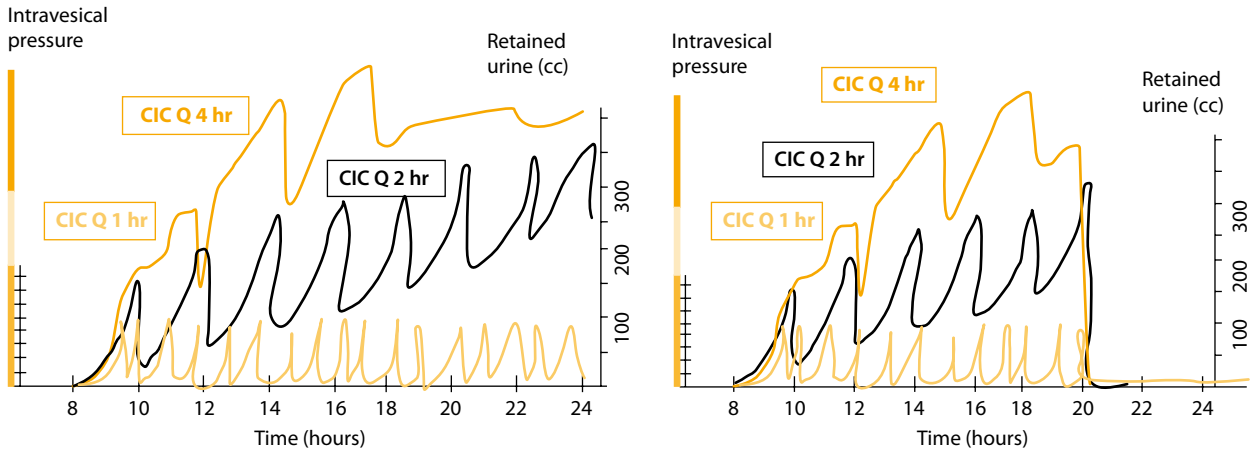

FIGURE 64.20 These two panels demonstrate the concepts of a safe pressure storage zone, and the role of overnight catheter drainage. As shown in both panels, maintaining a safe storage pressure (green zone on the left) for a patient with polyuria this severe is possible only with a regimen of CIC at 1-hour intervals. As CIC moves to 2-hour intervals, the daytime hours drift upward from the green to the yellow pressure zones as illustrated in the panel on the right. However, at 4-hour CIC intervals, the red zone of high intravesical pressures is reached during the waking hours, and prolonged exposures to high red zone pressures are maintained during the overnight hours. However, with overnight catheter drainage, the hours of exposure at high pressure at night are minimized. An additional benefit with this particular patient was that renal concentrating ability improved and the total volume produced per 24 hours dropped, making daytime dryness easier to attain and at lower intravesical pressures.

team as ESRD approaches. Boys undergoing transplantation with a poorly functioning bladder have higher complication rates and graft loss than those in whom lower urinary tract function has been optimized.[123,124] *We recommend videourodynamics assessment for any boy in whom transplantation is anticipated. This allows for determination of the volume for safe bladder storage pressure and assessment of whether CIC is required.* Videourodynamics studies may also reveal that high-grade reflux into the native ureters provides additional compliance to the system (Figure 64.17). For this reason, we rarely recommend nephrectomy. The principal indications for pretransplant native nephrectomy are the presence of severe polyuria or hypertension that is difficult to control. We have rarely witnessed new urinary tract infection into the native kidney following transplantation if infection was not common before the transplant. *If nephrectomy is indicated, consider preserving the ureters for catheterization, augmentation, or anastomosis to the transplanted kidney should problems arise within the transplanted ureter.*

If videourodynamics reveals that the bladder capacity must be expanded to provide safe storage pressures, ureteral augmentation is an option.[125] Very rarely, augmentation using a bowel segment may be necessary. In the past, dogma required that total bladder reconstruction, including augmentation if required, must occur before transplant. Our experience has been different. *We have been pleased with the results of transplantation to the vesicostomy in the unusual cases where low bladder volume and poor compliance resulted in lower tract diversion.*[126] Under these conditions, the transplant team should not hesitate to reimplant the transplant ureter into a diverted bladder that is draining via a vesicostomy.[127] With this approach, we have successfully postponed reconstruction with the associated CIC to an age-appropriate date and, in some cases, with the addition of overnight catheterization, avoided the need for augmentation altogether.

CHAPTER 65

Prune Belly Syndrome

Andrew W. Stamm, Steven J. Skoog, and R. Guy Hudson

INTRODUCTION

The classic definition of prune belly syndrome is the triad of bilateral cryptorchidism, deficiency of the abdominal wall musculature, and a dilated, dysmorphic urinary tract (Figure 65.1). The degree of involvement of the genitourinary system combined with the appearance of the abdominal wall engenders intense interest in the etiology, clinical features, and management of this developmental anomaly.

A rich history surrounds the clinical definition of prune belly syndrome (Table 65.1). In 1839, Frolich noted the abdominal wall "tumidity."[1] Parker, in 1895, recognized the essential elements of the syndrome, including a large flaccid abdominal wall with absent musculature, undescended testes, and a hypertrophied bladder and dilated renal collecting system without urethral obstruction.[2] William Osler is credited with giving the syndrome its name "prune belly" in 1901. Prune belly syndrome is, at present, the most widely accepted appellation.[3] Other popular synonyms—Eagle-Barrett syndrome, urethral obstruction malformation complex, the triad syndrome, abdominal muscle deficiency syndrome, and mesenchymal dysplasia syndrome—reflect the etiologic biases of the respective authors.[4–7]

Unfortunately, patients with prune belly syndrome can have many associated conditions that have a significant clinical impact. These include pulmonary hypoplasia, renal dysplasia/insufficiency, cardiac anomalies, lower extremity musculoskeletal malformations, imperforate anus, and intestinal malrotation/malfixation. These conditions impart a significant morbidity in prune belly patients and often influence urologic management. They have also been shown to be an important contributor to the decreased health-related quality of life in both children and their families with prune belly syndrome.[8]

A continued area of controversy in the management of prune belly syndrome is the role of surgical reconstruction. Prevention of urinary infection and preservation of renal function may be equally obtainable with observation.[9–12] Early series stressed the importance of relief of obstruction and stasis by high ureterostomies or catheter drainage. Indwelling catheter drainage often met with infectious complications with an additional 30% mortality reported in the first two years of life.[13,14] Later reports of successful early urinary reconstruction demonstrated both improved urinary drainage and radiologic configuration of the urinary tract. Long-term follow-up demonstrated stabilization of renal function.[6,15–18] However, with the development of improved prophylactic antibiotic therapy and utilization of advanced urodynamic equipment, the need for extensive tailoring of the urinary tract has been questioned. In fact, Woodhouse reported a normal serum creatinine in 27 patients with prune belly syndrome who had limited surgical intervention over a 29-year period.[19] Regardless, mindful of psychological and fertility considerations, current practice dictates an early surgical role in correction of the abdominal wall defect and the cryptorchid testes.[20–23] In fact, musculoskeletal reconstruction has been shown to be the factor with the largest positive impact on the patient quality of life.[24]

Further improvements in the treatment of prune belly syndrome include the application of prenatal diagnosis and intervention, dialysis, renal transplantation, and laparoscopic procedures. Transplantation offers hope to patients with poor renal function due to initial renal dysplasia or progressive chronic renal insufficiency despite appropriate urologic intervention. This chapter reviews proposed etiologies of the syndrome, associated malformations, and the spectrum of management of these patients.

SPECTRUM OF DISEASE

Prune belly syndrome represents a spectrum of disease. Classification systems based on the clinical spectrum have been formulated by numerous authors and all take into consideration initial and subsequent renal function.[6,23,25,26] The classifications have similar, clinically distinctive parameters to segregate the patients prognostically. The clinical classification of prune belly syndrome provides a framework for a more rational approach to overall management, which is determined on an individual basis.[27] Based on Woodard's classification, three major categories can be broadly defined (Table 65.2).

Category I patients exhibit the most severe form of the prune belly syndrome with pulmonary hypoplasia and severe renal dysplasia. Most patients in this category do not survive beyond the first few days of life. Stillborn births are often associated with oligohydramnios and the classic features of Potter's syndrome.[28,29] In this subset of patients with severe renal dysplasia, high urinary diversion is ineffective.[6] Initial normal serum creatinine progressively rises in spite of urinary diversion. These patients may also have complete urethral obstruction or atresia,

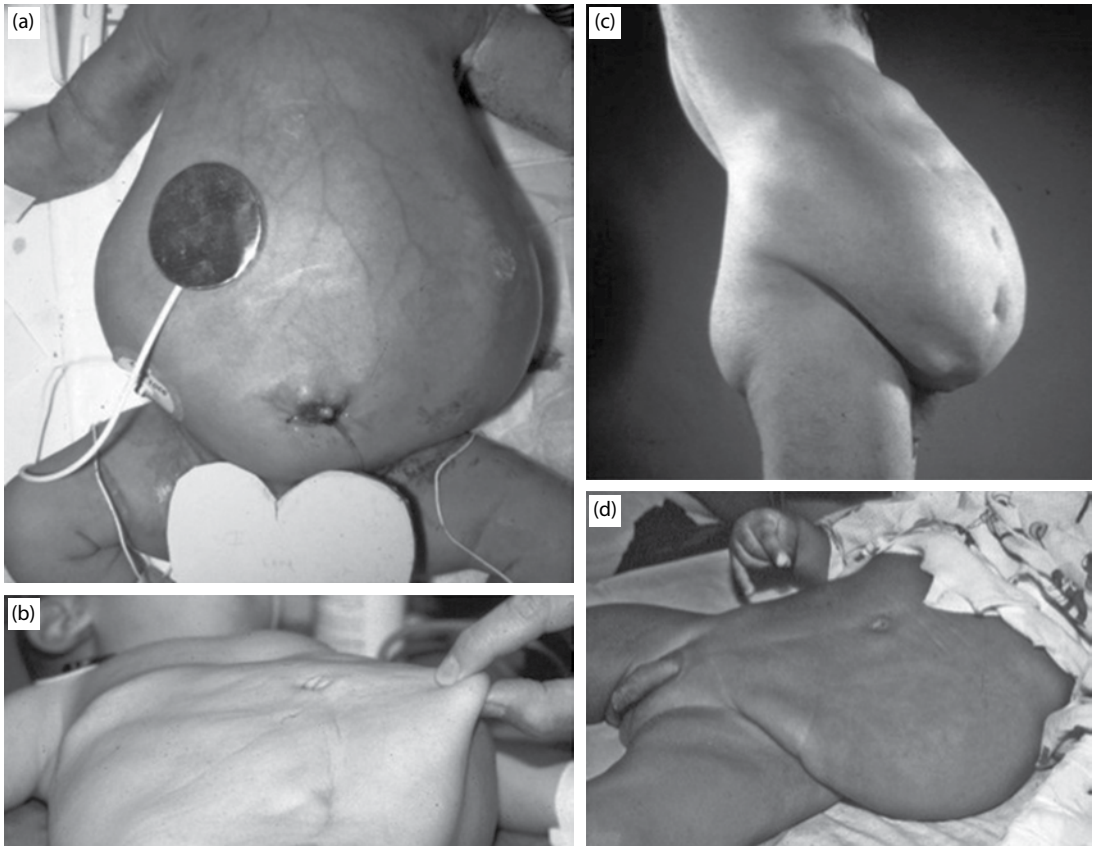

FIGURE 65.1 (a) A newborn with prune belly syndrome, urinary ascites, and pulmonary hypoplasia. Outline of the bowel is visible through the abdominal wall. (b) An infant with prune belly syndrome before comprehensive reconstruction. (c) An adult with prune belly syndrome exhibiting "pot belly" configuration. (d) A 4-year-old female child with hemiprune belly.

TABLE 65.1 History of prune belly syndrome

Year	Author	Discovery
1839	Frolich	Described abdominal wall abnormality
1895	Parker	Recognized all three components of the syndrome
1901	Osler	Coined the name prune belly syndrome
1903	Strumme	Proposed obstructive hypothesis
1961	Nunn and Stephens	Proposed theory of mesodermal arrest as an etiology of prune belly syndrome
1999	Thomas	First reported case of fertility in male with prune belly syndrome
2012	Hillman	First female patient to carry a pregnancy with prune belly syndrome

TABLE 65.2 Spectrum of prune belly syndrome

Category classification	Distinguishing characteristic
I	Oligohydramnios, pulmonary hypoplasia or pneumothorax. May have urethra obstruction or patent urachus and clubfoot
II	Typical external features. Uropathy and the full-blown syndrome but no immediate problem with survival. May have mild or unilateral renal dysplasia. May or may not develop urosepsis or gradual azotemia
III	External features may be mild or incomplete. Uropathy less severe. Stable renal function.

considered the "lethal variant" of the syndrome unless associated with a patent urachus.[30]

Category II includes those infants who do not have pulmonary hypoplasia but have significant involvement of the urinary tract. This can involve mild-to-severe renal dysplasia with potential azotemia and failure to thrive. The clinical course is one of either stabilization of renal function or progressive azotemia. Surgical intervention has been successfully performed to tailor the urinary tract to provide unimpeded drainage and decrease stasis. The impact of surgical intervention on long-term renal function remains debated and is a source of continued controversy.[13,18,31]

Category III patients with prune belly syndrome are associated with the external abdominal features and undescended testes but neither pulmonary nor renal function is severely impaired. They constitute the majority of patients with prune belly syndrome.[22,26] Although these infants may have severe dilatation of the urinary tract, they have stable renal function and usually do not require reconstructive urologic surgery.[23]

Prune belly morphology is not confined to the male gender. Females constitute about 3%–5% of recorded

cases.[16] The strict criterion of cryptorchidism effectively eliminates the syndrome in female patients, but the descriptive term "prune belly" still applies. There is a strong association with omphalocele and bladder outlet obstructive lesions in female patients with prune belly morphology.[32] In a review by Reinberg, 40% of female prune belly patients had anorectal anomalies and the perinatal mortality was 40%.[33] The term "pseudoprune" has been suggested to define females and males who do not have the complete triad of prune belly syndrome.[3] Hence, males with a lax abdominal wall but without undescended testes or without a dilated urinary tract and all females are considered pseudoprunes. The principles of management are essentially the same as in the classic syndrome patient. The underlying uropathy and clinical course in patients with pseudoprune belly syndrome are unpredictable and in one series 63% went on to renal failure.[34]

INCIDENCE AND INHERITANCE

The incidence of prune belly syndrome is 1/29,000 to 1/40,000 live births.[27,35] A variety of inheritance patterns have been associated with prune belly syndrome. The majority of cases are sporadic and have a normal karyotype.[23,35] Prune belly syndrome has been reported in male siblings, cousins, and twins.[36–40] However, the majority of twins are discordant for prune belly syndrome, which argues against a simple chromosomal etiology. Ives noted 11 pairs of twins discordant for the syndrome, 6 were monozygous and 5 were of unknown zygosity. Of the 250 cases of prune belly syndrome reviewed, 4% (11 cases) occurred in twins compared to the 1.25% incidence of twins in the general population. Unequal division of mesodermal cells during primitive streak formation may explain the discordant monozygotic twinning phenomenon.[7]

Williams was one of the first to suggest that prune belly syndrome was due to a sex-linked recessive trait, accounting for the male predominance of the syndrome, its occurrence in male siblings and concordant twins, and its association with Turner's syndrome.[9,41] However, the presence of prune belly syndrome in three females with documented 46 XX karyotype contradicts this pattern of inheritance.[16]

Autosomal dominant and autosomal recessive inheritance have also been reported.[36,42,43] It is difficult to make an association with single-gene inheritance at this time because of male predominance, lack of pedigrees with consanguinity, and limited number of offspring due to associated infertility.[35] Riccardi and Grum suggested a two-step autosomal dominant mutation with sex-limited expression that partially mimics X-linkage.[39] This genetic inheritance pattern would explain male predominance, as well as the small number of affected family members.

Specific chromosomal abnormalities are rare. Several cases of hepatic nuclear factor 1-beta (HNF1β) mutations have been reported—a gene thought to play a role in prostatic and ureteral development.[44] However, genetic analysis of 32 prune belly syndrome patients revealed only 1 case of an HNF1β mutation.[45] Therefore, the genetic basis of this disease remains largely unknown. Trisomies 18 and 21 have been demonstrated in prune belly syndrome.[46–49] Trisomy 18 is also associated with other genitourinary abnormalities including renal dysplasia and hypoplasia, horseshoe kidney, duplication anomalies, and persistent nodular renal blastema.[50] A cause and effect relationship is only speculative. A careful analysis of incidence and birth rates suggests that these are independent events, occurring together by chance alone.[51]

An association with Turners syndrome suggests that the gene responsible for the syndrome may be located on the X chromosome and is recessively transmitted. However, it likely represents the occurrence of the prune belly phenotype in the female as a result of other causes of abdominal distention such as impaired lymphatic development with chylous ascites.[4,36,41] Although mosaicism for a monosome of chromosome number 16 in two male siblings with prune belly syndrome has been documented, its importance etiologically cannot be determined.[52] An extracentric chromosomal fragment was reported in association with prune belly syndrome.[53] However, the same aberration was present in two phenotypically normal male family members.

Prune belly is occasionally described in association with other syndromes, chromosomal aberrations, and conditions. Perlman syndrome, Beckwith-Wiedemann syndrome, VACTERL association, Pfeiffer syndrome type 3, and megacystis–microcolon–intestinal hypoperistalsis syndrome have been described in patients with prune belly syndrome, suggesting the possibility of a common pathogenesis.[54–57]

EMBRYOGENESIS

Three major theories have been proposed to explain the clinical features of the prune belly syndrome. As with most theories, none completely explains the entire constellation of findings in the syndrome, and all are marred by conjecture and speculation.

Fetal Outlet Obstruction

In 1903, Strumme proposed that prune belly syndrome was the final expression of an obstructive urologic lesion producing significant backpressure at a critical time during development. The dilation of the urinary tract and secondary pressure atrophy of the abdominal wall produced the clinical features common to prune belly syndrome (Figure 65.2).[58] Subsequent clinical reviews reflected this belief and called attention to the need to alleviate the obstructing lesions commonly found in the posterior urethra.[14,25,30,59] Improved methods of radiographic diagnosis of obstruction with the voiding cystourethrogram, postmortem anatomic en-bloc dissections, and the application of urodynamics cast doubt on the anatomic presence of obstruction.[5,9,10,60] Clinical reports found evidence of an obstructing lesion in 10%–20% of patients contrasted with up to 80% in earlier series.[12,59] It has been proposed that those infants with the most severe manifestations of the syndrome have the "lethal variant" (an anatomic obstructing lesion) leading to pulmonary hypoplasia, renal dysplasia, and death.[30] This distinction is particularly important when studying the theories of pathogenesis,

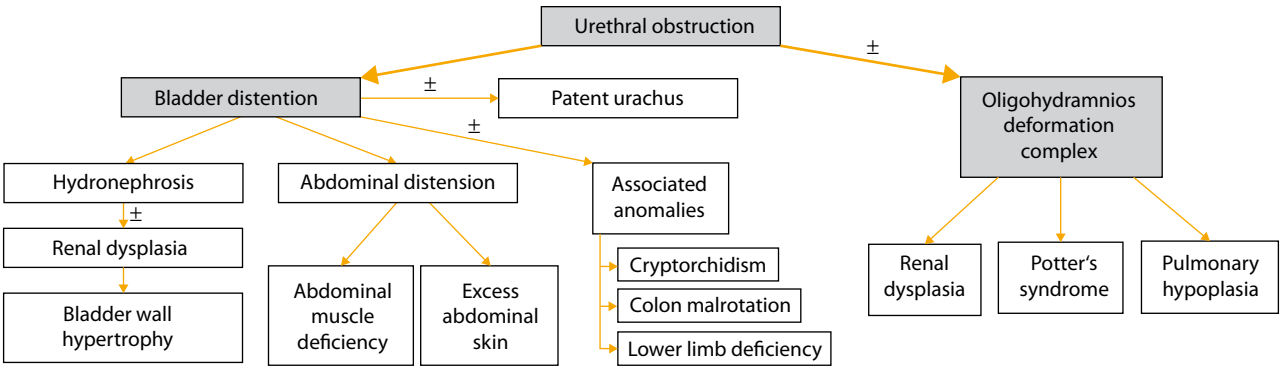

FIGURE 65.2 Urethral obstruction, whether anatomic or functional, is a proposed etiology of prune belly syndrome and its associated anomalies.

as most articles that indicate obstruction as the primary cause are based on autopsy information.[25,61–64]

The source of the obstruction may be true areas of stenosis, atresia, valves, or pinpoint diaphragms at the junction of the posterior and membranous urethra. Recent theories have suggested a "functional obstruction" present in utero, secondary to prostatic hypoplasia, as the specific etiology of the syndrome. This "obstruction" is thought to be the result of conformational changes in the prostatic urethra during voiding, creating a valve-like mechanism.[50,61] Haploinsufficiency of HNF1-β may be causally related to the production of the prune belly syndrome phenotype through a mechanism of prostatic and ureteral hypoplasia that results in severe obstructive uropathy with urinary tract and abdominal distension.[44] Another etiology suggested is a transient obstruction at the junction of the glandular and penile urethra. This was based on evidence of anterior urethral dilatation in patients with prune belly syndrome measured on radiographs from a voiding cystourethrogram. Comparisons were made with children with urinary tract infections and children with posterior urethral valves.[65] This theory is supported by the high incidence of megalourethra seen with prune belly syndrome.[66,67]

The obstructive theory contends that the abdominal wall findings are secondary to the pressure effects of the distended bladder on the developing myotomes of the abdominal wall. The muscles directly over the bladder: transversus abdominis, obliques and lower rectus are most severely affected, supporting this theory. However, histological studies and electron microscopy of the abdominal wall do not demonstrate a pattern of atrophy, but one of developmental arrest.[68–70] In addition, the absence histologically of any aponeurotic layer of the affected muscles opposes an atrophic cause.[70]

Evidence from prenatal ultrasound in patients with prune belly syndrome and other disease processes associated with the prune belly phenotype, suggests that the abdominal wall laxity is due to abdominal distention. A transient, ascitic distention accounts for patients with the syndrome who lack evidence of urethral obstruction.[4,71–74] One study indicates a heterozygous mutation in ACTA2 R179H that was present in a normal karyotype newborn with prune belly sequence without evidence of mechanical bladder outlet obstruction.[75] Urinary ascites has been demonstrated in utero in patients with prune belly syndrome. The urine is theorized to leak into the abdomen via the distended urinary tract and spontaneously reabsorbs at the end of gestation, which explains its clinical absence at birth.[72,74,76–78] Other causes of in utero abdominal wall distention and the prune belly phenotype include: nonimmune ascites, intestinal duplication, posterior urethral valves, amniotic band syndrome, visceromeglia, polycystic kidneys, impaired lymphatic drainage in Turner's syndrome, giant liver cyst, and cystic adenomatoid malformation of the lung.[4,73,79–81] The "urethral obstruction malformation complex" is applied to the theory of fetal outlet obstruction as the etiology of prune belly syndrome. The timing and severity of the obstructive phenomena are critical. The distension of the urinary tract at 13–15 weeks of gestation could produce the degenerative changes in the abdominal wall and urinary tract, preventing gut rotation and prostatic development.[82] This broader application of Strumme's original hypothesis fails to explain (1) the lack of hypertrophy and hyperplasia present in the obstructed urinary tract, (2) the replacement of smooth and skeletal muscle by fibrous and collagenous tissue, (3) normal or low intravesical pressures assessed urodynamically, (4) absent obstruction but presence of renal dysgenesis in the majority of patients, (5) other causes of in utero outlet obstruction not associated with abdominal wall laxity, and (6) the excessively high incidence of cryptorchid testes. All these factors are common in prune belly syndrome and cannot be completely explained on the basis of obstruction alone.[5,9,60,83,84]

Theory of Mesodermal Arrest

The theory of mesodermal arrest as an etiology of prune belly syndrome is based on an embryological aberration of mesenchymal development (Figure 65.3).[5] Urinary tract obstruction occurs in some patients as a consequence of the primary defect and may increase the pathological severity.[82] Stephens has proposed the genitourinary tract, the testes, and the abdominal wall would be vulnerable to a mesodermal defect occurring between the sixth and tenth weeks of gestation.[85] A noxious insult occurring when the lateral plate mesoderm has already extended to the midline, with failure of myoblast differentiation and migration ventrally and caudally, would explain the abdominal wall findings. At the same time, the urinary tract is developing from the

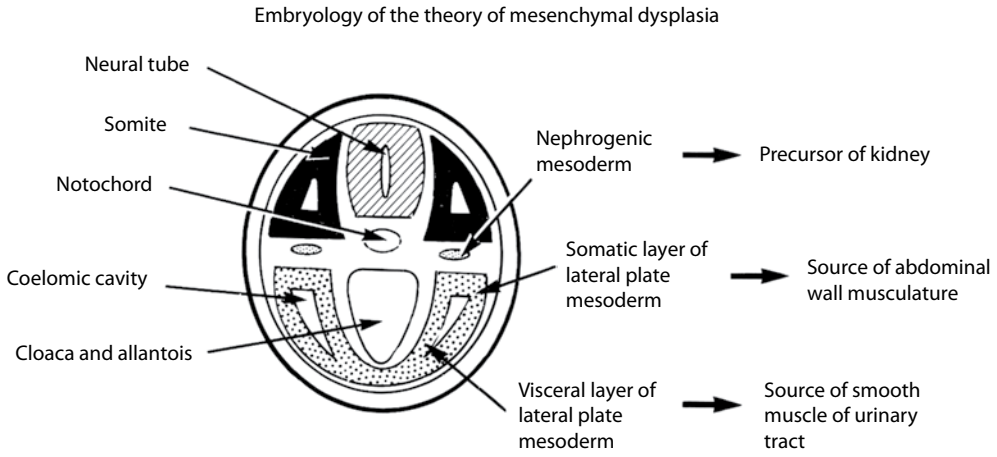

FIGURE 65.3 Cross section of a fetus at 6–10 weeks of gestation. An embryologic insult to both layers of the lateral plate mesoderm and the nephrogenic mesoderm could explain the majority of findings seen in the prune belly syndrome.

mesoderm of the visceral layer of the lateral plate mesoderm. The same insult would impair differentiation of the mesoderm that forms the smooth muscle of the urinary tract, resulting in the characteristic dilatation and dysmorphic features common to the syndrome. The kidneys are concurrently differentiating from the para-axial mesoderm. A defect in induction by the ureteral bud or an abnormality in the metanephric blastema, with or without subsequent urinary tract obstruction, would account for the renal dysplasia commonly associated with prune belly syndrome.[27,64,85]

Some authors have suggested that this insult must occur early in the third week of embryogenesis, at the primitive streak stage of development. At the division of the embryonic disk, an unequal distribution of mesoderm could explain the discordant occurrence in monozygotic twins.[7] This localized defect in mesodermal development would also explain the abnormalities seen in the prostate, urethra, and in testicular descent. According to this theory, the prostatic hypoplasia with poor glandular development, and abnormalities in the mesenchyme of the testicular gubernaculum, result in unresponsiveness of these tissues to hormonal stimulation.[64,86–88] This unresponsiveness of the gubernaculum to hormonal stimulation, the diminished intra-abdominal pressure, and potential mechanical obstruction by an enlarged bladder, all contribute to the maldescent of the testes in the prune belly syndrome.

The mesodermal arrest theory is further supported by histologic findings in the abdominal wall, the urinary tract, and the male genital tract. The abundance of fibrous tissue, collagen and connective tissue, in association with sparse smooth muscle throughout the urinary tract, indicates an inherent problem with mesodermal differentiation. Bladder outlet obstruction, as seen in posterior urethral valves, results in hypertrophy and hyperplasia in the urinary tract with normally developed seminal ducts, seminal vesicles, and prostate glands that are proximal to the obstruction. These features are noticeably absent in the prune belly syndrome.[5,60,68,85,86,89] The absence of anatomic obstruction in the majority of patients and the demonstration of urodynamically unobstructed urinary tracts supports this theory. It also provides an adequate explanation for the high association with megalourethra.[5,66,90]

Nevertheless, the mesodermal arrest theory does not explain the male predominance of the syndrome. It also fails to explain the myriad associated anomalies and the presence of the abdominal wall abnormalities with a normal urinary tract. In addition, obstructive urethra lesions, whether anatomic or functional, are associated with the syndrome. The development of an animal model, with all the features of the syndrome, due to urethral ligation has been reported.[50,61,90]

The Yolk Sac Theory

Stephens proposed an additional theory to explain the features of the prune belly syndrome. There is no genetic evidence to support this theory. Nevertheless, the premise is based on an error in embryogenesis of the yolk sac and allantois. Inherent in this theory is the contention that the bladder and prostatic urethra are derived from the allantois to a greater degree than customarily accepted. If an abnormally large amount of the yolk sac is retained inside the embryo, due to overgrowth of the lateral folds of the discord embryo, it could affect the development of the abdominal wall resulting in the prune belly phenotype. A critical aspect of this theory is the over development of the allantoic diverticulum. This structure grows out from the yolk sac contiguous with the body stalk. If it becomes excessively large due to the oversized intra-abdominal yolk sac, it would become incorporated into the urinary tract as the redundant enlarged urachus, bladder, and prostatic urethra which characterizes the syndrome.[70,85] Unfortunately, this theory does not explain the errors in development of the upper urinary tract or male genital tract.

CLINICAL FEATURES OF THE PRUNE BELLY SYNDROME

Extragenitourinary Manifestations

Associated Anomalies

Abnormalities of other organ systems result in long-term morbidity for as many as 75% of patients with prune belly

TABLE 65.3 Extragenitourinary abnormalities in prune belly syndrome

Organ system	Frequency (%)	Manifestations
Cardiopulmonary	49	Pulmonary hypoplasia Pneumothorax Pneumomediastinum Lobar atelectasis Pneumonia Chronic bronchitis Patent ductus arteriosus Atrial septal defect Ventricular septal defect Tetralogy of Fallot
Orthopedic	65	Congenital dislocation of hips Chest wall deformity: Pectus excavatum/ carinatum Scoliosis Genu valgum Talipes equinovarus Severe leg maldevelopment: Arthrogryposis
Gastrointestinal	63	Malrotation Intestinal atresia Intestinal stenosis Volvulus Anorectal agenesis Imperforate anus Omphalocele Gastroschisis Hepatobiliary anomalies Acquired megacolon

syndrome (Table 65.3).[91] Growth was impaired in 32% of surviving patients in one large series and was poorly correlated with renal function. This impairment was most manifest in the first year of life with subsequent stabilization but incomplete catch-up growth.[91] Developmental delay was reported in 43% of the most contemporary cohort.[24]

The non-urological associated anomalies in patients with prune belly syndrome are a major source of morbidity and mortality. Care of these patients requires close cooperation with all caregivers. The urological manifestations of prune belly syndrome rarely require emergent treatment.

Cardiopulmonary

Cardiopulmonary anomalies have been reported in up to 49% of patients with prune belly syndrome (see Table 65.3).[24] Patent ductus arteriosus, atrial and ventricular septal defects, and tetralogy of Fallot occur with increased frequency in prune belly syndrome.[92,93] The severity of the cardiac involvement will dictate initial care of the infant, as the urologic anomalies rarely demand immediate treatment.

Pulmonary and respiratory difficulties pervade the lives of these patients from birth to adulthood. Severe pulmonary hypoplasia, with associated oligohydramnios and renal dysplasia, is fatal. Initial prognosis is dependent upon pulmonary development. A review of most series demonstrates that approximately 20% of newborns will die in the perinatal period as a consequence of pulmonary complications.[18,20,21] Of those that survive the newborn period, clinically significant pulmonary problems were noted in 55% of patients.[91] Pneumothorax and pneumomediastinum may be present at birth, with or without pulmonary hypoplasia and an early chest x-ray is advised. Chest wall deformities and abdominal muscle deficiency impair mechanical ventilation, which results in a ventilatory limitation and a high incidence of lobar atelectasis and pneumonia.[94,95] Chronic bronchitis and the development of respiratory insufficiency following upper respiratory infections or anesthetics are well recognized, and appropriate pulmonary support must be provided.[91,94]

Gastrointestinal

Gastrointestinal anomalies are present in up to 63% of patients with prune belly syndrome (see Table 65.3).[24] These anomalies are commonly recognized in the postnatal period. The majority of anomalies such as malrotation, atresia, stenosis, and volvulus are due to persistence of the wide embryonic mesentery, without fixation to the posterior abdominal wall.[96] This same suspension abnormality allows the spleen to wander freely in the abdominal cavity and acute splenic torsion has been reported on two occasions.[97] It has been recommended that all patients with prune belly syndrome have radiographic assessment of their alimentary tract.[96] Anorectal agenesis, imperforate anus, omphalocele, pouch colon, and gastroschisis have been reported in association with prune belly syndrome.[96,98–102] Chronic constipation is a frequent problem with these children, attributed to a decrease in abdominal wall pressure aiding evacuation. Acquired megacolon can result. Chronic constipation requires continuous attention with dietary and cathartic intervention.[27,91]

Orthopedic

Orthopedic-related problems in prune belly syndrome are present in up to 65% of cases (see Table 65.3).[24,103] In most series, musculoskeletal anomalies predominate in frequency of occurrence with congenital dislocation of the hips, clubfoot, and/or scoliosis the most frequent findings.[100,104] Congenital dislocation of the hip requires early institution of treatment and may be resistant to conventional therapy.[103] Lateral dimples of the elbows and knees are the mildest manifestation of the compression effect of intrauterine oligohydramnios (Figure 65.4). More severe deformities, attributed to oligohydramnios and intrauterine compression, are recognized usually at autopsy as lower limb deficiencies and arthrogryposis.[4,105] Talipes equinovarus, polydactyly, syndactyly, and torticollis have been reported.[10,64] Pectus carinatum and pectus excavatum deformities are frequently present. Scoliosis is the most common spinal deformity.[104] In one instance, scoliosis was associated with thoracic segmental insensibility.[106] As prognosis improves in these patients, orthopedic interventions will play a greater role in management.

Abdominal Wall

The wrinkled, floppy abdominal wall that characterizes the syndrome results from a deficiency of the underlying

FIGURE 65.4 Lateral dimple of the knee in this infant with prune belly syndrome is a mild manifestation of the compression effects of intrauterine oligohydramnios.

musculature. The functionally impaired abdominal wall can result in significant morbidity. Affected infants are unable to sit up directly from the supine position, delaying the onset of walking.[3] The lack of mechanical assistance from the abdominal wall contributes to difficulties with respiratory infections and chronic constipation.[91] In addition, patients suffer long-term psychosocial effects of poor body image.[22,23]

Autopsy studies have shown that the muscles most severely affected are those ventral and lateral in location. The epaxial and hypaxial trunk muscles develop normally. The order of severity of involvement from most to least is: transversus abdominis, rectus abdominis below the umbilicus, internal oblique, external oblique and rectus abdominis above the umbilicus (Figure 65.5).[2,14] There is cephalic displacement of the umbilicus due to unopposed contraction of the upper rectus abdominis muscle. The diminished muscle mass, if severe, allows one to observe bowel peristalsis and easily palpate the abdominal organs and kidneys. Because the muscular deficiency may not be symmetric, a more dominant flank bulge on one side of the abdomen is often present and coincides with the dilated distal ureter (Figure 65.6).

Electromyographic studies of the abdominal wall have confirmed the anatomic findings. The lower midline musculature demonstrates the least amount of electrical activity. Recruitment of voluntary motor units is greatest in the upper lateral musculature.[107]

Autopsy studies of the abdominal wall have demonstrated normal segmental nerve distribution and normal blood supply.[64,70] The distribution of muscle fibers is haphazard. In more severe cases, the entire thickness of the abdominal wall consists of skin, connective tissue, superficial fascia, and peritoneum (Figure 65.7). In the infant there is no aponeurotic layer that might represent atrophied muscle.[9] Fortunately, the poorly developed abdominal wall heals well despite the muscular layer deficiencies.

Microscopic examination demonstrates fat interdigitating with muscle fibers. These fibers have been characterized as hypoplastic, atrophic, and hypertrophic adding further confusion to an apparent etiology.[68,108] Others have found the muscle cells to be clear and normal in appearance and

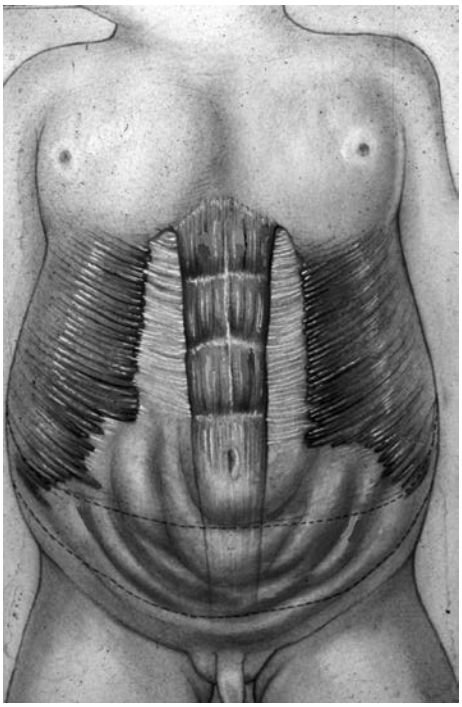

FIGURE 65.5 Abdominal wall deficiencies in prune belly syndrome. The epaxial and hypaxial trunk muscles develop normally. The order of severity of involvement from most to least involved is: transversus abdominis, rectus abdominis below the umbilicus, internal oblique, external oblique, and rectus abdominis above the umbilicus.

at times associated with myotubular embryonic cells similar to that seen in the fetus of about 10 weeks gestation.[69,70] Ultrastructural abnormalities, demonstrated by electron microscopy, include loss of coherence and orientation of the Z bands, mitochondrial disruption, and clumping of glycogen granules. These changes are nonspecific, but are consistent with hypoplastic histologic changes.[68]

Genitourinary Manifestations

Kidneys

Renal dysplasia and hydronephrosis are the common denominators of the upper urinary tract in prune belly syndrome. Both grossly and radiographically, cystic dilatation of the calyces and renal pelvis is present. Infundibular narrowing without obstruction and occasional ureteropelvic junction obstruction may be evident.[18] Wide variations may exist in individual renal unit appearance, function, location, and rotation (Figure 65.8).[64]

Prognosis is directly related to renal function and the degree of renal dysplasia. Stephens proposed pathogenic mechanisms to explain the development of renal dysplasia. These include (1) defects of the ureteric bud or its branches, (2) qualitative or quantitative deficiencies of the nephrogenic mesenchyme, and (3) vascular ischemic insults with resultant ureteric obstruction and renal cystic dysplasia. He suggested that the renal dysplasia of the prune belly syndrome is due to a combination of a ureteric bud and metanephric defect.[70]

The most severe degree of renal dysplasia is recognized from autopsy studies and associated with both Potters type II and IV renal cystic changes.[64,83] These patients have associated distal outlet obstruction (urethral atresia) with a non-patent urachus, and they are usually stillborn. The kidneys are small, with disorganizational features of dysplasia and are most likely injured prior to significant nephron formation at the stage of ampullary development.[25]

In contrast, some patients have hydronephrosis but adequate renal function. The degree of hydronephrosis may not correlate with the ureteral dilatation or the abdominal wall deficiency. The renal parenchyma is often well preserved despite a grossly abnormal drainage system. Urinary infection rather than obstruction represents the greatest threat to the renal parenchyma. The dilatation is attributed to the mesenchymal defect and deficient smooth muscle, not to obstruction. Consequently, some resolution in the degree of dilatation can occur spontaneously in follow-up.

Ureters

The ureters are elongated, tortuous, and dilated forming the radiographic hallmark of the syndrome (Figure 65.9).[109] The lower one third of the ureter is more profoundly affected than the proximal portion and occupies the flared out flanks of the abdomen. Although fluoroscopic studies demonstrate ineffective peristalsis over its entire length, true obstructive lesions of the ureter are the exception. However, pleat-like valves at the ureterovesical junction (UVJ) have been documented in two cases.[110]

Vesicoureteral reflux is seen in up to 85% of patients. The conventional system of grading reflux is difficult to apply due to the dysmorphic features of the ureter, renal pelvis, and calyces.[21]

Histologic examination of the ureter demonstrates a profound alteration in the content and architecture of the ureteral wall. Prune belly ureters lack the hypertrophy and hyperplasia of the smooth muscle cells seen in dilated ureters due to obstruction or vesicoureteral. A diffuse increase in the connective tissue with replacement of the smooth

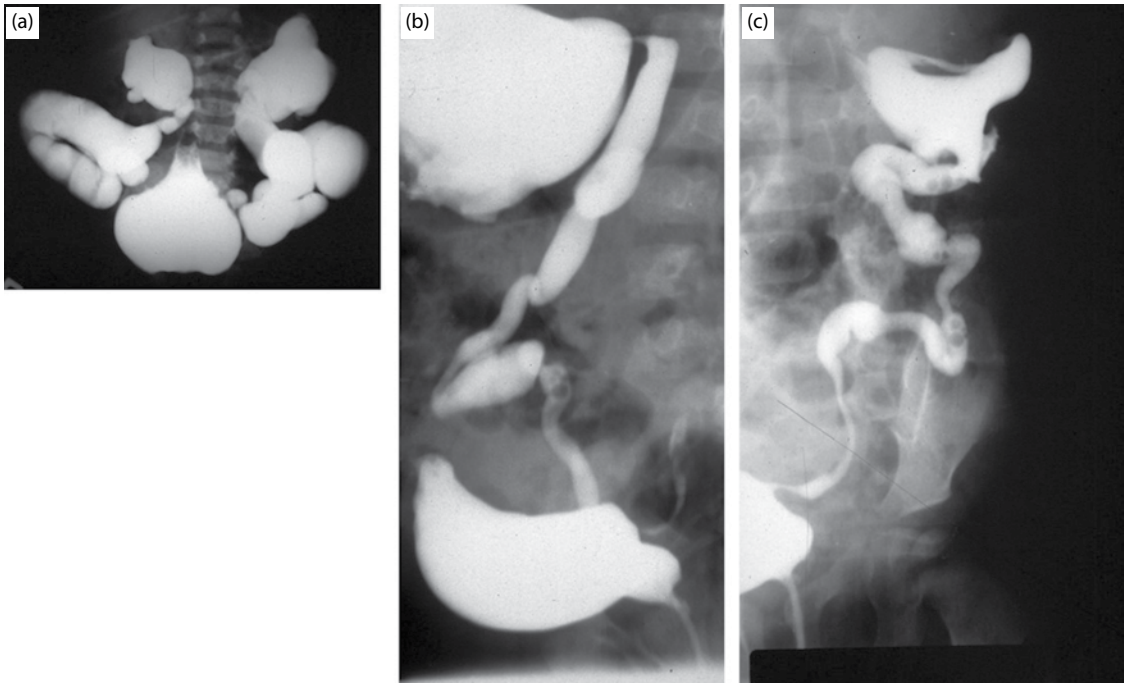

FIGURE 65.8 (a) Retrograde cystogram demonstrates dilated, tortuous, refluxing ureters; enlarged, floppy renal pelvis; and distended bladder, with urachal remnant. muscle is present. The ratio of collagen-to-smooth muscle, especially in refluxing ureters, is markedly elevated.[111] There is no differentiation into longitudinal and circular muscle layers. The patchy distribution of smooth muscle is present in both the dilated and narrowed ureteral segments. The upper ureter has more smooth muscle cells than the lower portion.[5,84] A marked decrease in the number of nerve plexuses, with degeneration of non-myelinated Schwann fibers, has been reported. This may contribute to the poor ureteral peristalsis even after corrective surgery.[91] Ultrastructural examination of the smooth muscle cells of the ureter reveals a decrease in the number of thick and thin myofilaments, which contributes to poor muscle cell performance.[84,112] The histologic and pathologic features are important to remember during genitourinary reconstructive efforts. The upper ureter is potentially best suited for definitive reconstruction and its future should not be risked by using it for temporary cutaneous diversion. The dilatation and ineffective peristalsis of the ureters result in urinary stasis and a heightened risk of infection.

Bladder

The bladder is thick walled and grossly enlarged and trabeculations are usually absent (Figure 65.10). The normal bladder contour is deviated by a pseudodiverticulum which consists of the urachal remnant giving the bladder an hour-glass configuration. A patent urachus may be present, especially in association with urethral atresia or microurethra. The trigone is splayed and the ureteric orifices are located laterally which explains the common association with vesicoureteral reflux.[70] The bladder neck is characteristically quite wide at its junction with the

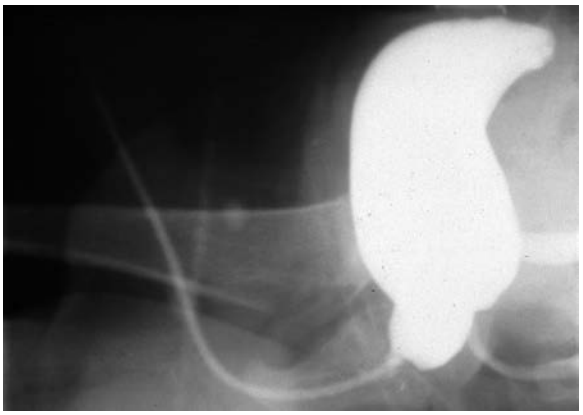

FIGURE 65.10 Voiding cystourethrogram details the grossly enlarged, but non-trabeculated bladder. The bladder neck is widely patent, with hypoplastic urethra.

FIGURE 65.11 Voiding cystourethrogram of a 1-year-old child demonstrating the classic radiographic appearance of the posterior urethra in prune belly syndrome. The open bladder neck and dilated prostatic/posterior urethra is evident. No urethral obstruction is present. (Courtesy of George W Kaplan, MD.)

prostatic urethra. Histologic evaluation of the bladder demonstrates an alteration in the ratio of connective tissue to smooth muscle. The extent of involvement is less than the ureter, and smooth muscle hypertrophy can be present.[64,113] The increased bladder thickness is largely due to fibrocytes and collagen. The anatomic innervation of the bladder is normal. No abnormality in the distribution of ganglion cells is present.[5,10] One study indicates an increase in alpha 1a-adrenoceptor immunostaining intensity in the detrusor muscle. In bladder outlet obstruction these receptors are up or down regulated.[114] In addition, muscarinic acetylcholine receptor M3 (CHRM3) (1q41–q44) homozygous frameshift mutation in familial congenital bladder malformation has been associated with a prune belly-like syndrome.[115]

The bladder in prune belly syndrome has efficient low-pressure storage and good compliance. However, its ability to empty is compromised by vesicoureteral reflux and poor contractility. Urodynamic assessment of the bladder has demonstrated normal balanced voiding in some patients regardless of the gross anatomic and radiologic features.[5] Three distinct patterns of voiding have been observed; normal, prolonged voiding with a low peak, and an intermittent pattern. The voiding pattern did not correlate with residual urine volume.[116] Maximum urinary flow rates and voiding pressures can be within normal limits for age. The filling phase of the cystometrogram is shifted to the right, with a markedly delayed first sensation to void. Bladder instability with uninhibited contractions is infrequent and usually not the explanation for urinary incontinence.[9,116,117] In those patients with unbalanced voiding manifested by urinary incontinence, an increase in residual urine with a decreased flow rate may be noted. Changes in voiding efficiency are not unusual and mandate the need for regular urodynamic assessment. Surgical intervention or intermittent self-catheterization may be necessary. Two cases of nephrogenic adenoma have been reported which initially presented with gross hematuria.[118,119]

Prostate and Posterior Urethra

The radiographic appearance of the prostatic urethra is quite distinctive. The bladder neck is open and the posterior urethra is dilated, elongated, and tapered at the membranous urethra (Figures 65.10 and 65.11). The anterior wall of the prostate is shorter than the posterior wall. It frequently has a localized sacculation, which represents a utricular diverticulum. Reflux into the vas deferens may be present and the verumontanum is small or absent. True obstructive lesions at the junction of the prostate and membranous urethra have been described in 20% of infants, usually those with the worst prognosis. These obstructions have been described as stenosis, true valves, atresia, diaphragms, and diverticula.[25,59,64,120] A kinking of the prostatic urethra during voiding, as a result of asymmetry of its anterior and posterior walls, has been suggested as a functional obstruction in prune belly syndrome. Stephens assigned a type IV valve classification to these lesions.[61,70]

Lack of development of the epithelial portion of the prostate is a constant component of the syndrome. When compared to normal children and children with posterior urethral valves, patients with prune belly syndrome have either absent or sparsely distributed prostatic epithelial glands.[5,85,86] The prostatic hypoplasia results from an inability of the urogenital mesenchyme to induce epithelial differentiation.[86] Prostatic hypoplasia is one of the etiologies of infertility in this syndrome.[121]

Accessory Male Sexual Organs

As with the other mesenchyme-derived genitourinary organs in the prune belly syndrome, abnormalities of the epididymis, seminal vesicles, and vas deferens have been noted. Autopsy findings have noted lack of continuity between the ductuli efferentes and rete testis. The body of the epididymis is frequently detached from the testes; a common finding with abdominal undescended testes. The vas deferens is abnormally thickened and may drain ectopically.[122] The seminal vesicles may be dilated with diverticular formation but usually are atretic or absent, which may be a diagnostic feature of prune belly syndrome.[85] All of these findings have significance in regards to the known infertility associated with prune belly syndrome.[70]

FIGURE 65.12 A newborn with prune belly syndrome with evidence of megalourethra and penoscrotal transposition.

Anterior Urethra

The recognized abnormalities of the anterior urethra in prune belly syndrome range from urethral atresia to fusiform megalourethra (Figure 65.12). Surviving patients with urethral atresia or microurethra have a patent urachus. It is possible that the microurethra is normally formed but unused and can be progressively dilated to a functional caliber.[123]

Bulbous urethral dilatation was evident in 68% of patients with prune belly syndrome.[66] Two of these patients had a fusiform megalourethra. Comparative measurements of anterior urethral diameters in patients with prune belly syndrome and normal patients, have confirmed a dilated anterior urethra in prune belly syndrome patients (Figure 65.13).[124] A transient obstruction during fetal development at the junction of the glandular and penile urethra may explain this common radiographic finding, as well as the known association of prune belly syndrome with megalourethra.[67]

Both types of megalourethra—scaphoid and fusiform—are associated with prune belly syndrome. The fusiform megalourethra, accompanied by deficient corpora cavernosa, is a more severe defect frequently associated with renal dysplasia and lethal anomalies. Scaphoid megalourethra is characterized as a deficiency of the corpus spongiosum with normal glans and fossa navicularis. In a series of 26 patients with this anomaly, 10 had prune belly syndrome.[125] The mesenchymal developmental arrest that accounts for the major features of the syndrome may also explain the urethral malformations.[66]

Testis

Bilateral cryptorchidism is an essential component of the prune belly syndrome. In the majority of patients the testes are intra-abdominal, overlying the ectatic ureters at the pelvic inlet. The epididymal abnormalities associated with abdominal undescended testis are present.[1] The intra-abdominal position of the testes predisposes these patients to increased risk of malignant degeneration of 30–50 times that of a normally descended testes.[126] At least three documented cases of testis tumor in prune belly syndrome have been reported, one of which was retroperitoneal.[3,127,128]

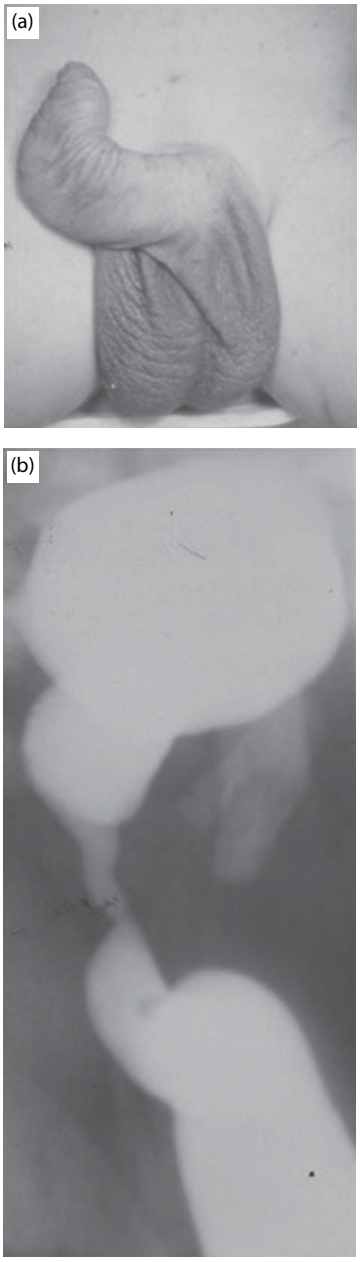

FIGURE 65.13 (a) A newborn with prune belly syndrome and megalourethra. (b) Voiding cystourethrogram in this patient demonstrates a large dilated bladder, open bladder neck, dilated posterior urethra, and wide, patent megalourethra. (Courtesy of George W Kaplan, MD.)

The gubernaculum is normally attached proximally to the tail of the epididymis, travels via the inguinal canal, and attaches distally at the pubic tubercle.[70] No histologic abnormality has been noted, and the nerve supply of the gubernaculum is intact.[129]

The etiology of testicular maldescent in prune belly syndrome is multifactorial. Mechanical obstruction by the enlarged bladder is contributory, as the incidence of cryptorchidism is increased in other diseases associated with an enlarged bladder, such as posterior urethral valves.[130] The mechanical effects of the intramuscular pressure of the abdominal muscles pushing the testis toward the scrotum,

are obviously deficient in the prune belly syndrome. In addition, given the mesenchymal abnormalities of the syndrome, the ability of the gubernaculum to respond hormonally to guide the testes to the scrotum may be impaired.[87]

Comparative quantitative analysis of spermatogonia in fetuses with prune belly syndrome has demonstrated a significantly decreased number of spermatogonia and marked Leydig cell hyperplasia. These changes are evident before expected testicular descent, implying intrinsically abnormal testes.[131] Absent spermatogenesis due to prolonged intra-abdominal location has been histologically documented.[132] Azoospermia was present in adults when a semen sample was obtained.[133] Early orchiopexy is advocated for these patients to optimize potential spermatogenesis, to enable evaluation for malignancy, and to promote better psychological health.[21,134] With assisted reproductive techniques, specifically intracytoplasmic sperm injection, paternity in prune belly patients is possible.[135]

Sexual Function and Fertility

Woodhouse and Snyder studied sexual function in nine adult patients with prune belly syndrome. All had normal libido, with normal erections and orgasms. Seven had retrograde ejaculation. All patients studied to date are azoospermic on semen analysis.[20,133] These patients all had orchiopexy performed late in childhood. Earlier orchiopexy may improve spermatogenesis because germ cells have been found in these patients.[134]

There is no report of a patient with prune belly syndrome becoming a father naturally. However, the first reported case of paternity in a prune belly patient involved the use of intracytoplasmic sperm injection (ICSI) and produced twins.[135] It was subsequently reported that prune belly syndrome is not transmitted to male offspring using ICSI (Table 65.1).[136] Additionally, the first successful pregnancy of a female patient with prune belly syndrome has been reported (Table 65.1).[137] Male patients with prune belly syndrome have multiple factors, other than spermatogenesis, that contribute to infertility. An open bladder neck and poorly developed prostate result in retrograde ejaculation. Associated abnormalities of the prostatic epithelium and seminal vesicles affect the amount and content of the seminal fluid. Vas deferens obstruction and epididymal abnormalities associated with maldescent affect sperm delivery and maturation.

PATIENT EVALUATION

Prenatal

Prenatal diagnosis of prune belly syndrome has been made as early as 11 weeks of gestation on ultrasound.[138] With improved ultrasonic capability and surveillance protocols, the ability to diagnose major genitourinary abnormalities in the early gestational period has increased.[139] However, distinguishing among causes of hydronephrosis, such as posterior urethral valves, can be difficult. Reported ultrasonic diagnostic accuracy varies from 30% to 85%.[140]

The development of vesicoamniotic shunt procedures make possible in utero treatment of patients with obstructive uropathy.[141–143] Specific criteria for in utero intervention include: normal karyotype, severe oligohydramnios, and predicted good renal function.[142,144] The timing for intervention is critical as renal dysplasia is more pronounced with increasing gestational age. Although several reports of vesicoamniotic shunt procedures for fetal obstructive uropathy exist, reviews have failed to document a beneficial effect of fetal intervention on subsequent renal function.[140,145]

Hence, prenatal intervention to relieve potential obstruction in a fetus is difficult to justify. As the majority of patients with prune belly syndrome have no demonstrable evidence of obstruction and renal function does not correlate with the amount of dilatation present in the urinary tract, the risks and benefits of in utero intervention must be carefully weighed.[77,146,147]

Newborn

The appearance of the abdominal wall is diagnostic in the newborn. Given the wide range of disease severity, a multisystem evaluation to rule out significant cardiac, pulmonary, or other associated malformations must take place in the neonatal period.[94] An immediate chest x-ray is necessary to exclude associated pneumothorax and pneumomediastinum. The presence of severe pulmonary hypoplasia affects prognosis in the progressive inability to oxygenate the infant. Antenatal oligohydramnios in these infants indicate impaired renal function.[28]

Initial creatinine measurements reflect maternal renal function and repetitive sampling is necessary. If after 48–72 hours the serum creatinine is greater than 1.0 in the term infant or 1.5 in the preterm infant, a degree of renal insufficiency is present. A progressive rise in serum creatinine over the first few weeks of life, portends a poor outcome. If initial nadir creatinine is less than 0.7 mg/dl, then subsequent renal failure is unlikely.[148] Urine is sent for baseline culture and antibiotic prophylaxis is initiated. Measurement of serum and urinary electrolytes at birth can be helpful in assessing sodium conservation, implying adequate renal function.[149] In the premature and full-term infant, the glomerular filtration rate is initially low, then rapidly increases.[150] This must be remembered in relation to the administration of intravenous contrast agents, which may rapidly elevate plasma osmolality, causing intraventricular hemorrhage as well as further impairment of renal function.[151]

Diagnostic Evaluation

A thorough urologic evaluation proceeds after stabilization of the patient due to other comorbidities. Physical examination and ultrasonography of the urinary tract are initially required. Renal sonograms provide information on cortical thickness, presence of cystic changes and renal size. Sonographic examinations before and after voiding give a clue to the presence of vesicoureteral reflux and post void residual urine. Serial serum electrolyte determinations, urinalysis and urine culture are essential.

Radiologic assessment in the newborn is tempered by the known risks of intravenous contrast and the introduction of infection with retrograde studies. Initially, a

voiding cystourethrogram (VCUG) is performed in those infants with abnormal renal function to insure that a true anatomic, urethral obstruction is not present. This "lethal variant" and the potential confusion with posterior urethral valves "masquerading" as prune belly syndrome must be diagnosed, as treatment changes dramatically.[30,152,153] In addition, the VCUG demonstrates vesicoureteral reflux in up to 85% of patients and assesses bladder emptying. All infants are treated with antibiotics prior to sterile catheterization to decrease the risk of infection. In general, the radiologic assessment of the urinary tract is tailored by the management philosophy of the individual urologic surgeon. Contrast studies requiring risky instrumentation are avoided in those infants with good renal function.

After initial evaluation, a mercaptoacetyltriglycine (MAG 3) renal scan can provide both functional and anatomic information. Blood flow, differential renal function and drainage in response to furosemide (Lasix) can be assessed and compared with subsequent studies. The limitations of diuresis renography in demonstrating obstruction in patients with prune belly syndrome have been noted. A Whitaker test is occasionally necessary as the definitive study to demonstrate significant obstruction, although this is mostly of historical significance.[109] Dimercapto-succinic (DMSA) acid renal scan is performed rather than an excretory urogram (IVP) to evaluate renal size, tubular mass, and differential function. Comparative studies are invaluable to assess renal growth and scarring as these patients require long-term follow up.[154] Some groups have advocated for magnetic resonance urography (MRU) in these patients due to its high resolution and excellent functional and anatomic data.[155] However, the clinical significance of long-term follow-up with MRU remains to be determined.

PATIENT MANAGEMENT

The overall goals of initial management are to preserve renal function and prevent infection. The attainment of these goals are possible via a variety of therapeutic approaches, which range from watchful waiting to immediate surgical reconstruction of the urinary tract.[13,17,19]

Early surgical intervention in the neonate is avoided, unless a rising creatinine or infection occurs, requiring early vesicostomy. Unless salvaged by extraordinary means (extracorporeal membrane oxygenation with or without dialysis), patients with *Category I* disease associated with prenatal oligohydramnios and postnatal pulmonary hypoplasia usually die in the immediate postnatal period due to pulmonary complications. In those few infants surviving the pulmonary insult, high urinary diversion by cutaneous pyelostomy has been attempted to provide optimal urinary drainage.[31] Unfortunately, recovery of renal function is not usually possible as a result of severe underlying renal dysplasia.

Patients with *Category II* involvement are serially monitored for infection and a decrease in renal function. These infants and children are placed on long-term prophylactic antibiotics. With documentation of infection, failure of adequate renal growth, or decreasing renal function, aggressive reconstruction of the urinary tract is pursued. To allow pulmonary maturation, surgical reconstruction is usually delayed until the infant is 3 months of age or more. Our approach involves a surgical remodeling to eliminate urinary stasis and vesicoureteral reflux, and promote optimal urinary drainage (Figures 65.14 and 65.15).[17] If renal insufficiency is severe or infection is initially present, a period of urinary diversion by means of cutaneous vesicostomy is recommended.[156] Cutaneous ureterostomies probably add little to improve drainage. In addition, the upper ureter is anatomically and histologically the most normal and should be preserved if later tailored reconstruction is elected.[84,112] Combining urinary tract reconstruction, orchiopexy, and abdominoplasty at or prior to one year of age is our preferred approach. This optimizes the potential for improved urinary drainage, as well as addressing the issues of subsequent fertility and psychological well-being.[21]

Patients with *Category III* prune belly syndrome demonstrate good renal function, despite gross dilatation of the upper and lower urinary tract and constitute the majority of patients. Serial assessment of renal function by selective imaging techniques is performed. Surgical intervention to reconstruct the urinary tract is not usually necessary. Antibiotic prophylaxis is recommended. Development of urinary infections or decrease in renal function mandates urodynamic assessment of the urinary tract. The demonstration of significant residual urine with unbalanced voiding, warrants surgical intervention to promote emptying.[26,117] Upper tract stasis should be evaluated and a Lasix renal scan performed, to rule out obstruction.[157] The results of these specific tests will help determine the type of surgical intervention. These patients benefit from early orchiopexy and abdominoplasty as correction of the abdominal wall may improve defecation and voiding efficiency.[158]

OPERATIVE INTERVENTIONS IN PRUNE BELLY SYNDROME

In Utero Intervention

With improved maternal–fetal advanced imaging and diagnostic techniques, prune belly syndrome can be suspected by imaging early in pregnancy. Intervention in these patients usually addresses the cause of amniotic fluid reduction which leads to oligohydramnios or anhydramnios. The reduced or absent volume of amniotic fluid is associated with pulmonary hypoplasia, the leading cause of perinatal mortality. Vesicoamniotic shunting can be a consideration with a normal fetal karyotype, limited extent of other detected congenital anomalies, and serial favorable fetal aspirated urinalyses. Vesicoamniotic shunting in patients with suspected bladder outlet obstruction does not improve renal outcomes, but would assist in pulmonary maturation and function.

Anesthetic Considerations

The patient with prune belly syndrome presents unique problems to the anesthesiologist. Several reports have commented on respiratory difficulties due to the abnormal mechanics of pulmonary ventilation. The deficient

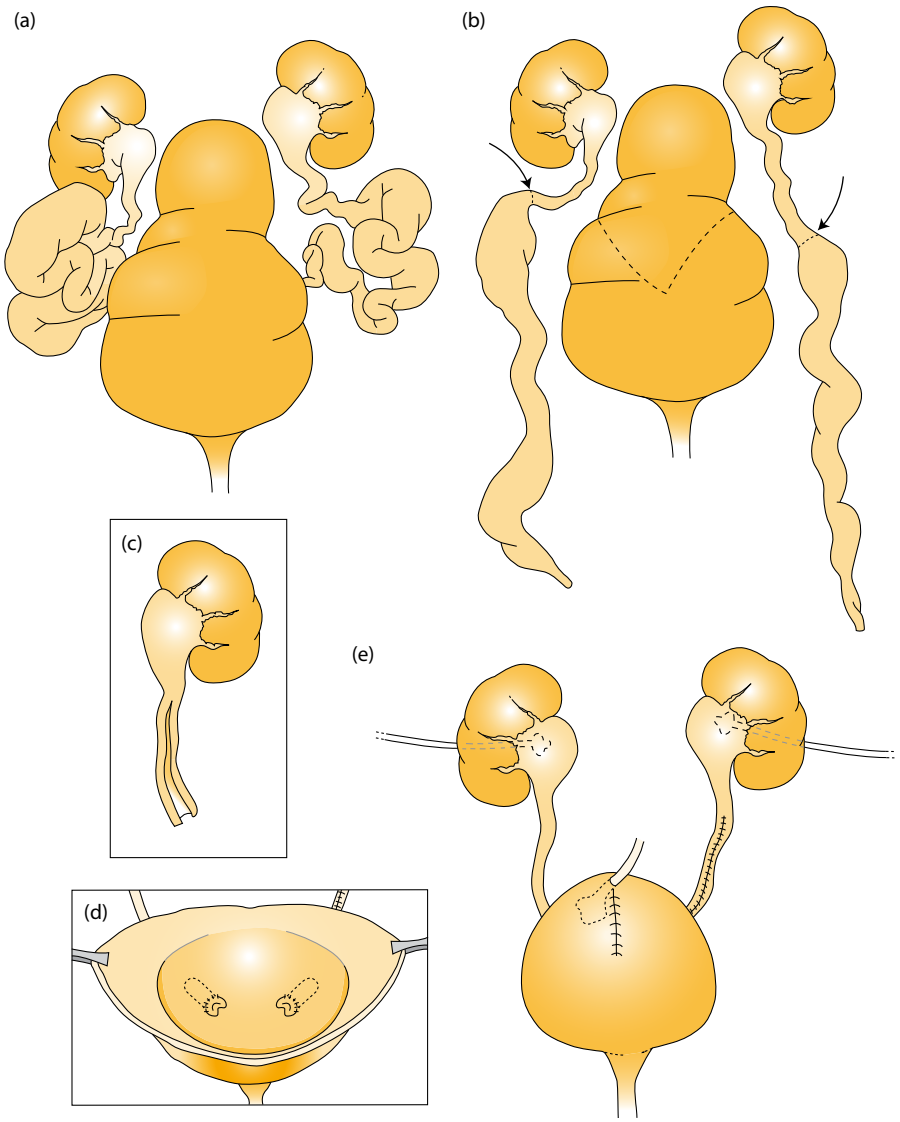

FIGURE 65.14 (a–e) Surgical technique used for extensive reconstruction of prune belly uropathy. The operation is performed transperitoneally. No attempt is made to straighten the lower ureter, as only the upper portion of the ureter is needed for reimplantation. The ureter may require tapering. The dome of the bladder is excised (b. dotted line) in most patients. Ureteral stents (not shown) are used; nephrostomy tubes are rarely required.

abdominal musculature weakens the ability to cough effectively and predisposes these patients to postoperative atelectasis and infection.[159] In one case, prolonged, postoperative ventilation was necessary to effectively clear secretions and adequately oxygenate the patient.[160] In a review of 36 patients with prune belly syndrome, postoperative respiratory infection developed following eight of 133 anesthetics, all of which resolved with antibiotics and physiotherapy.[161] There were no intraoperative respiratory difficulties. Three deaths occurred in the postoperative period; one of which was partially contributed to by pneumonia, as a result of ineffective cough.

All patients with prune belly syndrome require careful preoperative pulmonary assessment. An antecedent history of recurrent respiratory infections warrants aggressive physiotherapy, postural drainage, and intermittent positive pressure breathing treatments. Specific antibiotic therapy should be given.[160] Judicious use of postoperative analgesics, which may produce respiratory depression, is advised.

Vesicourethral Dysfunction

Internal Urethrotomy

In rare cases, an internal urethrotomy is indicated in patients with an anatomic urethral obstruction. At the junction of the prostatic and membranous urethra, a "Type 4" valve may be present. This redundancy partially obstructs the membranous urethra. A transurethral incision at the 12 o'clock position has been advised to improve voiding and decrease residual urine.[162]

Urodynamic assessment, including pressure flow studies, in patients with prune belly syndrome may prove valuable.[5,10,117] The demonstration of residual urine with

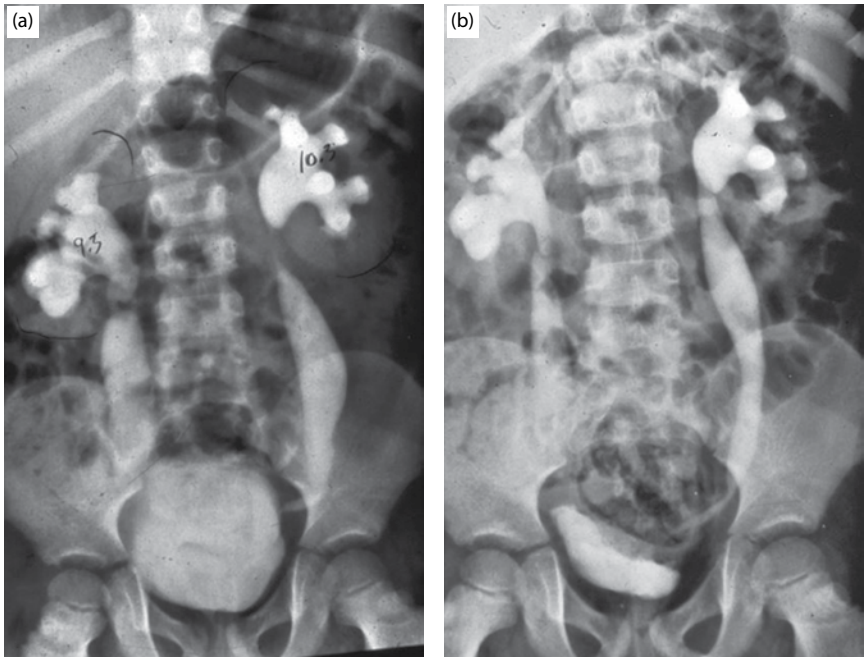

FIGURE 65.15 (a) and (b) Intravenous pyelogram (two views) obtained postoperatively in a child with prune belly syndrome after a single, comprehensive reconstruction.

infection indicates the need for further testing. If a low flow rate is associated with significant residual urine and normal voiding pressure, then intervention to lower urethral resistance is warranted.[117] Endoscopic urethrotomy by hot or cold knife, to decrease outlet resistance, was successful in 10 of 11 cases improving emptying.[163] Most authors who advocate minimal surgical intervention stress the need to closely monitor patients in follow up. Assessment of lower urinary tract dynamics, routine urinary flow rates, and the amount of residual urine are monitored with follow up. Internal urethrotomy is a potential first step to balanced voiding, but clean intermittent catheterization should be considered if the urodynamic criteria of outlet obstruction are not present.[19,116,117,163]

Vesicostomy

When the patient's condition is complicated by urinary infection or deteriorating renal function in the perinatal period, a cutaneous vesicostomy is the drainage procedure of choice.[3,164] This provides a vent that decompresses the entire urinary tract. The vesicostomy is performed through a small transverse incision midway between the umbilicus and the pubic symphysis. The rectus fascia is incised and a small amount of it and the skin removed. The dome of the bladder is mobilized and brought to the skin. The wall of the bladder is sewn to the fascia and matured to the skin. A generous stoma is advocated to prevent stomal stenosis.[109] A urachal diverticulum can be excised, if present. The vesicostomy can serve as an initial temporary drainage procedure prior to more extensive reconstruction.[165] A potential disadvantage is ineffective drainage of the redundant, tortuous, upper ureters or an associated ureteropelvic junction obstruction. This is unlikely, as true supravesical obstruction is rarely a component of prune belly syndrome.

Reduction Cystoplasty

Reduction cystoplasty has been suggested in order to reduce volume and improve emptying.[113] Bladder volumes in excess of 3 L have been recorded in children with prune belly syndrome.[117] Concomitant removal of a dilated urachal diverticulum, which contributes to inefficient voiding, is performed. According to the law of LaPlace, a spherical shape of the bladder should allow maximal intravesical pressure with each detrusor contraction. A variety of techniques to reduce bladder volume and produce a more efficient spherical shape have been proposed.[23,113,166] A vest–over-pants closure of the bladder wall after removal of bladder epithelial strips or simple resection and watertight closure has been performed in the majority of cases.

Reduction cystoplasty has clinically resulted in fewer hospitalizations for urinary infections and initially improved voiding. However, the long-term bladder capacity and voiding efficiency were not improved.[167] Comparison of urodynamic voiding parameters between reconstructed voiding patients and non-reconstructed voiding patients did not show significant differences. Consequently, some authors do not recommend reduction cystoplasty in light of the effective and safe application of clean intermittent catheterization except for the removal of a urachal pseudodiverticulum.[109,116]

Anterior Urethra

Prune belly syndrome is associated with microurethra and megalourethra. Utilization of the unused "micro" anterior urethra is advocated. Successful progressive soft dilation or intermittent hydrodistension of the urethra with normal voiding has been reported.[123,168] If the anterior urethra is not usable, urethroplasty techniques combining skin flaps

and grafts are necessary to bridge the anterior urethral defect. Megalourethra can be repaired by application of hypospadias operative techniques.

Upper Urinary Tract

Vesicoureteral Dysfunction

Vesicoureteral dysfunction is manifested most commonly as vesicoureteral reflux in up to 85% of patients. Ureteral valves and ureterovesical junction obstruction have been described.[110] Both conditions potentially contribute to urinary stasis, and increased risk of infection. The indications for surgical correction of obstructing lesions should be based on the demonstration of decreasing renal function, infection, or parental preference at the time of comprehensive reconstruction.

Surgery to repair vesicoureteral reflux has been contested because of the poor peristaltic activity of the ureters and their dissipation of voiding pressure due to increased capacity.[3] Observation of these patients, who remain infection free on or off prophylactic antibiotics, has confirmed preservation of renal function.[12,26] When urinary infection becomes problematic, correction of reflux and reduction of urinary stasis become necessary. Formal tapering and reimplantation, as well as ureteral imbrication have been used as part of the comprehensive approach to management.[21] We found no difference in the complication rate with either procedure, and 9 of 13 patients had successful elimination of their reflux. Ureteral imbrication may produce fewer problems with stenosis.[3] However, the imbricated ureter is very bulky requiring a long, wide subepithelial tunnel for reimplantation.

Temporary diversion of the upper tract by pyelostomy or ureterostomy is rarely necessary. Vesicostomy is preferred, but in those neonates with unresponsive urosepsis, high diversion to optimize drainage may be required.

Cryptorchidism

The early correction of the cryptorchid intra-abdominal testes by a transabdominal approach is recommended to optimize spermatogenesis, facilitate examination for testicular malignancy, and improve testicular salvage. If orchiopexy is performed in the first year of life, a standard technique with preservation of the spermatic vessels can usually be performed pending testis location. Orchiopexy in older children frequently requires division of the spermatic vessels, with results based on a one- or two-stage Fowler-Stevens technique.[169–171] To avoid atrophy, a broad, peritoneal pedicle mobilized with the long-looping vas; combined with early ligation of the spermatic vessels above the point of confluence of the vas and spermatic artery is recommended.[172] Utilizing this two-stage approach, an 80%–83% success rate for intra-abdominal testes has been attained.[170,171] Overall, successful orchiopexy can be expected in the majority of patients.

Open and laparoscopic techniques have been described with similar results.[173–175] Unique technical considerations exist with the laparoscopic approach in these patients. A lax abdominal wall creates technical challenges that are not present in other infants/children. With the thin abdominal wall, air leak can be troublesome, hence, lower abdominal pressures are need for insufflation with smaller port site incisions. In addition, longer working instruments may be required.[176,177] Open or laparoscopic orchiopexy can be performed at the time of comprehensive reconstruction with a high success rate.[17–19,178]

Microvascular testicular autotransplantation has been utilized in patients with prune belly syndrome. The spermatic vessels are anastomosed to the inferior epigastric vessels, with microsurgical vascular techniques.[179] This has normally been performed in older patients as a last salvage effort.[165] Prior to 1999, all boys with prune belly syndrome were considered infertile. However, with recent advances in male factor infertility and assisted reproductive techniques, the first assisted conception of a man with prune belly syndrome was reported.[135] Consequently, an early orchiopexy to preserve spermatogonia and testicular function in these patients is warranted.

Abdominal Wall Reconstruction

Abdominal wall reconstruction has a significant role in the treatment of patients with prune belly syndrome. Abdominoplasty had previously been performed to improve body image, self-esteem, and psychological well-being.[22–24] Recent studies suggest that the improved abdominal contour, with repositioning of the most functional musculature, improved voiding efficiency.[106,158] The decrease in residual urine has obvious benefit in the prevention of urinary infection. In addition, abdominoplasty was subjectively felt to improve defecation and sensation of bladder fullness.

The surgical approaches to performance of the abdominoplasty are based on preservation of the lateral and upper parts of the abdominal wall, the sites of most normal musculature. Our early experience was quite positive with the cosmetic and functional results provided by the abdominoplasty as described by Randolph et al.[107] This technique excises the most abnormal segment of redundant abdominal wall, provides excellent exposure for urinary reconstruction and orchiopexy, and preserves segmental motor nerves to the retained abdominal musculature. In 16 patients where this technique was utilized, 9 had an excellent cosmetic improvement in abdominal contour and in 7 a slight protuberance remained. There were no serious complications related to the abdominoplasty procedure (Figures 65.16 and 65.17).[21] The major criticisms of this technique are that it does not improve abdominal wall thickness, and lateral bulging is not completely eliminated. However, this technique has been favored by a number of surgeons historically.[3,109]

More recently, a surgical approach to abdominal wall reconstruction, utilizing a ellipsoid midline incision with extensive subcutaneous dissection, and a pants over vest closure has been described (Figures 65.17 and 65.18).[23,180–182] This technique preserves the umbilicus, uses the full thickness of abdominal wall, and provides narrowing at the waist. Excellent cosmetic results with a high degree of patient satisfaction have been reported with both the Ehrlich and Monfort techniques (Figures 65.19 and 65.20).[180,181] An adaptation utilizing an extraperitoneal

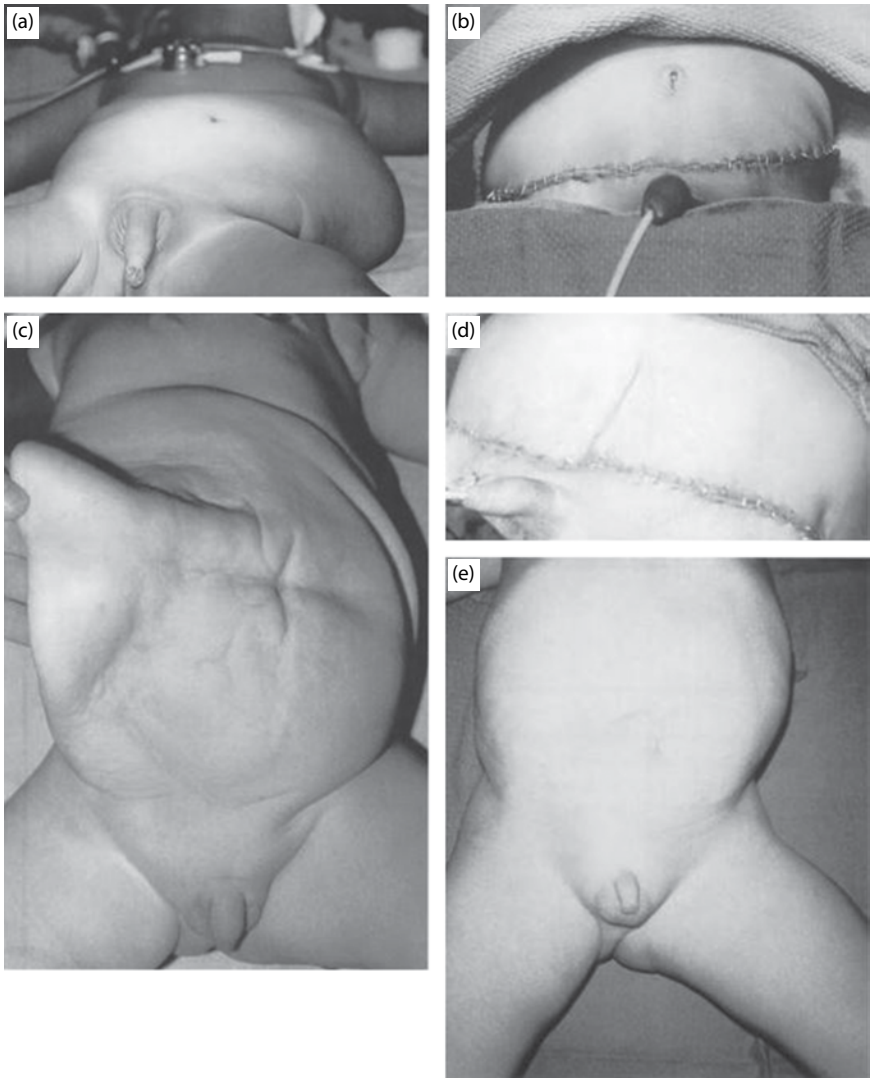

FIGURE 65.16 (a) Preoperative depiction of a 2-year-old child with bilateral cutaneous loop ureterostomies prior to comprehensive surgical reconstruction. (b) Same child after comprehensive reconstruction of the urinary tract and Monfort abdominoplasty. (Courtesy of George W Kaplan, MD.)

plication of the abdominal wall through a midline incision decreases the extent of facial dissection, avoids entering the peritoneal cavity, and decreases postoperative recovery time.[183] This simplification seems most appropriate for patients not requiring other concomitant surgical procedures. A modification of the Monfort abdominoplasty includes a neoumbilical revision to provide a normal anatomic placement of the umbilicus (Figure 65.21).[184]

Other modifications to this approach have continued to evolve over the last couple decades. For instance, varying the width of the central plate can be used to correct asymmetry.[185,186] Additionally, central plate plication has been reported to reduce vertical redundancy, and flank plication to decrease fascial weakness.[186] The use of laparoscopy for visualization of intra-abdominal contents and assistance in abdominal wall reconstruction has also been described by several centers.[186,187] Functional and aesthetic outcomes have been excellent with these advancements, although "retightening" of the fascia has remained a persistent challenge (Table 65.4). Fearon et al. report successful reduction of this complication with the use of rectus femoris muscle transpositions (Table 65.4[188]).

Other treatment possibilities include abdominal binders and elasticized corsets. These aids do not address the psychological implications of the abdominal disfigurement, which have generally been ignored in the past.[180] The importance of body image during the formative years of childhood cannot be overestimated. The abdominoplasty provides these males with freedom from abdominal binders, a more natural waisted physique, ability to wear normal pants, and participate in sports.[21]

Comprehensive Reconstruction

Comprehensive reconstruction in the prune belly patient involves reduction cystoplasty, resection of the distal ureter and bilateral ureteral tapered reimplantation (see Figure 65.14). Reconstruction may be combined with the performance of the abdominoplasty and bilateral orchiopexy, usually prior to two years of age.[17,22] This aggressive

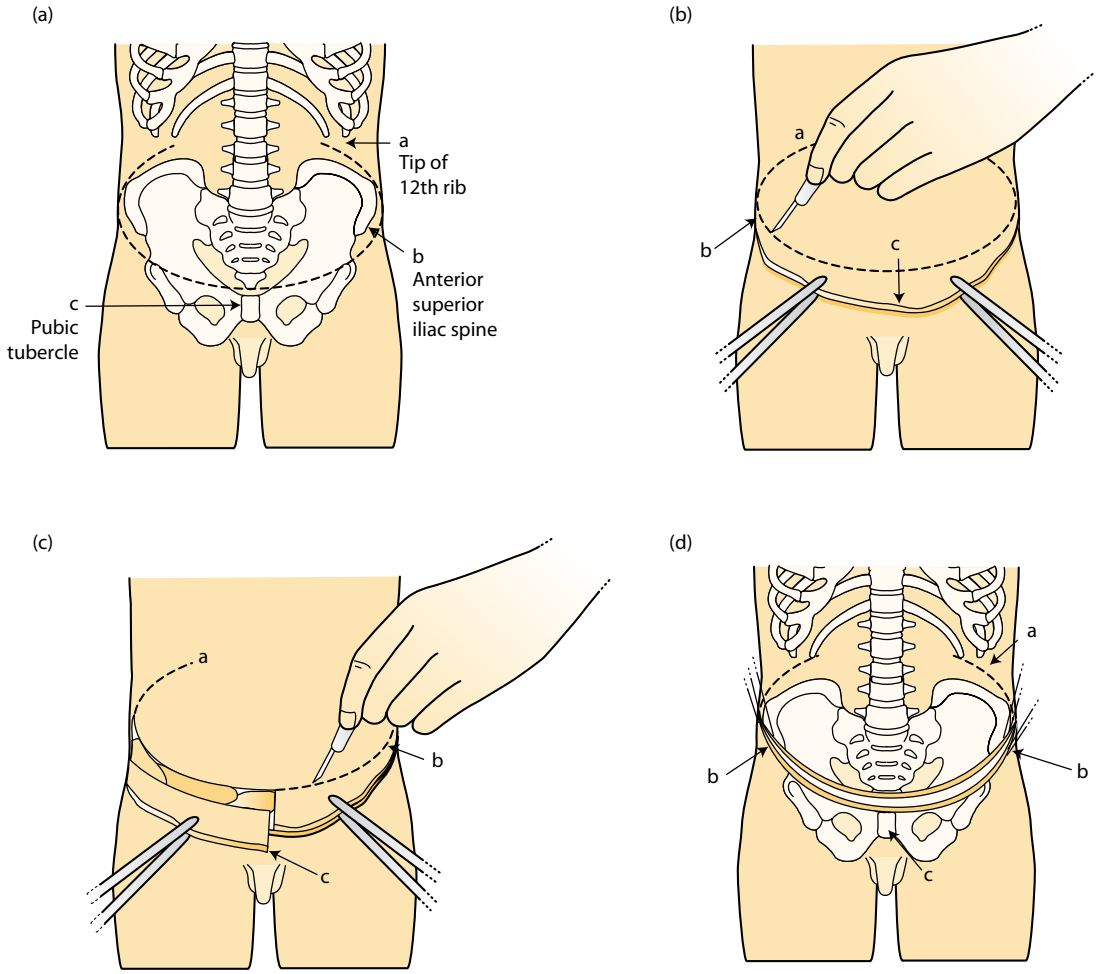

FIGURE 65.17 Technique of the Randolph abdominoplasty. (a) A curvilinear incision extends from the tip of the 12th rib, along the anterior superior iliac spine to the pubic tubercle and onto the opposite 12th rib. (b) A parallel incision is made, avoiding the removal of too much abdominal wall. (c) Rhomboid-like pieces of abdominal wall are removed. (d) Critical non-absorbable sutures are placed at the anterior iliac spines and pubic tubercle. These are placed through full thickness of the abdominal wall including the periosteum.

approach was utilized in 15 patients in our series. Serial measurements of creatinine up to 13 years later documented preservation of renal function.[21] Vesicoureteral reflux was corrected in 9 of 13 patients and improved in 3. Because of the known urinary stasis that occurs in these children, all are maintained on antibiotic prophylaxis. Therefore, our ability to decrease urinary infection cannot be totally attributed to the surgical result.

Complete surgical reconstruction, as reported by Denes et al., involved abdominoplasty, urinary tract reconstruction, and orchiopexy in a select group of 32 patients. A morbidity rate of 18.7% and a re-operation rate of 15.6% was reported. In all, 30 of 32 patients demonstrated stable or improved renal function at a mean follow up of 5 years.[178]

One surgical approach is that proposed by Woodward (see Figure 65.14). A wide lower abdominal incision is made that extends from the tip of the 12th rib, along the anterior superior iliac spine to the pubis and then curves upward to the opposite 12th rib.[107] This tends to spare the segmental nerve and vascular supply of the abdominal wall left for reconstruction. In addition, at the time of excision of the redundant abdominal wall, that portion with the most muscle fibers is preserved. The exposure of the urinary tract provided with this incision is exceptional. However, use of this technique has decreased given concerns regarding interruption of the epigastric vessels and redundant lateral abdominal tissue. Instead, most surgeons favor the Monfort approach as described above (see Figure 65.21).

The posterior peritoneum is incised along the length of the ureters. The spermatic vessels are mobilized distally; care being taken not to compromise the peritoneal attachments of the vas deferens if a Fowler-Stephens orchiopexy is required. The bladder is opened in the midline with cautery. The laterally placed ureteral orifices are recognized and each ureter is mobilized. The extreme length of the mobilized ureters allows for resection of its distal third, usually the most abnormal portion. Formal tapering or imbrication is performed (Figure 65.22).[189,190] The ureters are then reimplanted, using a transtrigonal or Leadbetter Politano technique. Stenting of the operated ureters is performed and these are brought out through the bladder and separate abdominal incisions.

[a] Diagnostic laparoscopy performed.

Prior to reduction cystoplasty, the testes are mobilized with a wide apron of posterior peritoneum (Figure 65.23). In some cases, the testes may be adherent to the enlarged bladder and must be meticulously mobilized to preserve blood supply (Figure 65.24). If the reconstruction is performed prior to 2 years of age, a standard orchiopexy with intact spermatic vessels can be performed 80% of the time.[18,21] Otherwise, a delayed or formal Fowler-Stephens orchiopexy will be necessary.[174]

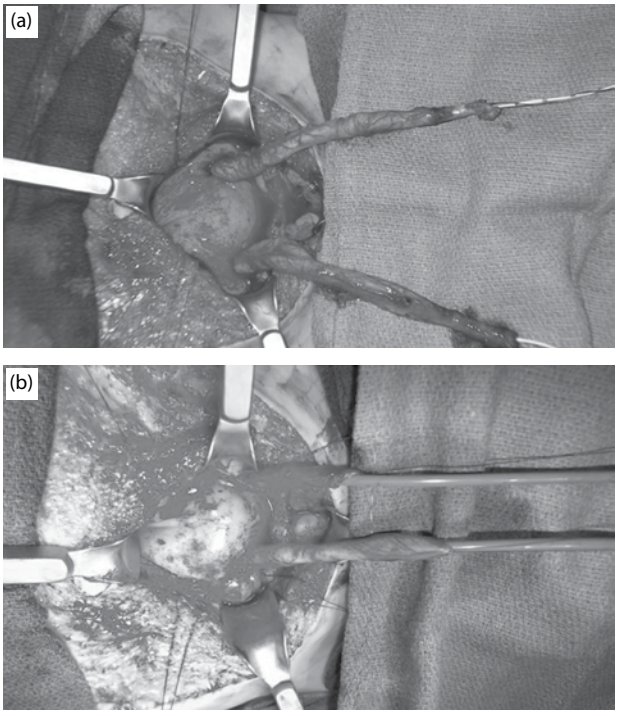

FIGURE 65.22 (a) Both ureters have been mobilized prior to (b) implantation and tapering.

The bladder is reduced in size by resection of the urachal remnant and the huge bladder dome. A strip of bladder epithelium can be removed from one of the lateral walls and closed by the vest-over-pants technique. The bladder is drained with a Malecot catheter. The previously mobilized testes are brought up through the distal abdominal wall at the pubic tubercle. A dartos pouch is created in the scrotum and each testis is secured in the pouch with permanent sutures.

The redundant abdominal wall is then held taut and marked in the midline and laterally at the costovertebral angles to outline the tissue to be excised (see Figure 65.17).[107] Avoidance of removal of excessive amounts of abdominal wall is critical. The second line of incision parallels the previous incision. A large wedge of full thickness abdominal wall is removed. The closure of the abdominal wall is commenced by placement of key sutures of 0 or 1–0 non-absorbable sutures at the anterior iliac spines and at each pubic tubercle. These sutures should include the periosteum of the bone and a full thickness of the proximal opposing tissue edge. The tension created occasionally allows for removal of additional lateral redundant abdominal wall. Each section between the key sutures is closed with interrupted sutures opposing the full thickness of the abdominal tissue. The subcutaneous tissue is closed to prevent dead space and the skin is approximated with a subcuticular absorbable suture. Other techniques include modification of laparoscopic and open approaches with preservation of the umbilicus, "double-breasted" medial fascial closure, and excess abdominal skin removal, in association with urinary tract reconstruction.[187,191–193]

Renal Transplantation

Progressive renal insufficiency resulting from renal dysplasia, reflux nephropathy, and recurrent pyelonephritis can be successfully treated by renal transplantation. Renal transplantation in patients with prune belly syndrome

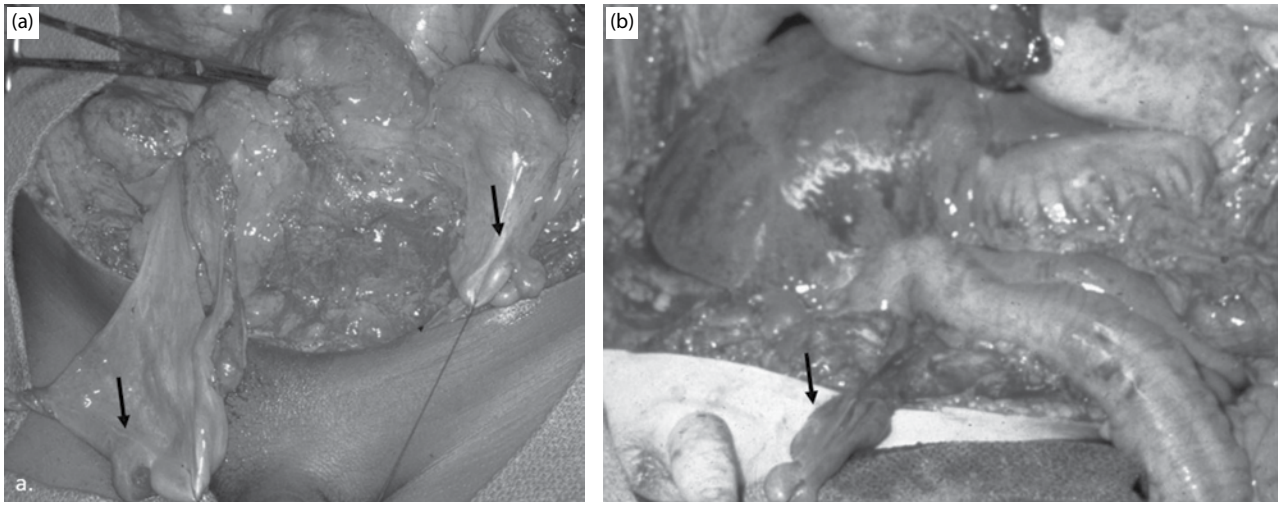

FIGURE 65.23 (a) Widely mobilized peritoneum with intact spermatic vessels (arrows) ensures good blood supply to the testis. (b) Achieving adequate length to secure the testes in the scrotum is usually not difficult in the child less than 2 years of age.

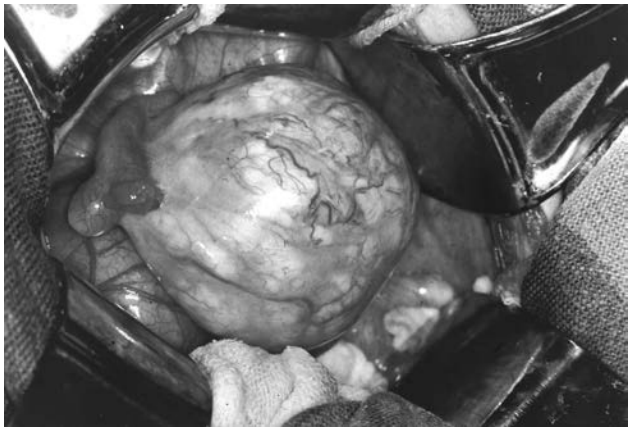

FIGURE 65.24 The intraabdominal testicle is densely adherent to the enlarged bladder. It was meticulously mobilized off its peritoneal attachments and a single-stage Fowler-Stephens orchiopexy was performed to allow normal testicular growth.

was first reported in 1976.[194] The age at transplantation has ranged from 8 months to 21 years of age.[195,196] Both cadaver and living-related donor kidneys have been successfully transplanted. In a retrospective review of eight patients with prune belly syndrome who underwent transplantation, there was no statistically significant difference in patient deaths, graft survival or graft function when compared to age-matched controls.[196] A more recent retrospective analysis of graft survival at 10 years of 47% was not statistically significantly different from age-matched controlled patients.[197] The success of renal transplantation was in part attributed to the low-pressure urine storage provided by the bladder in prune belly syndrome.[198]

Prior to transplantation, bilateral nephroureterectomies were performed in all reported cases. Radiographic and urodynamic assessment of the lower urinary tract is recommended to insure absence of obstruction and balanced voiding.[199] The use of clean intermittent catheterization to empty the decompensated bladder is not a contraindication to renal transplantation.[196,200] All patients should be kept on antibiotic prophylaxis. An unusual complication of transplantation in prune belly syndrome is allograft torsion.[201] The torsion, with resultant graft loss, was a result of lack of abdominal wall tone. Nephropexy has been recommended to avoid this disastrous complication.

Future Considerations

Minimally invasive techniques are more commonly available in the pediatric urologist's armamentarium. Laparoscopic orchiopexy, laparoscopic appendicovesicostomy with robot assistance and laparoscopic-assisted abdominoplasty are increasingly utilized in the management of these patients.[187,191,202,203]

CONCLUSIONS

Given the wide spectrum of disease, the treatment of prune belly syndrome is patient specific. When infection and stasis compromise renal growth or function, aggressive surgical intervention to promote drainage is advised. The testes in these infants are placed in the scrotum early for improved fertility purposes and can be accomplished by laparoscopic or open techniques. Because of the changing urodynamic condition of the lower urinary tract and its effects on renal function and urinary infection, all patients with prune belly syndrome require careful lifelong urologic surveillance.

CHAPTER 66

Surgical Excision of Urachal Anomalies

Heidi A. Stephany, Jathin Bandari, and Steven G. Docimo

BACKGROUND

The urachus is the fibrous remnant that represents the intraembryonic communication between the bladder and the allantois. The urachus closes by progressive accumulation of desquamated epithelium within the lumen early in gestation and becomes the median umbilical ligament. When this process has been disrupted, a patent urachus or urachal remnant will persist in the form of a cyst, sinus, or diverticulum (Figure 66.1).[1] A complete review of urachal anomalies can be found in Chapter 63.

Indications for excision of urachal anomalies include the risk of malignant change and recurrent infections. Various approaches have been described, including both open and laparoscopic techniques. Regardless of the technique used, surgical excision of a bladder cuff is recommended to ensure that all remnants of the urachus are removed. Cystoscopy to visualize and confirm the anomaly may be of benefit, and placement of a catheter with intermittent distension of the bladder may assist with dissection.

OPEN APPROACHES

Traditionally, the open approach utilizes a low transverse or midline incision. This exposes the bladder so that the urachus may be traced from the bladder dome toward the umbilicus.[2]

Another technique, which is used preferentially by the authors, is using an open, scarless incision. The urachus is circumferentially dissected out down to the bladder dome through a single intraumbilical incision. The umbilicus can then be reconstructed, leaving the patient with no scar (Figures 66.2 and 66.3). This technique is particularly suited to children due to the higher position of the bladder dome, but it has also been used in young adults. Patients are routinely treated as outpatients without bladder catheterization or drains.[3] (Video 66.1).

LAPAROSCOPIC APPROACHES

Alternatively, laparoscopic excision, with or without the use of the da Vinci surgical robot system (Intuitive Surgical, Sunnyvale, California), has also been successful. Advantages of this minimally invasive technique include a panoramic view of the surgical field and improved cosmesis as a result of smaller incisions. There are multiple reports in the literature describing outcomes in small cohorts of patients for this uncommon condition. During dissection, however, care must be taken to not spill infected cyst contents. Cysts are delivered through a trocar site after drainage by needle aspiration.[4] The mean operative times with this approach have ranged from 50 to 180 minutes for traditional laparoscopic techniques.[4–7]

Robotic-assisted laparoscopy has been used increasingly in the pediatric population for a multitude of reconstructive procedures, including excision of urachal remnants.[8] The advantages of robotic-assisted laparoscopy include a high-resolution, magnified three-dimensional view and increased dexterity and articulation of the robotic instruments, all of which can lead to more precision, particularly of benefit with suturing.[9] The first robotic-assisted excision of a pediatric urachal cyst was reported by Yamzon et al. The authors describe using a 30° angled lens positioned upward to allow visualization of the bladder and anterior abdominal wall. Placing the camera port superior to the umbilicus in the midline allows complete resection of the umbilical attachments

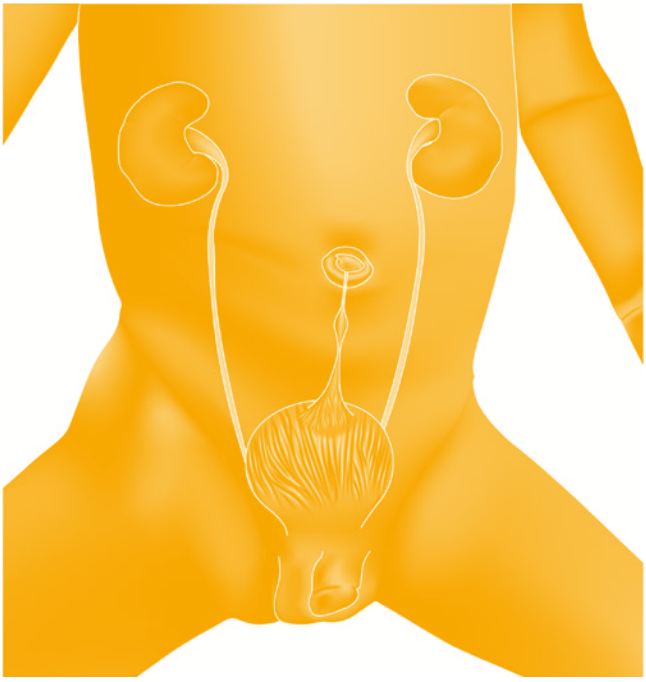

FIGURE 66.1 Urachal remnant.

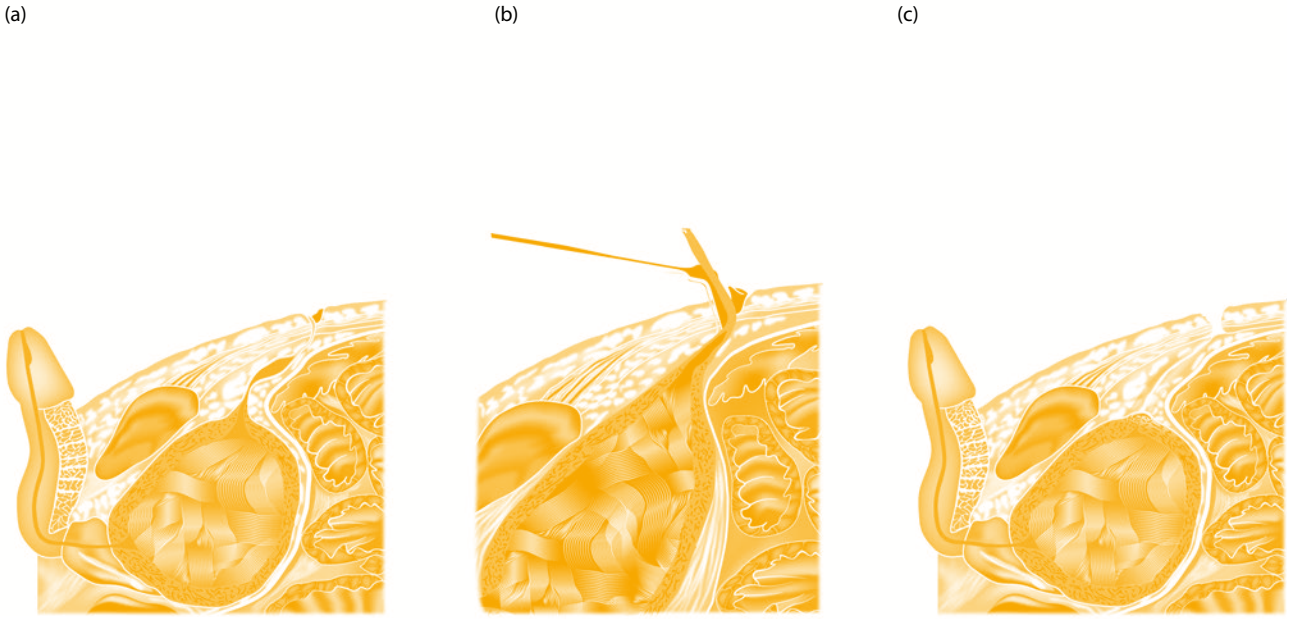

FIGURE 66.2 (a) The umbilicus is everted and stay sutures placed around the edges of the sinus or cyst to assist in retraction. (b) A U-shaped flap is raised at the lower lip of the umbilicus, and a circumferential dissection around the urachus is completed down to the posterior rectus fascia. (c) Stay sutures are placed in the bladder, and a small cuff of bladder is excised with urachus and the bladder closed in two layers.

of the urachal remnant.[10] Robotic assistant arms can be placed above the level of the umbilicus at the anterior axillary line, as described by Yamzon et al., or inferior to the Pfannenstiel line and medial to the anterior superior iliac spine, as recently reported by Rivera et al.[10,11] The urachal remnant is detached superiorly with cautery and taken down from the anterior abdominal wall toward the bladder (Figure 66.4). A hitch stitch can be used to assist with countertraction, as well as stability during sewing. The bladder cuff and remnant are excised, and a two-layer, watertight closure is performed (Figure 66.5).

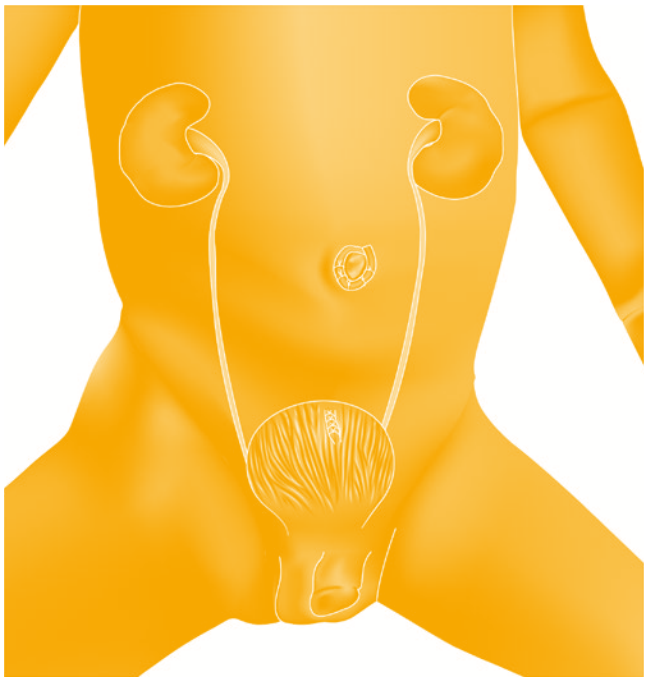

FIGURE 66.3 The rectus fascia was closed, and the umbilicus was reconstructed to its anatomic position.

CONCLUSIONS

Surgical excision remains the mainstay of management for urachal anomalies. The majority of these anomalies can be removed through the base of the umbilicus with no resulting visible scar. Laparoscopic approaches, with or without robotic assistance, have been described with excellent results and recovery. Larger incisions for open removal should only be necessary if there is concern for malignancy, there is active infection requiring drainage and removal,

or the remnant is too large to be conveniently removed through a minimally invasive approach. Full excision requires removal of a bladder cuff and a watertight closure.

CHAPTER 67

Basic Science of the Genitalia

Laurence S. Baskin

INTRODUCTION

Genital anomalies are the most common birth defects, with the exception of cardiac malformations.

Hypospadias is defined as an arrest in normal development of the urethra, foreskin, and ventral aspect of the penis; it is the most common genital anomaly, occurring in approximately 1:250 newborns, or roughly 1 out of 125 live male births.[1] Hypospadias results in a wide range of abnormalities, with the urethral opening located anywhere along the shaft of the penis, within the scrotum, or even in the perineum (Figure 67.1a–c).[2]

Hypospadias is also associated with ventral penile curvature (chordee). Left uncorrected, patients with severe hypospadias may need to sit down to void and tend to shun intimate relationships because of fears related to abnormal sexuality. Babies born with severe hypospadias and penile curvature may have "ambiguous genitalia" in the newborn period, making an immediate and accurate sex assignment difficult.

Epispadias is a urethral defect on the dorsal aspect of the penis (Figure 67.1d). Epispadias is associated with a short penis, dorsal penile curvature, and in the most severe forms, bladder exstrophy. Females (as well as males) can also suffer from these genital anomalies and others, such as genital duplication or malformations, but these problems are extremely rare (Figure 67.1e and f). Understanding abnormal development of the external genitalia requires a concise knowledge of normal genital development.

NORMAL SEXUAL DIFFERENTIATION

Chromosomal Sex

The genetic material necessary for the development of the male phenotype is normally located on the short arm of the Y chromosome. The critical gene or sex-determining region on the Y chromosome is known as the *SRY* region.[3] The gene products of the *SRY* genetic cascade will subsequently direct the development of the testis by interacting with multiple other genes, such as *SOX-9*. Genetic information that is necessary for male and female development beyond gonadal differentiation is located on the X chromosome and on the autosomes.

Gonadal Differentiation

The gonads develop from the urogenital ridges (Figure 67.2), which are formed during the fourth week of gestation by the proliferation of the coelomic epithelium and condensation of the underlying mesenchyme along the mesonephros. The germ cells located in the endoderm of the yolk sac migrate to the genital ridges. At the early stage of development, the gonad is bipotential, capable of forming into either a testis or ovary. During the sixth to seventh week of gestation, at least four different genes—Wilms' tumor suppressor gene (*WT-1*), Fushi–Tarza factor 1 (*FTZ-F1*), steroidogenic factor 1 (*SF-1*), and *LIM-1*—induce the development of the testis. The primordial germ cells differentiate into the Sertoli cells and associated Leydig cells, which aggregate into spermatogenic cords. Loose mesenchymal tissue condenses into a thick layer, the tunica albuginea, that surrounds the testis and separates it from the coelomic epithelium, thereby preventing further migration of mesonephric cells into the testis.

Classic teaching is that the female phenotype is the default developmental pathway in the absence of the *SRY* cascade. It is now known that at least one gene—dosage-sensitive sex reversal (*DAX-1*)—is essential for ovarian development. *DAX-1* is located on the short arm of the X chromosome. The gene products of *SRY* and *DAX-1* compete to stimulate the steroidogenic acute regulatory protein (StAR). The StAR protein is the first step in steroidogenesis, facilitating the conversion of cholesterol to pregnenolone (Figure 67.3). In the normal XY male, *SRY* overwhelms the one functional *DAX-1* gene, stimulating testicular development and subsequent testosterone production. In the normal XX female, two *DAX-1* genes are present without the competitive *SRY*, downregulating StAR and hence inhibiting testicular development, which results in ovarian development. In the fetal ovaries, the germ cells differentiate and are arrested in the last phase of meiotic prophase, forming the oocytes. The cells in the genital ridges develop into granulosa cells, which surround the oocytes and complete the formation of the ovaries.

Hormones

At 3.5 weeks' gestation, the Wolffian system appears as two longitudinal ducts connecting cranially to the

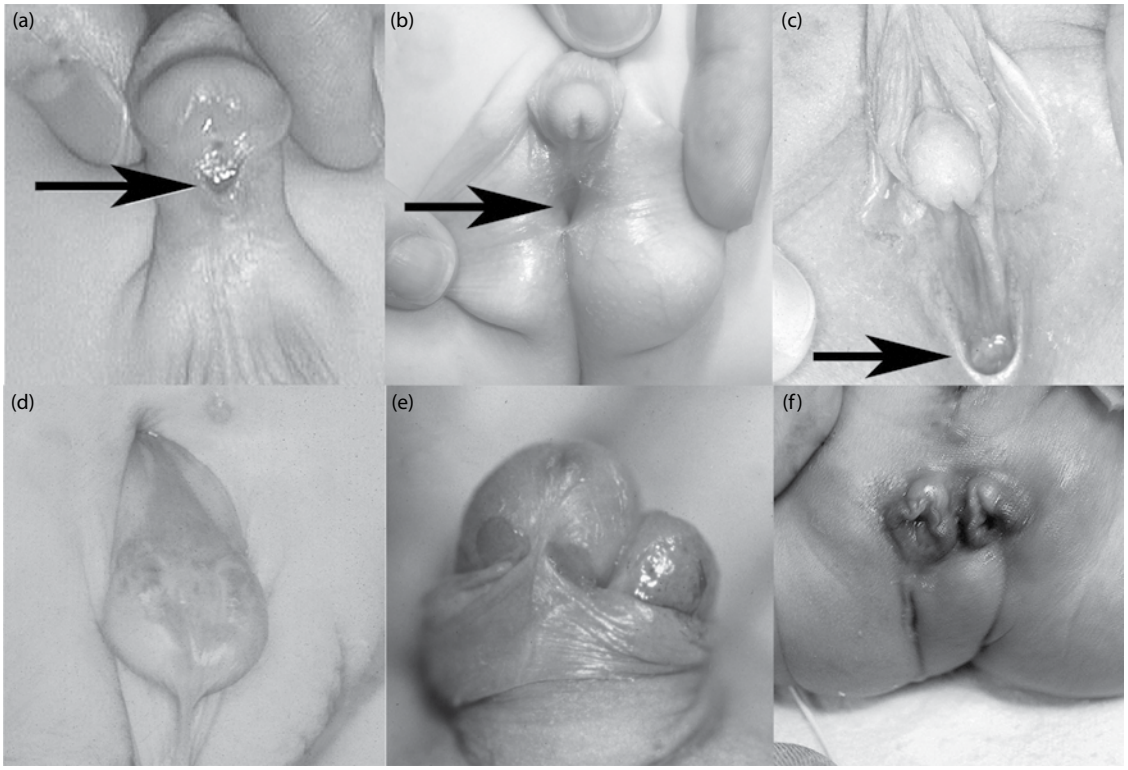

FIGURE 67.1 Genital abnormalities: (a) distal hypospadias, (b) scrotal hypospadias, (c) perineal hypospadias secondary to type 2 5α-reductase deficiency, (d) epispadias, (e) penile duplication anomaly, and (f) complete duplication of the female external genitalia.

mesonephros and caudually draining into the urogenital sinus (Figure 67.4). At approximately the sixth week of gestation, the Müllerian duct develops as an evagination in the coelomic epithelium just lateral to the Wolffian duct.

During the eighth to ninth week of gestation, Sertoli cells of the fetal testis secrete a glycoprotein, Müllerian inhibiting substance (MIS) or anti-Müllerian hormone. This protein induces the regression of the Müllerian ducts through the dissolution of the basement membrane and condensation of mesenchymal cells around the Müllerian duct. Because MIS acts locally, Müllerian duct regression occurs only on the ipsilateral side of the fetal testis, producing this hormone. MIS also induces the formation of seminiferous tubules and further differentiation of the testis. At the 9th or 10th week of gestation, the Leydig cells appear in the testis and begin to synthesize testosterone. This hormone transforms the Wolffian duct into the male genital tract, which is completed by the end of the 11th week of gestation.

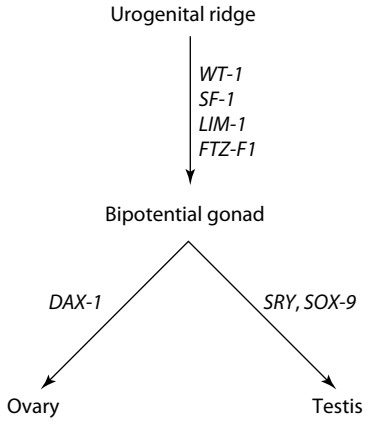

FIGURE 67.2 Sex-determining genes involved in testes and ovarian development.

Beginning in the ninth week of gestation, testosterone also induces the development of the external genitalia (Figure 67.5) from the genital tubercle, urogenital sinus, and genital swellings. At the molecular level, testosterone is converted to 5α-dihydrotestosterone (DHT) by the microsomal enzyme, type 2 5α-reductase, which is responsible for complete differentiation of the penis with a male-type urethra and glans. Testosterone dissociates from its carrier proteins in the plasma and enters cells via passive diffusion. Once in the cell, testosterone binds to the androgen receptor (AR) and induces changes in conformation, protecting it from degradation by proteolytic enzymes. This conformational change is also required for AR dimerization, DNA binding, and transcriptional activation, which are all necessary for testosterone to be expressed. Androgen binding also displaces heat shock proteins, possibly relieving constraints on receptor dimerization or DNA binding.

After entering the nucleus, the AR complex then binds androgen response element DNA regulatory sequences within the androgen-responsive genes and activates them. DHT also binds the AR, with greater androgenic activity than testosterone, in part because of its slow dissociation rate from the AR.

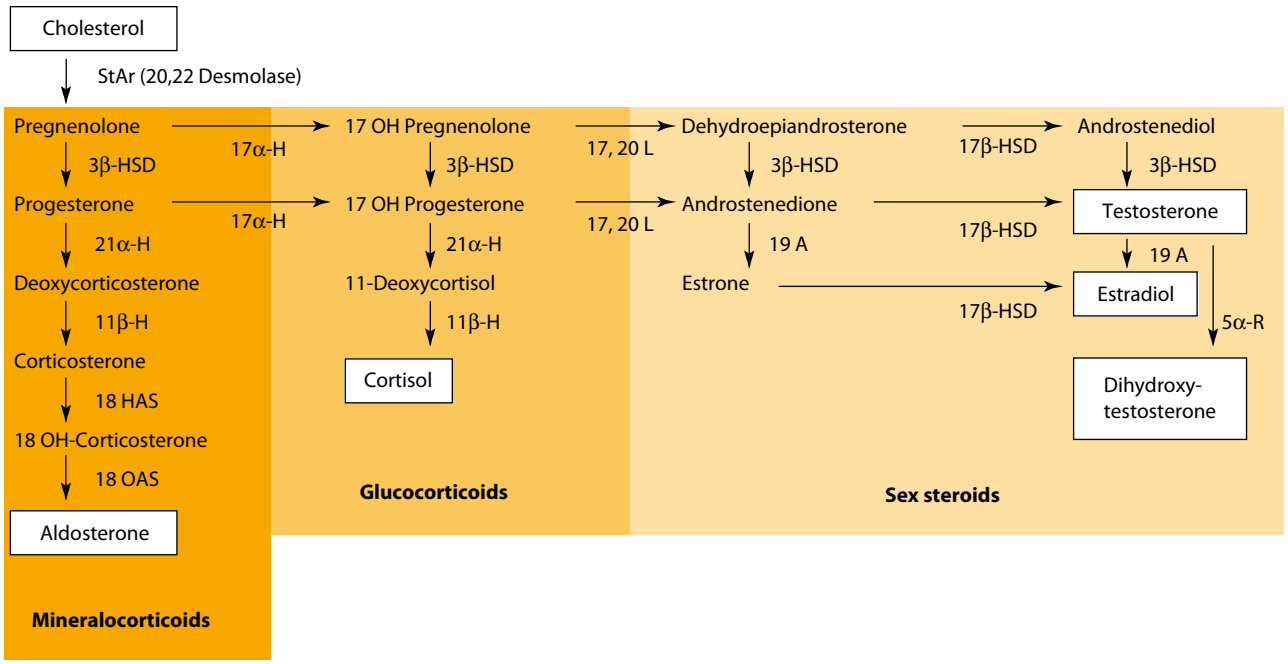

FIGURE 67.3 Pathway of steroid hormone biosynthesis and possible enzyme deficiencies. 3β-HSD = 3β-hydroxysteroid dehydrogenase; 17α-H = 17α-hydroxylase; 21α-H = 21α-hydroxylase; 11β-H = 11β-hydroxylase; 17, 20 L = 17,20-lyase; 17β-HSD = 17β-hydroxysteroid dehydrogenase; 18 HAS = 18-hydroxyaldosterone synthetase; 18 OAS = 18 oxidase-aldosterone synthetase, 5α-R = 5α-reductase; 19 A = 19-aromatase.

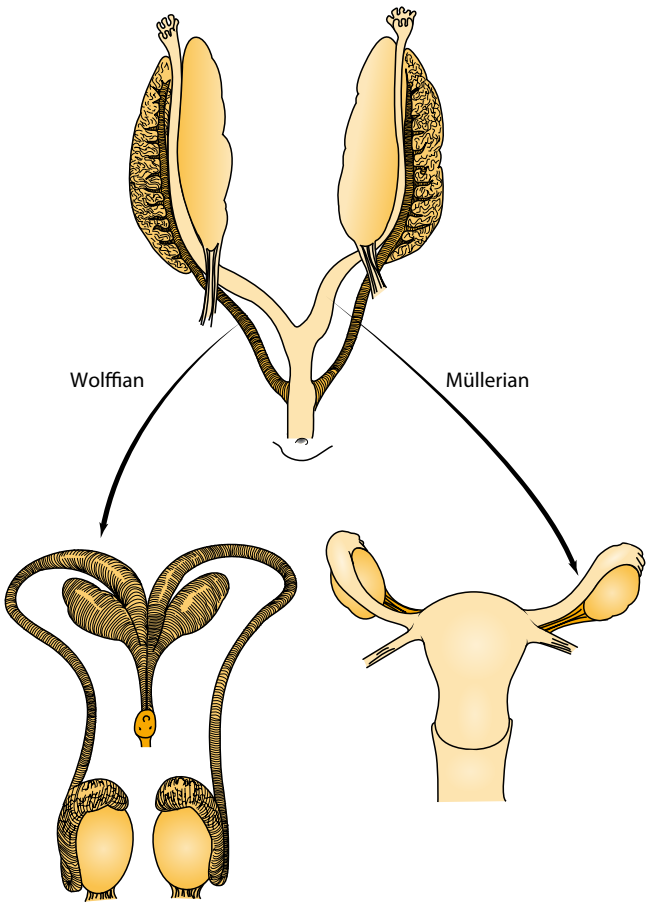

FIGURE 67.4 Schematic of male (Wolffian) and female (Müllerian) internal and external genital development from a common origin.

DHT then binds to nuclear receptors, forming a complex that regulates the transformation of these tissues into the glans penis, penile and cavernous urethra, Cowper's glands, prostate, and scrotum. At the 28th–37th week of gestation, testicular descent into the scrotum begins. Although its mechanism is not completely understood, it is clearly an androgen-dependent process.

The female internal genitalia develop from the Müllerian ducts. Without the hormones produced by the testis, the Wolffian ducts regress at the ninth week of gestation. At the same time, the Müllerian ducts begin to differentiate; the cranial portions form the fallopian tubes, while the caudal portions fuse to form the uterus, cervix, and upper portion of the vagina.

Concurrently, the external genitalia, defined as the lower portion of the vagina, the vestibule, Bartholin's and Skene's glands, the clitoris, and the labia minora and majora, develop from the urogenital sinus and genital tubercles. Like the testis, the ovary undergoes a partial transabdominal descent. However, transinguinal descent of the ovary does not occur, leaving the ovaries just below the rim of the true pelvis. The role of estrogen in the differentiation of the female phenotype is unclear.

EMBRYOLOGY: DEVELOPMENT OF THE MALE EXTERNAL UROGENITAL SYSTEM

Formation of the external male genitalia is a complex developmental process involving genetic programming, cell differentiation, hormonal signaling, enzyme activity,

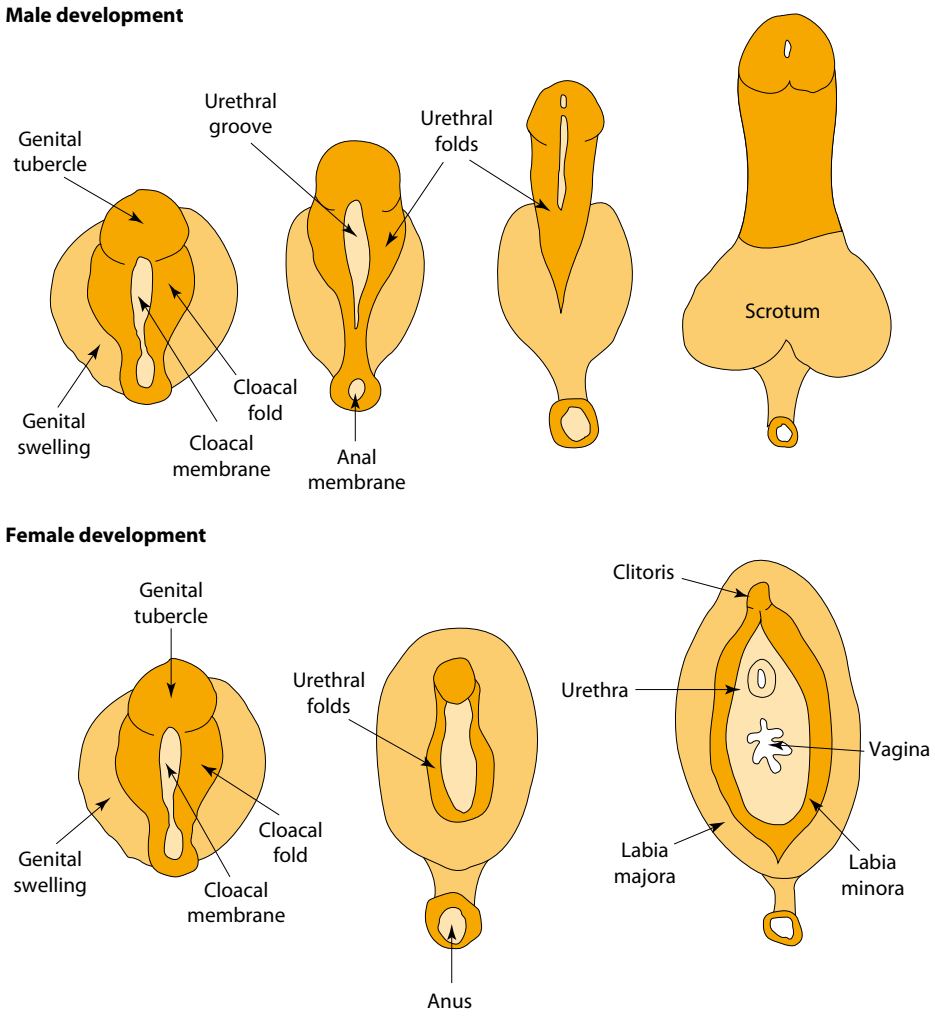

FIGURE 67.5 Differentiation of the male and female external genitalia from the indifferent stage to full differentiation (8–16 weeks).

and tissue remodeling.[4] By the end of the first month of gestation, the hindgut and future urogenital system reach the ventral surface of the embryo at the cloacal membrane.[5] The cloacal membrane divides the urorectal septum into a posterior, or anal, half and an anterior half, the urogenital membrane. Three protuberances appear around the latter. The most cephalad is the genital tubercle. The other two, the genital swellings, flank the urogenital membrane on each side. Up to this point, the male and female genitalia are indistinguishable. Under the influence of testosterone in response to a surge of luteinizing hormone from the pituitary, masculinization of the external genitalia takes place (Figure 67.5). One of the first signs of masculinization is an increase in the distance between the anus and the genital structures, followed by elongation of the phallus, formation of the penile urethra from the urethral groove, and development of the prepuce.[6,7] At 8 weeks' gestation the external genitalia remain in the indifferent stage (Figure 67.5). The urethral groove on the ventral surface of the phallus is between the paired urethral folds (Figure 67.6). The penile urethra forms as a result of fusion of the medial edges of the endodermal urethral folds.[8,9] The

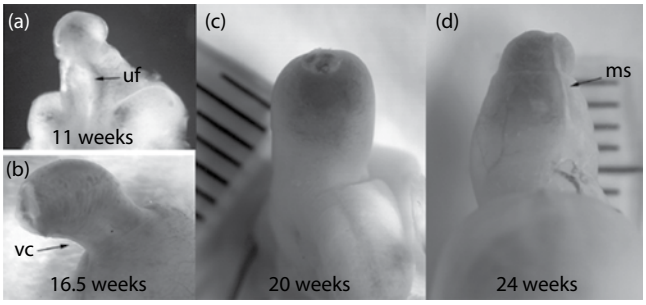

FIGURE 67.6 Male human fetal external genitalia during gestation. (a) At 11 weeks' gestation, note that the urethra is open and the urethral fold (uf) and groove are prominent in the transillumination view of the phallus. (b) At 16.5 weeks' gestation, note that the normal ventral curvature (vc) is shown, as well as the foreskin, which is almost completely formed. (c) At 20 weeks' gestation, penile and urethral development looks complete, with the prepuce covering the glans and the penile curvature resolving. (d) At 24 weeks, the prepuce covers the whole glans; note the midline seam (ms). Note the progression of natural curvature to a straight phallus during development.

ectodermal edges of the urethral groove fuse to form the median raphe. By 12 weeks, the coronal sulcus separates the glans from the shaft of the penis. The urethral folds have completely fused in the midline on the ventrum of the penile shaft. During the 16th week of gestation, the glandular urethra appears. The mechanism of the glandular urethral formation remains controversial. Evidence suggests two possible explanations: endodermal cellular differentiation or primary intrusion of the ectodermal tissue from the glans (Figure 67.7).

Anatomic and immunohistochemical studies advocate the new theory of endodermal differentiation, which shows that epithelium of the entire urethra is of urogenital sinus origin.[10] The entire male urethra, including the glandular urethra, is formed by dorsal growth of the urethral plate into the genital tubercle and ventral growth and fusion of the urethral folds. Under proper mesenchymal induction, urothelium has the ability to differentiate into a stratified squamous phenotype with characteristic keratin staining, thereby explaining the cell type of the glans penis.[11] There is no evidence of an ectodermal ingrowth, as was historically proposed (old theory).[12]

The future prepuce is forming at the same time as the urethra and is dependent on normal urethral development. At about 8 weeks' gestation, low preputial folds appear on both sides of the penile shaft, which join dorsally to form a flat ridge at the proximal edge of the corona. The ridge does not entirely encircle the glans because it is blocked on the ventrum by incomplete development of the glandular urethra. Thus, the preputial fold is transported distally by active growth of the mesenchyme between it and the glandular lamella. The process continues until the preputial fold (foreskin) covers all of the glans (Figure 67.6). The fusion is usually present at birth, but subsequent desquamation of the epithelial fusion allows the prepuce to retract. If the genital folds fail to fuse, the preputial tissues do not form ventrally; consequently, in hypospadias, preputial tissue is absent on the ventrum and is excessive dorsally.

GENITAL MALFORMATIONS

Unfortunately, to date there is no sound understanding of the etiology of genital anomalies and specifically hypospadias (which is the most common defect) that can inform primary prevention efforts and improve therapeutics. However, much is known about the genetics of hypospadias, hormone requirements for normal development, and environmental toxins, and a possible explanation for the increasing incidence of hypospadias that has already been noted.

Genetic Impairment

Uncertainty about the etiology of hypospadias is in part a reflection of the complicated and incompletely understood molecular and cellular basis for normal phallus and urethral development.[13] It is well established that the urethral folds fuse during the formation of the penile urethra in the 7th–12th week after ovulation.[4] Fusion of the folds eventually leads to a fully formed penis, a process that is dependent on the synthesis of testosterone by the fetal testis. Adequate virilization of the urogenital sinus and external genitalia during embryogenesis is also dependent on the conversion of testosterone to DHT by 5α-reductase.

Increasingly, researchers are examining the role of cellular signals other than testosterone and DHT in the morphogenesis of the phallus and the etiology of hypospadias. Normal embryogenesis of the urogenital system depends on epithelial–mesenchymal interactions, and it

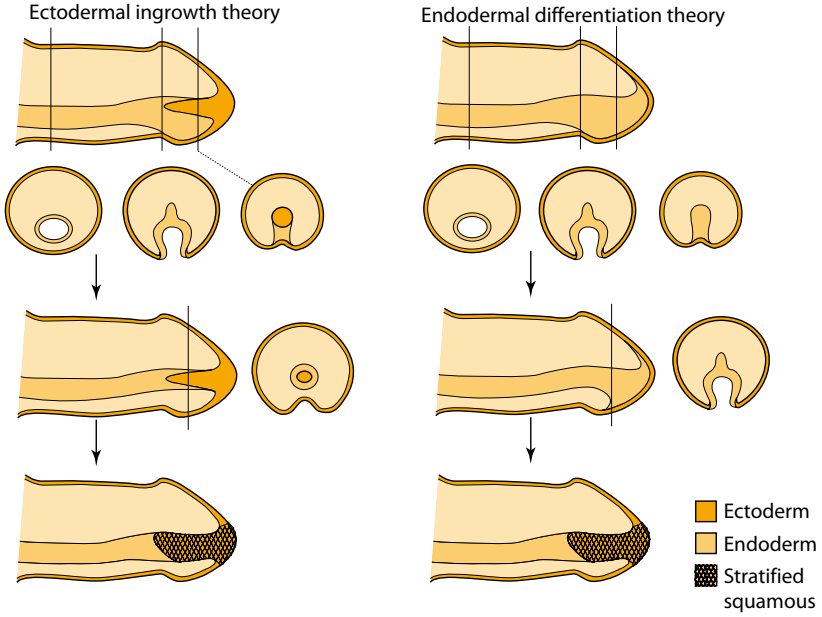

FIGURE 67.7 Theories of human penile urethral development. The ectodermal ingrowth theory, as described in most textbooks of embryology, postulates that the glandular urethra is formed by ingrowth of the epidermis. More recent data support the formation of the entire urethra via endodermal differentiation alone.

has been hypothesized that aberrant signaling between epithelium and mesenchyme could lead to hypospadias.[11] For example, prostate development requires "testosterone-dependent Sonic hedgehog (Shh) expression in the epithelium of the urogenital sinus."[14] In the mouse null for Shh, not only is penile development inhibited, but also there is a cloacal defect.[15,16] Mice null for fibroblast growth factor 10 have a proximal urethra opening and a flattened glans consistent with the hypospadias defect.[15] It is likely that researchers may find similar genetic, signaling molecules involved in epithelial–mesenchymal interactions in the phallus that play a role in its development.

Another area of investigation with respect to the etiology of hypospadias is the expression and regulation of homeobox (*Hox*) genes. These genes are transcriptional regulators that play an essential role in directing embryonic development. Genes of the *Hox A* and *Hox D* clusters are expressed in regionalized domains along the axis of the urogenital tract. Transgenic mice with loss of function of single *Hox A* or *Hox D* genes exhibit homeotic transformations and impaired morphogenesis of the urogenital tract.[17–20] Human males with hand–foot–genital (HFG) syndrome, an autosomal dominant disorder characterized by a mutation in *HOXA13*, exhibit hypospadias of variable severity, suggesting that *HOXA13* may be important in the normal patterning of the penis.[21–23] Furthermore, recent research has shown that the embryonic expression of certain *Hox* genes is regulated by hormonal factors.[24] Estrogen and the synthetic estrogen diethylstilbestrol (DES), for example, inhibit *HOXA9*, *HOXA10*, *HOXA11*, and *HOXA13* genes in mice. Thus, in addition to defects in *Hox* genes, it is possible that improper regulation or expression of hormonal factors during embryogenesis could disrupt normal expression of *Hox* genes and lead to reproductive tract anomalies.

Hormone Receptor Impairment

Studies examining the AR have yielded even less insight into the etiology of hypospadias. In fact, a number of studies have concluded that defects in the AR or mutations in the AR coding sequence are rare in patients with hypospadias.[25,26] In addition, Bentvelsen et al. measured AR expression in the foreskins of boys with hypospadias and age-matched controls and found no significant difference in mean AR content.[27]

Enzyme Impairment

Despite the central role that testosterone plays, attempts to ascribe all hypospadias to an underlying genetic defect in this pathway have only rarely been successful. Holmes et al. determined the incidence of defects in three major enzymes in the biosynthetic pathway of testosterone: 3β-hydroxysteroid dehydrogenase, 17α-hydroxylase, and 17,20-lyase (Figure 67.3). Morning fasting serum samples of pregnenolone, progesterone, 11-deoxycorticosterone, 17-hydroxypregnenolone, 17-hydroxyprogesterone, 11-deoxycortisol, cortisol, dehydroepiandrosterone (DHEA), androstenedione, androstenediol, testosterone, and DHT were obtained.[28] No significant differences in the androgen precursors and metabolites were found between the controls and the individuals with hypospadias. The response to adrenocorticotropic hormone (ACTH) was variable, without a significant difference between the patients with different degrees of hypospadias and/or published controls. These data indicate that enzymatic defects in the steroidogenic steps from cholesterol to DHT are not a frequent etiology of hypospadias.

Environmental Factors and Endocrine Disruptors

In the past, environmental factors were generally ruled out as causes for hypospadias.[29,30] More recently, multicausality models include environmental contaminants to determine the risk of developing a given phenotype. For example, familial clustering of hypospadias among first-degree relatives has been perceived as under the influence of a strong genetic and heritable component, but there have been many exceptions where genetics were ruled out. More recently, it has been suggested that environmental influences should be considered as well, taking into consideration that families share similar exposure: especially in those cases where the effects are the most profound, genetic predisposition exacerbated by environmental exposure should be considered.[31,32]

Attempts to determine risk factors for hypospadias have yielded a number of maternal and paternal risk factors. Among traditional studies of maternal risk factors for congenital anomalies, maternal age and primiparity are significantly associated with hypospadias, although some studies have contested the maternal age effect.[29] Paternal risk factors associated with hypospadias include abnormalities of the father's scrotum or testes[33] and low spermatozoa motility and abnormal sperm morphology.[31] It has been suggested that the recent increase in hypospadias reflects the improvement in fertility treatment, contributing to more subfertile men fathering children. As the authors state, this "relaxed-selection hypothesis, which states that there is a redistribution in the number of children born to fertile and infertile (subfertile) couples, may account for the increasing number of other defects and cancers of male genitalia observed today and the fall in sperm counts."[31]

In addition to parental risk factors, there is strong consensus in the literature that boys with hypospadias have lower birth weight.[34] Fredell et al. examined hypospadias in discordant monozygotic twins and found that the twin with hypospadias weighed 78% of the twin without hypospadias. The birth weight difference was still significant when compared with the birth weight difference between healthy monozygotic twins. Another study found that boys with hypospadias have a lower placental weight than control boys.[30] A 1995 meta-analysis of first-trimester exposure to progestins and oral contraceptives did not indicate an increased risk of hypospadias.[35] Exposure to DES was excluded in this study. However, a number of studies do list gestational exposure to progestins as a causal agent. Another recent study links a maternal vegetarian diet during pregnancy with an increase in the incidence of hypospadias.[36] This study looked at 51 boys with hypospadias from a group of 7928 boys born to mothers taking part in

the Avon Longitudinal Study of Pregnancy and Childhood (ALSPAC). The authors hypothesize that vegetarians have a greater exposure to phytoestrogens than omnivores. The phytoestrogens may come in the form of soy, which is high in isoflavones, or be related to endocrine disrupters in pesticides and fertilizers.[37] Whereas these risk factors do not reveal direct information about the etiology of hypospadias, they provide additional information that may reveal a common developmental pathway and can inform future research. For example, there is growing evidence that androgens play a central role in the lower birth weight of girls than boys.[38] They are also crucial to the development of the male reproductive tract; thus, perhaps exposure to an agent that compromises the weight-gaining advantage of an androgen during gestation could play a role in the development of hypospadias and lowered birth weight.

Increasing rates of hypospadias have paralleled reports of other untoward end points related to male reproductive health, including increases in testicular cancer,[39] increasing incidence of cryptorchidism, and decreasing semen and sperm quality.[40] In another study, 8% of patients diagnosed with undescended testes ($n = 252$) had urogenital anomalies and more than 50% of those had hypospadias.[41] The increasing incidence over the past 50 years of multiple end points, co-occurring with increasing production and use of synthetic chemicals, has raised concerns that environmental factors may play a role in the etiology of these problems.[32,42] It is now well documented, from wildlife studies and accompanying laboratory data, that a number of synthetic and natural chemicals commonly found in the environment can mimic or antagonize hormones or otherwise interfere with the development and function of the endocrine and reproductive systems.[43,44] Pregnant mice subjected to in utero exposure to both estrogen and prednisone have been shown to develop hypospadias.[45] Whether endocrine disruptors are having an impact on human male reproductive health and on hypospadias in particular is difficult to determine.[46] Regardless, public health agencies worldwide are increasingly concerned about endocrine disruption, and it remains an active area of research.[47–49]

GENETIC SUSCEPTIBILITY

A number of genes have been shown to infer an increased risk of hypospadias. For example, activating transcription factor (ATF3) and MAMLD1 (previously Cxorf6) are newly described candidate genes that are both associated with hypospadias.[50] ATF3 is an estrogen-responsive gene whose expression is increased in hypospadiac boys.[51,52] MAMLD1, which is expressed in the gonad during sex differentiation and interacts with steroidogenic factor 1, a transcription factor expressed in the mammalian sex-determining pathway, has also been shown to be mutated in patients with isolated hypospadias.[53] ZEB1, another estrogen-responsive gene, is overexpressed in penile skin in patients with severe hypospadias.[54] Genome-wide association studies have also shown that DGKK, which encodes diacylglycerol kinase κ, is strongly associated with hypospadias.[55] The implications of these studies is that in the future, it may be possible to predict genetic risk factors by identifying carriers of specific genetic polymorphisms.

EPIGENETIC CHANGES

Epigenetic changes may also be a possible mechanism explaining the etiology of hypospadias. Changes in DNA methylation level caused by either endogenous steroid hormones or exogenous endocrine disruptors may affect the expression of genes and, consequently, may contribute to abnormal male sexual differentiation and hypospadias. Epigenetic changes at the DNA level contribute to the control of transcription by both androgens and the AR. The first study supporting the role of DNA methylation as a possible cause of human hypospadias utilized high-throughput DNA methylation 450 K array-based assays.[56] Fourteen CpG sites were identified that were associated with hypospadias. These CpG sites were either in or near SCARB1, MYBPH, SORBS1, LAMA4, HOXD11, MYO1D, EGFL7, C10orf41, LMAN1L, and SULF1 genes. Two CpG sites in particular, SCARB1 and MYBPH, were highly associated with hypospadias.

ROLE OF ESTROGEN IN SEXUAL DIFFERENTIATION

While Alford Jost's theory of external genitalia development focusing exclusively on the presence or absence of androgen action is undoubtedly correct, it neglects the possibility of other endocrine mechanisms, such as estrogen action, and relegates female development as a default pathway.[57] Recent murine work has emphasized that normal female sex differentiation of the external genitalia is a uniquely active process and not simply a default pathway associated with the absence of androgen.[58–60] The presence of estrogen receptor α, estrogen receptor α, and aromatase in the developing external genitalia, as well as estrogen ligands in serum, when sex differentiation is occurring emphasizes the potential importance of estrogenic mechanisms during external genitalia development.[61] Finally, signaling via AR and ER can be antagonistic at cellular, tissue, and systemic levels, and thus the balance between AR and ER signaling may be critical in normal male and female development of the external genitalia.

CONCLUSION

Great strides have been made in understanding the molecular mechanism of genital formation. Understanding normal development is necessary to elucidate the etiology of abnormalities such as hypospadias. Recent work suggests that environmental exposure to endocrine disruptors may account for the increase in incidence of hypospadias cases. Prevention by reducing exposure may be the best strategy to reverse the increasing incidence of hypospadias.

CHAPTER
68

Basic Science of the Testis*

Julia Spencer Barthold

INTRODUCTION

The testis is a highly complex organ with multiple interacting cell types that undergo rapid changes in the fetal, perinatal, and peripubertal male. The two main testicular compartments, the interstitium and the seminiferous tubules, respectively, reflect the two major functions of the testis: endocrine (hormone production) and exocrine (spermatogenesis). Several cell types exist in the interstitial space, including the hormone-producing Leydig cells, peritubular myoid (PTM) cells, peritubular nonmyoid cells, perivascular smooth muscle cells, and vascular endothelial cells. The tubules contain Sertoli cells and germ cells at various stages of development. After establishment of spermatogenesis, a blood–testis barrier (BTB) exists that separates the tubules into a basal compartment containing spermatogonia, leptotene, and preleptotene spermatocytes, and an adluminal compartment, containing meiotic spermatocytes, spermatids, and spermatozoa.

A coordinated program of fetal developmental signaling establishes an immature organ with full potential for fertility in adulthood; alterations in this program produce a spectrum of disease, ranging from subtle long-term deficiencies in testicular function to complete dysgenesis. Testicular hormones play key roles in the maturing testis and in the development and maintenance of reproductive tract structures and nonreproductive organs, such as brain and bone. Nontesticular hormones, growth factors, and microRNAs also impact testis development and function. This review summarizes our present knowledge of the key events in testis development and normal and abnormal testis function during the major periods of activity: fetal, neonatal, and pubertal.

Key areas that are reviewed in this chapter include

- Basic events in testis determination
- Patterning of testicular cords and establishment of cell types within the testis
- Establishment of the spermatogonial stem cell (SCC) niche and inhibition of meiosis
- Nuclear receptors and their ligands in the developing testis
- Fetal, neonatal, and pubertal activation of testicular hormone production and correlation with testis function
- Biology of the BTB and pathogenesis of germ cell injury

TESTIS DETERMINATION

Significant advances have been made in recent years that further elucidate mechanisms of testicular determination and will improve the diagnosis and treatment of children with disorders of sex development.[1–7] New insights from developmental studies in mice make clear that development of the indifferent gonad into a testis or ovary requires a balancing act of signaling pathways (Figure 68.1) that is triggered toward the male pathway by expression of *Sry* (sex-determining region on the Y chromosome).[6] Steroidogenic factor 1 (*Sf1*; now called *Nr5a1* based on updated nuclear receptor terminology) is expressed early in somatic (supporting and steroidogenic) cells and contributes to activation of *Sry*.[5] Other genes upstream of *Sry* discovered to date include *Wt1* (Wilms' tumor 1), *Lhx9*, *Cbx2*, *Gata4* and its cofactor *Fog2/Zfpm1*, *Pod1/Tcf21*, *Map3k4*, and several insulin receptors.[2,5] *Sry* expression is transient but in cooperation with *Sf1/Nr5a1* induces rapid and prolonged expression of another transcription factor, *Sox9* (SRY box-containing 9), in pre-Sertoli supporting cells.[2] The location and timing of *Sry* expression are critical for Sertoli cell specification and proliferation in mice; if inadequate or delayed, testis development fails or ovotestis formation occurs (Figure 68.2). As testis formation is triggered first in the midportion of the gonad, delay or deficiency that leads to ovotestis formation produces central testicular and polar ovarian differentiation.[3]

SOX9 upregulates its own expression and interacts with multiple other testis-determining molecules (Figure 68.1) that sustain and reinforce the male pathway and promote Sertoli cell proliferation via positive regulatory loops, including *Fgf9* (fibroblast growth factor 9), *Amh* (anti-Müllerian hormone), and *Ptgds* (prostaglandin synthase).[2] While important in male development, *Fgf9* and its receptor *Fgfr2* were also recently shown to play a key role in actively repressing the female-determining gene *Wnt4*, which, when expressed at endogenous levels in XX gonads, is sufficient to repress male development, supporting a mutual antagonism program during gonadal determination (Figure 68.1 inset).[8] Cell-specific gene expression studies in developing gonads confirm that the female program is dominant in pre-Sertoli progenitor cells and the male program, i.e., meiotic arrest, is the default in germ

* Standard vertebrate gene and protein symbol conventions are used throughout: italicized all uppercase (*HUMAN/PRIMATE*) and first letter only uppercase (*Mouse/Rat*) for *genes* and nonitalicized all uppercase for *proteins*.

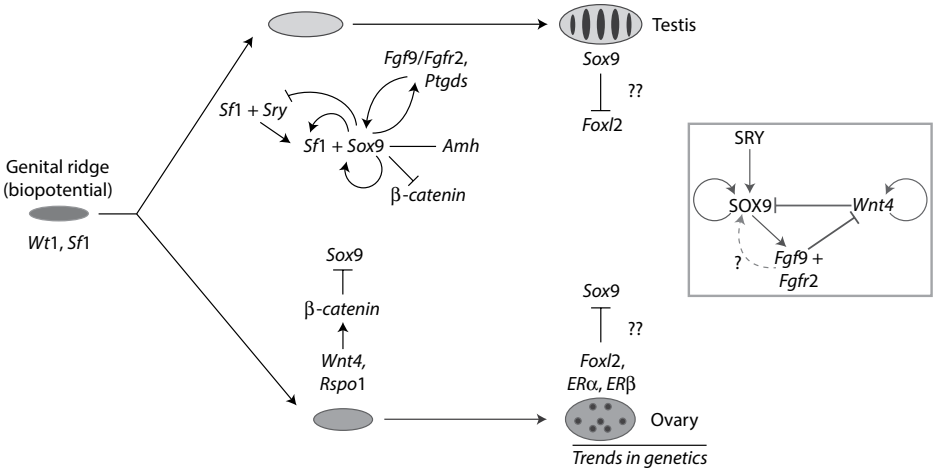

FIGURE 68.1 Molecular and genetic events in mammalian sex determination. The bipotential genital ridge is established by genes including *Sf1* and *Wt1*. In XY supporting cell precursors, increasing levels of SF1 activate *Sry* expression, and then SRY, together with SF1, boosts *Sox9* expression. Once SOX9 levels reach a critical threshold, several positive regulatory loops are initiated, including autoregulation of its own expression and formation of feed-forward loops via FGF9 or PGD2 (prostaglandin D2) signaling. If SRY activity is weak, low, or late, it fails to boost *Sox9* expression before β-catenin levels accumulate sufficiently to shut it down. SOX9 promotes the testis pathway, including *Amh* activation, and it also probably represses ovarian genes, including β-catenin and Foxl2. Inset: SOX9 upregulates *Fgf9* to repress *Wnt4*. In *Fgf9* or *Fgfr2* mutants, failure to repress *Wnt4* results in repression of SOX9 by *Wnt4* signaling and loss of male development. (From Sekido R, Lovell-Badge R. *Trends Genet* 2009;25(1):19–29. Inset: Jameson SA et al. *Dev Biol* 2012;370(1):24–32.)

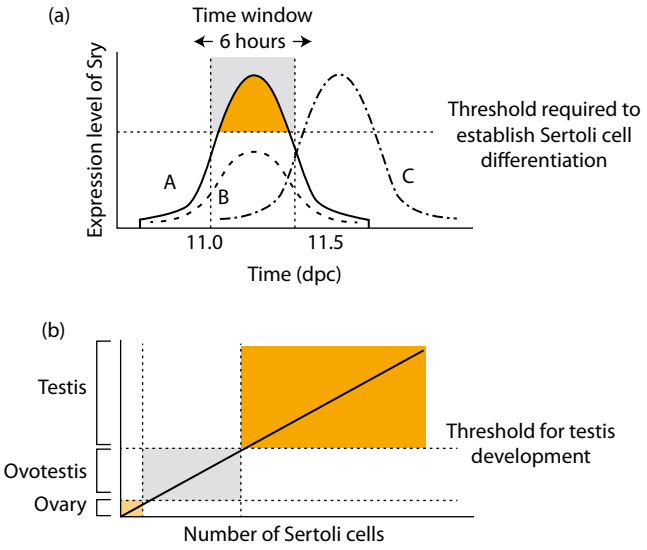

FIGURE 68.2 Two thresholds important for mouse sex determination. (a) *Sry* expression levels must exceed a certain threshold (blue) within a narrow time window (gray) in individual somatic gonadal cells of developing mouse gonads in order to induce Sertoli cell differentiation (curve A). If the level of *Sry* expression does not reach the threshold, as in WT1(+KTS)-null mice (curve B), or is delayed and misses the critical window, as in YDOM sex reversal (curve C), somatic gonadal cells fail to differentiate into Sertoli cells. (b) The number of supporting cell precursor cells that differentiate as pre-Sertoli cells must also reach a certain threshold level in order to induce testis formation (blue). In XXXY mouse chimera experiments in which the proportions of XY and XX cells making up an embryo vary, the gonad fails to form a testis if the number of Sertoli cells is below a threshold, resulting in the development of an ovotestis (gray) or an ovary (red). (From Kashimada K, Koopman P. *Development* 2010;137(23):3921–30.)

cells, with sex-specific repression of the alternative program required for cell fate commitment.[9]

In the human fetus, the indifferent gonadal ridge is established anterior to the mesonephros by postovulatory day 32, and expression of gonadal determination genes, such as *WT1* and *SF1* (*NR5A1*), is present.[10,11] *DAX1*, a dosage-sensitive nuclear receptor associated with male-to-female sex reversal and testicular dysgenesis with over- and underexpression, respectively, is also present in both sexes.[10] Expression of *SRY* transcripts commences after day 41 and peaks at day 44; however, unlike in the mouse fetus, *SRY* expression persists at low levels into at least the second trimester. *SOX9* expression peaks after day 44 and declines by day 52, at which time testis cords have formed.

TESTICULAR PATTERNING AND CELL-SPECIFIC DEVELOPMENT

Detailed information regarding how testicular organization occurs is emerging based on recent experiments in the fetal mouse. Patterning of the testis requires a temporal series of events (Figure 68.3):[3,4,6,7,12] (1) germ cell migration from the extraembryonic mesoderm to the genital ridge prior to gonad differentiation, (2) specification of Sertoli cell precursors arising from the coelomic surface epithelium of the genital ridge, (3) proliferation and migration of additional Sertoli and interstitial cell precursors from the coelomic epithelium, (4) migration of vascular endothelial and interstitial cells from the mesonephros near its border with the gonad, and (5) establishment of testicular cords and, in rodents, a prominent testicular vessel.[13] After specification of Sertoli cells, vascular endothelial cells migrate into the genital ridge

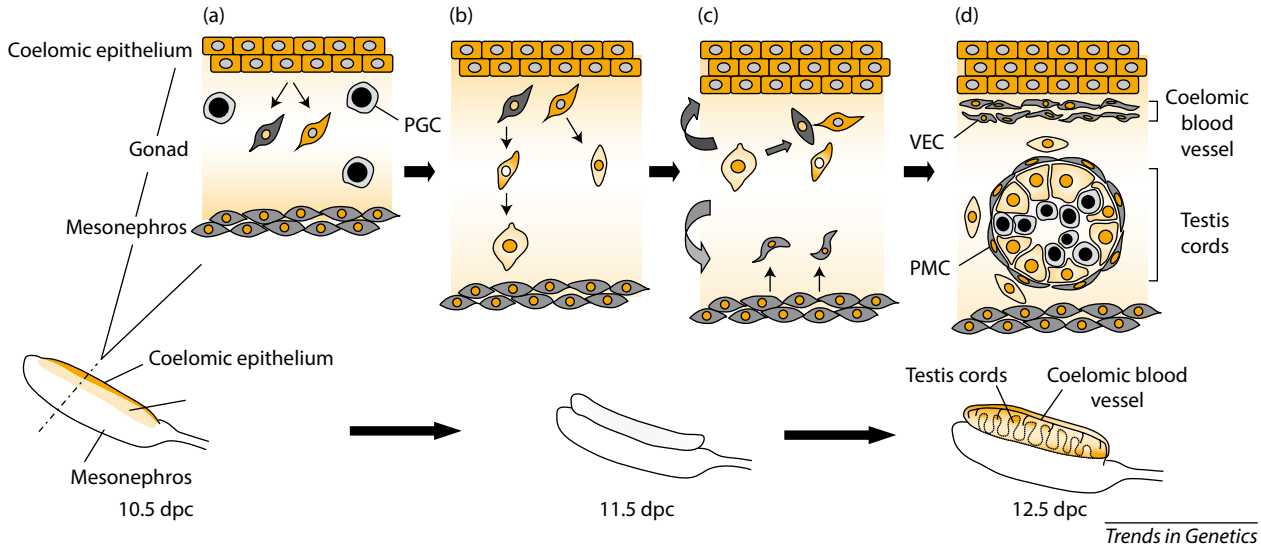

FIGURE 68.3 Cellular organization during testis development. (a) The testis arises from the genital ridge, a thickening under the coelomic epithelium (CE) adjacent to the mesonephros. PGCs (black) have migrated from the extraembryonic ectoderm by 10.5 days postcoitum (dpc); Sertoli (red) and Leydig (blue) cell precursors migrate from the CE. (b) With expression of SRY, *Sox9* is upregulated in Sertoli cells (yellow); *Sry* is then downregulated in SOX9-positive cells (green), and other CE cells give risk to interstitial (including Leydig) cells (pink). (c) Sertoli cells induce proliferation of CE cells (yellow arrows) and migration of mesonephric cells (purple arrow), which are primarily vascular endothelial cells (VEC) but also include Leydig and possibly PTM cells (PMC). (d) VECs help to partition the developing cords and form a characteristic ventral coelomic blood vessel. (From Sekido R, Lovell-Badge R. *Trends Genet* 2009;25(1):19–29.)

from the mesonephros and stimulate interstitial cell proliferation in response primarily to vascular endothelial growth factor A (VEGFA) (highly expressed in interstitial cells) and platelet-derived growth factor (PDGF) signaling, a process that drives testicular cord formation.[14] The mesenchyme expands along the developing vasculature to form partitions around existing Sertoli–germ cell clusters, although cords can still form in the absence of germ cells.[12] Sertoli cell signals that additionally appear to contribute to migration of mesonephric cells into the gonad include FGF9, AMH, transforming growth factor β (TGFβ), inhibin β B (INHBA) (also known as activin A), and neurotrophin 3.[5,12,15,16] In addition, secretion of extracellular matrix components by Sertoli and PTM cells contributes to organization of tubular architecture and requires direct physical interaction between the two cell types.[17]

In the developing human, testicular cords are established and the internal genitalia become nearly fully masculinized in the first trimester, and Leydig cell proliferation levels off after 15 weeks' gestation.[18] In contrast, Sertoli and germ cell proliferation continues, associated with increasing expression of conserved cell-specific transcripts, including *SOX9*, *FGF9*, *WT1*, *c-Kit*, and *KITL* (kit ligand), well into the second trimester.[18]

Sertoli Cells

Sufficient expansion in response to autoregulatory SOX9 signaling is required for adequate Sertoli cell function, which includes most notably AMH secretion and Müllerian duct regression in the first trimester in human fetuses. However, proliferation continues in a second wave that extends postnatally, which in humans ceases after the first year of life but resumes just prior to puberty.[19] Postnatal Sertoli cell proliferation correlates directly with spermatogenic capacity in adulthood and is enhanced by follicle-stimulating hormone (FSH),[19] autocrine expression of the chromatin remodeling protein ATRX (α-thalassemia/mental retardation X linked),[20] paracrine Inhba signaling by Leydig cells,[6] and androgen receptor (AR) signaling, probably via PTM cells.[21] Conversely, Sertoli cell proliferation is repressed by thyroid hormone (TH)[22] and nitric oxide (NO).[23] Immature Sertoli cells express AMH, aromatase, NCAM (neural cell adhesion molecule), and cytokeratin 18 and switch to WT1, GATA1 (GATA-binding factor 1), p27KIP1 (a cyclin-dependent kinase inhibitor [CDKI]), and AR expression during pubertal maturation.[19]

Multiple endocrine, paracrine, and autocrine pathways regulate Sertoli cell maturation (Figure 68.4) (reviewed in Tarulli et al.[24]). TH terminates proliferation and enhances maturation via regulation of CDKIs, including p27KIP1, which accounts for the excess testicular growth seen in neonatal hypothyroidism.[22] Additional factors required for Sertoli cell survival and maturation and consequent organization of testis cords include *Dicer*, encoding an enzyme that processes microRNAs, which regulate gene expression,[25] and *Dmrt1* (*doublesex*- and *mab-3*-related transcription factor), encoding a DNA-binding protein that is a conserved regulator of postnatal testis differentiation.[26]

Activin A (encoded by the *Inhba* gene), a developmental protein of the TGFβ superfamily produced by Leydig cells, is a key paracrine regulator of Sertoli cell proliferation via interactions with downstream SMAD proteins.[27] Activin A dosage defines the balance between Sertoli and germ cell proliferation and the ultimate Sertoli–germ cell ratio,[28] while SMAD3 dosage fine-tunes the balance of

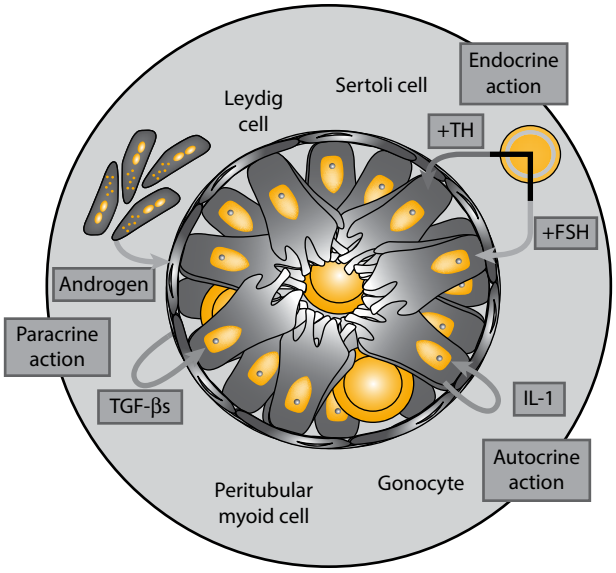

FIGURE 68.4 Major factors regulating Sertoli cell maturation in the pre- and postpubertal testis. Pubertal Sertoli cell proliferation is regulated by numerous endocrine (FSH and TH), paracrine (TGFβ and androgen), and autocrine (IL-1) factors that exert positive (green arrows) and negative (red arrows) effects. The balance of these factors, with their combined effect on specific cell cycle regulators, determines the size of the adult Sertoli cell population. The establishment of a high Sertoli cell number is central to maximal fertility in adulthood. (From Tarulli GA et al. *Biol Reprod* 2012;87(1):13, 1–11.)

proliferation versus maturation of Sertoli cells via regulation of AR expression.[29]

Interstitial Cells

The interstitial compartment of the fetal testis contains a number of cell types, including Leydig and PTM cell precursors, vascular endothelial cells, and unidentified mesenchymal cells. Many of these cells originate as coelomic epithelial cells that undergo epithelial-to-mesenchymal transition and proliferate.[12,30] Mesonephric cell migration also contributes to the interstitial compartment, with the primary, if not exclusive, migrating cell type initially thought to be endothelial.[13] However, recent experiments in which physical separation of the genital ridge and mesonephros was avoided showed that Leydig and potentially other interstitial cell precursors clearly do migrate from the adjacent mesonephros into the gonad along existing perivascular pathways.[31]

Leydig Cells

The identification of two distinct sources of progenitor Leydig cells is of potential importance considering that heterogeneous populations occur postnatally. In humans, *fetal Leydig cells* become active at 6–7 weeks' gestation; proliferate, differentiate, and mature between 8 and 18 weeks; and involute after 24 weeks.[32,33] Sertoli cell–secreted paracrine factors that contribute to Leydig cell differentiation include desert hedgehog (DHH) and PDGFs.[34,35] Interstitial autocrine factors that support Leydig cell differentiation and survival include the transcription factors GATA4 and ARX (aristaless-related homeobox), insulin-like growth factors (IGFs), the nuclear receptor COUP-TFII (NR2F2), TGFBR3 (TGFB receptor 3 or β-glycan), and hepatocyte growth factor (HGF).[36–39] In contrast, Notch signaling promotes interstitial progenitor cell maintenance and inhibits Leydig cell differentiation.[40]

After birth, a *neonatal Leydig cell* population emerges that likely includes differentiating interstitial precursors.[39,41] After transient activation of the hypothalamic–pituitary–gonadal (HPG) axis (see below), these cells either degenerate or regress to form small, *immature Leydig cells* that may persist during childhood and, along with stem cell precursors, contribute to a distinct *adult Leydig cell* population.[41] The progenitor Leydig cells that contribute to later waves of development at puberty may originate from peritubular and/or perivascular mesenchymal precursors, but their ontogeny is not defined.[31,42,43]

Peritubular Myoid Cells

The PTM cell forms a subset of the interstitial population that is unique to the male gonad. PTM cells participate in formation of the testicular cords; form a distinctive, elongated cell layer surrounding the tubules; and in adulthood, participate in contractile function of the seminiferous tubules.[44] They are one of two peritubular cell subtypes, myoid and nonmyoid,[45] the latter being potential Leydig cell precursors. No early specific marker that defines the origin of the myoid population exists, since most proteins expressed in PTM cells are also expressed in other interstitial cells.[46] However, smooth muscle α-actin, initially present in both gonadal interstitial and mesonephric cells, becomes specifically localized in PTM cells by late gestation.[30] In addition to the role of PDGF signaling in interstitial cell proliferation during testis determination, PTM cells continue to express PDGF receptors,[47] which may in part mediate postnatal testicular growth.[48]

Two Sertoli cell signals, DHH and DAX1 (dosage-sensitive sex reversal, adrenal hypoplasia critical region on chromosome X, 1), participate in PTM cell differentiation and organization in mice and are required for correct cord formation.[49,50] Similarly, the ARX protein required for Leydig cell differentiation is expressed in interstitial (including PTM) but not Leydig cells,[36] reinforcing the importance of cell–cell signaling in testis development. Other types of paracrine signaling between PTM and Sertoli and/or Leydig cells is also likely but not well characterized, particularly in fetal life, but androgen signaling may be a major component since AR expression is consistently present in these cells beginning in the fetus (see below).

Germ Cells

Primordial germ cells (PGCs) are specified by the extraembryonic ectoderm via bone morphogenetic protein (BMP) signaling to pluripotent epiblast cells in mammalian fetuses.[51] They then migrate from the primitive streak to the future hindgut in response to signaling via the c-Kit receptor tyrosine kinase and its ligand, stem cell factor

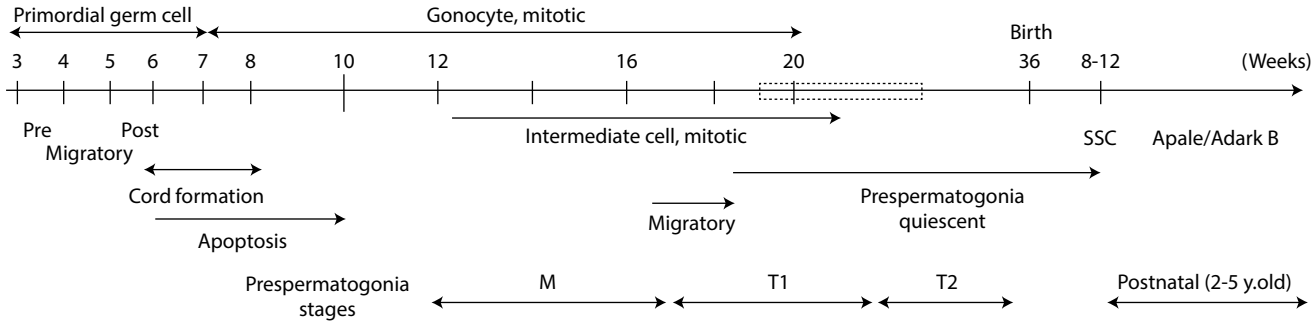

FIGURE 68.5 Schematic representation of the timeline of human gonocyte development. Apale/Adark/B, stages of spermatogonial development; M, mitotic; T1, transitional 1; T2, transitional 2. The box indicates the period between gestation weeks 19 and 25, at which time a progressive shift occurs between OCT4 and MAGE-A4 expression in the germ cell. (From Culty M. *Birth Defects Res C Embryo Today* 2009;87(1):1–26.)

(SCF) (or kit ligand [KITL]),[51] and in human fetuses arrive by the sixth week and become localized within the testicular cords by the eighth week of gestation (Figure 68.5).[52] Prior to the end of the first trimester of gestation, subpopulations of both proliferating and degenerating germ cells exist. By the second trimester, three subpopulations of germ cells—gonocytes, intermediate spermatogonia, and prespermatogonia (also called prospermatogonia)—are distinguishable by loss of POU5F1 (POU domain class 5 homeobox 1, also known as OCT4) and c-Kit and gain of MAGE-A4 (melanoma antigen, family A, 4) immunopositivity with developmental stage.[53] By the 20th week (Figure 68.5), gonocytes are no longer present and prespermatogonia evolve as M (mitotically active), T1 (quiescent), and T2 (resuming mitosis) cells.[52,53] Both differentiation and apoptosis (programmed cell death) occur in phases during development of human germ cells, as well as of Sertoli and Leydig cells, and have important roles in establishing a normal cellular population in the testis.[54]

The postnatal period is a critical developmental window for germ cells as prespermatogonia (still called gonocytes in neonatal rodents) proliferate and migrate to the tubular basement membrane or undergo apoptosis.[55] Failed migration leads to excess apoptosis and possibly to persistence of abnormal undifferentiated cells that may predispose to future malignant transformation.[52] After migration, prespermatogonia become undifferentiated type A spermatogonia; in humans and primates, this includes types Ad and Ap spermatogonia,[56] and a subset of these become the population of SSCs.[57] Type Ad are presumed to be resting and Ap to be active SSCs because the conserved stem cell markers GFRA1 (glial cell–derived neurotrophic factor [GDNF] receptor α1) and PLZF (promyelocytic leukemia zinc finger protein, now known as ZBTB16, zinc finger, and BTB domain–containing protein 16) are expressed in most Ad and about half of Ap spermatogonia, while progenitor-specific NGN3 (neurogenin 3) expression is acquired in a subset of Ap spermatogonia.[56] Progenitor type A spermatogonia differentiate into c-Kit-positive type B spermatogonia, which appear by 5 years of age.[56,58]

Sertoli cells provide critical physical support and orchestrate creation of a microenvironment for SSCs at the tubular basement membrane.[59,60] Proper establishment of this SSC niche is critical for future germ cell differentiation and for the SSC self-renewal that occurs through life. Sertoli cells are stimulated by FSH, growth factors, and cytokines and in turn produce factors such as GDNF, KITL, ETV5, and SIN3A that promote stem cell renewal within this niche.[59,61] GDNF signaling is dose dependent in that high levels promote SSC self-renewal, while low levels promote SSC differentiation.[52] Sertoli cell proliferation also occurs in this time-frame and is a key element in determining the adequacy of the SSC niche.[62] Sertoli cells can also indirectly influence SSC self-renewal by inducing Leydig and PTM cells to secrete factors such as CSF1 (colony-stimulating factor).[63] In fact, SSCs may preferentially locate adjacent to interstitial areas rich in vasculature and Leydig cells.[64]

Factors that directly or indirectly regulate migration of prespermatogonia to the basement membrane and/or proliferation are incompletely characterized but are known to include PDGF, c-Kit, estrogens, TH, and proteins involved in cellular adhesion.[52,55,60,65–67] Although expressed in Sertoli cells and required for their maturation and support of the germ cell population, recent work suggests that conditional deletion of *Dmrt1* in germ cells specifically prevents their radial migration to the basement membrane.[26] In human males, neonatal migration and proliferation of prespermatogonia coincides with activation of the HPG axis, which occurs in the first few months of life (see below). While FSH-regulated secretion of growth factors by Sertoli cells is important in establishing the SSC niche, a role for luteinizing hormone (LH) or testosterone in gonocyte migration or proliferation has not been identified and, at least in the fetal mouse, androgen action correlates with inhibition of gonocyte proliferation.[52] In addition, tubules contain adluminal spermatogonia and degenerating cells throughout childhood, suggesting that population renewal continues to occur without significant hormonal stimulation.[58]

Meiosis begins in female germ cells prenatally, but in males is largely suppressed until puberty, although prepubertal testes contain occasional spermatocytes. Retinoic acid (RA) induction of *Stra8* (stimulated by RA gene 8) appears to be the primary trigger for meiotic entry.[68,69] In males, the RA-metabolizing enzyme CYP26B1 was considered primarily responsible for the inhibition of meiosis. However, recent evidence in mice suggests that other male-specific factors act to prevent meiosis in male germ

cells,[70] and interestingly, these appear to include DMRT1 and TGFβ proteins,[71–74] which also have key roles in other aspects of testis development. Similar to upstream factors like SOX9, which both reinforce the male pathway and inhibit female development, these proteins activate markers of spermatogonial differentiation (*Sohlh1/2*, *Nanos2*, and *Dnmt3l*) while blocking female-specific (*Foxl2*) gene expression in somatic cells. Interesting, recent data indicate that human carcinoma in situ (CIS) cells can simultaneously express meiosis-inducing and meiosis-inhibiting regulatory proteins, supporting the hypothesis that they are dysregulated persistent gonocytes.[75]

Major advances in basic research in recent years have improved understanding of testicular developmental mechanisms. It is increasingly evident that key participants, including DMRT1, PDGF, and TGF (including TGFβ, BMPs, AMH, activin, and GDNF) proteins, activate signaling pathways in multiple cell types and are pivotal in cell-specific testis development. For many of these pathways, there is strong evidence for mammalian conservation. Although some differences exist, many meiotic and spermatogonial markers identified in mice are also expressed in the human fetal testis.[76] Overlap in SSC-specific mRNAs found in man and mouse also suggests mammalian conservation in regulation of the germ cell niche, particularly with regard to expression of GDNF pathway genes involved in SSC self-renewal.[77] This increased knowledge of the biology of germ cell development has the potential to impact fertility potential and outcomes. For example, potential SCC isolation, identification, and expansion in long-term culture or cryopreservation may create future possibilities for stem cell transplantation[78–80] and allow fertility preservation in males undergoing gonadotoxic therapy for cancer.[81] In addition, recent evidence suggests a direct relationship between epigenetic modifications in sperm and expression of developmental genes in offspring, which may improve our understanding of the etiology of birth defects.[82]

NUCLEAR RECEPTORS IN THE TESTIS

Nuclear receptors, particularly the steroid androgen and estrogen receptors, are expressed in testicular cells and are particularly important in Leydig cell differentiation and function,[83] but also play key roles in other testicular cell types (Table 68.1). However, their physiologic role in testis and relevance to human disease is not always clear, since expression and function may differ with species and developmental stage. Receptors of particular clinical relevance during development include an AR (NR3C4), estrogen receptors ERα (NR3A1) and ERβ (NR3A2), SF1 (NR5A1), and DAX1 (NR0B1). SF1 and DAX1 are key regulators of somatic and tubular development; mutations of either *NR5A1* or *NR0B1* are associated with hormonal insufficiencies of adrenal and testis and testicular dysgenesis.[50,84] Androgen and estrogen receptors are of interest as potential targets of exogenous agents that are considered endocrine disruptors.[85,86] Androgens and estrogens also signal through nonclassical receptors located in the cytoplasm or at the plasma membrane, but a role for such signaling in testis development or function remains undefined.

Despite interspecies differences, PTM and other interstitial cells, including some Leydig cells, most consistently express AR in the fetus and prepubertal male,[87,88] and human fetal PTM cells expand in culture medium containing dihydrotestosterone (DHT).[89] Lack of AR expression in the immature Sertoli cell explains why initiation of spermatogenesis does not occur with increased androgen production in the fetal and postnatal periods.[90,91] Developmental acquisition of AR expression in Sertoli and Leydig cells allows androgen-regulated processes to proceed normally at puberty, including establishment of the adult Leydig cell population, repression of AMH expression, meiotic entry, establishment of the BTB, and support of spermatogenesis.[83,92]

Estrogens signal through two classic nuclear receptors, ERα and ERβ. In addition, the androgen 5α-androstane-3β,17β-diol (3β-diol), a metabolite of DHT, is a known alternative ERβ ligand.[93] Studies of ERKO (ERα knockout) mice suggest that estrogenic suppression of steroidogenesis and INSL3 is mediated by ERα,[83] but human studies suggest little, if any, expression of ERα in fetal,[53,88] postnatal,[87] or adult[94] testes, although ERα expression is reported in postnatal germ cells.[95] In contrast, ERβ is expressed in Leydig, PTM, Sertoli, and germ cells at all time points[53,87,88,94] and may mediate what appears to be the main effect of estrogen signaling in testis: stimulatory effects of estradiol and 3β-diol on germ cell proliferation and maturation.[66,93,94] Local conversion of testosterone to estradiol by aromatase is possible in the testis because Leydig, Sertoli, and some germ cells express this enzyme.[94]

Differences between species with regard to AR and ER localization and their potential role in mediating the effects of endocrine-disrupting (antiandrogenic and estrogenic) compounds provide uncertainty about the relevance of these agents to human health.[85] Therefore, newer efforts are directed at determining the specific response of human testis, either in culture or via xenografting into nude mouse recipients, potentially a more physiologic approach.[85] Available data suggest species differences not only between man and rodent but also between mouse and rat. For example, while similarly susceptible to germ cell toxicity, xenotransplanted human fetal and mouse testes are resistant to the phthalate-induced inhibition of steroidogenesis seen in rats.[96–98] In contrast, cultured human testes are more sensitive than rodent testes to the inhibitory effects of bisphenol A (BPA) on testosterone production and *INSL3* expression.[99]

HORMONAL ACTIVITY AND TESTICULAR FUNCTION

Three phases of testicular hormone activation occur in normal humans (Figure 68.6): the first trimester of gestation, the neonatal period, and puberty. These are necessary for masculinization of the male reproductive tract and brain and for activation and support of the developmental program of the testis. Circulating hormones of major importance during this period include human chorionic gonadotropin (hCG) produced by the placenta,

TABLE 68.1 Cell-specific functions of selected nuclear receptor (NR) proteins in testis

NR nomenclature	Mouse gene name	Common name/symbol	Target cell	Function based on available data
NR1A1, NR1A2	*Thra*, *Thrb*	Thyroid hormone receptor/TRα, TRβ	LC	Stimulates postnatal differentiation and steroidogenesis
			SC	Represses proliferation and enhances maturation[146]
			GC	Indirectly promotes gonocyte migration[55]
NR1B1, NR1B2, NR1B3	*Rara*, *Rarb*, *Rarc*	Retinoic acid receptor/RARα, RARβ, RARγ	LC	Stimulates fetal steroidogenesis
			GC	Meiosis initiation[68,69]
NR1C1, NR1C2, NR1C3	*Ppara*, *Ppard*, *Pparg*	Peroxisome proliferator-activated receptor/PPARα, PPARβ/δ, PPARγ	LC	Represses steroidogenesis
			SC, GC	Lipid metabolism
NR2F2	*Nr2f2*	Chicken ovalbumin upstream promoter-transcription factor II/ COUP-TFII	LC	Stimulates formation of progenitor cells and Leydig cell maturation
NR3A1	*Esr1*	Estrogen receptor α/ERα	LC	Represses fetal differentiation, steroidogenesis, and *Insl3* expression in mice; not expressed in humans
			SC	Stimulates peripubertal proliferation[147]
NR3A2	*Esr2*	Estrogen receptor β/ERβ	LC	Represses proliferation, stimulates steroidogenesis in adult LCs
			SC	Stimulates peripubertal proliferation[147]
			GC	Represses gonocyte proliferation[86]
NR3C1	*Nr3c1*	Glucocorticoid receptor/GR	LC	Represses steroidogenesis; apoptosis of adult LCs
NR3C4	*Ar*	Androgen receptor/AR	LC	Development/maturation of adult LCs
			SC	Proliferation, formation of the BTB, meiosis progression, support of spermatogenesis[148,149]
			PTM	Differentiation,[150] proliferation,[89] indirect effect on development/maturation of adult LCs[151]
NR4A1	*Nr4a1*	Nerve growth factor induced-B/ NGFI-B, NUR-77	LC	Stimulates steroidogenesis and *Insl3* expression in cell lines, repressed by NR3C1
NR5A1	*Nr5a1*	Steroidogenic factor 1/SF1	LC	Stimulates fetal differentiation, steroidogenesis, and *Insl3* expression
			SC	Stimulates maturation[152]
NR5A2	*Nr5a2*	Liver receptor homolog 1/LRH1, FTF	LC	Stimulates steroidogenesis
			SC, GC	Expression dependent on differentiation state and heat exposure[153]
NR0B1	*Nr0b1*	Dosage-sensitive sex reversal, adrenal hypoplasia critical region on chromosome X, 1/DAX1	LC	Stimulates migration during testis determination;[50] represses adult LC steroidogenesis via altered *Nr4a1*, *Nr5a1*, and aromatase expression
			SC	Stimulates survival and differentiation[154]
			PTM	Indirectly stimulates differentiation[50]

Source: Data for Leydig cells from Martin LJ, Tremblay JJ. *Biol Reprod* 2010;83(1):3–14. Additional data as referenced.
Abbreviations: LC, Leydig cells; SC, Sertoli cells; GC, germ cells; PTM, peritubular myoid cells.

LH and FSH by the pituitary, AMH and inhibin B by Sertoli cells, and androgens (including testosterone) and INSL3 by Leydig cells.

Fetus

During fetal life, testicular hormones promote masculinization via testosterone and DHT, Müllerian duct regression via AMH, and testicular descent via INSL3 and testosterone. Soon after their differentiation, Sertoli cells begin AMH secretion, which persists at high levels well into the third trimester[21] and remains detectable in cord blood.[100] Inhibin B levels are also elevated in male fetuses in the last half of gestation and much higher than those observed in females.[101] Testosterone is initially produced at about 8 weeks' gestation in the human fetus, and levels in amniotic fluid and testis peak at 12–14 weeks.[85] INSL3 levels in amniotic fluid also appear to peak in this time frame,[102] and *INSL3* mRNA is measurable at 12 weeks' gestation,[18] but protein levels have not been measured in first-trimester fetuses.

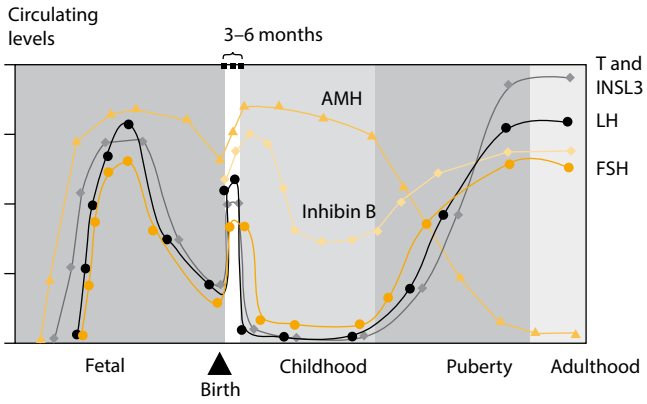

FIGURE 68.6 HPG axis activation in males. Schematic ontogeny of circulating levels of LH, FSH, testosterone (T), insulin-like 3 (INSL3), anti-Müllerian (AMH), and inhibin B in males from conception until adulthood. (From Grinspon RP et al. *J Pediatr Endocrinol Metab* 2012;25(1–2):3–11.)

Initial testosterone production may be independent of pituitary hormones in human fetuses, as it is in rodents.[85] Nonetheless, the subsequent peak in production is most likely regulated primarily by hCG or LH, since by 10 weeks' gestation hCG levels are peaking and LHCGR (LH/hCG receptor) and fetal LH are measurable in testis and amniotic fluid, respectively (Figure 68.6).[85] Moreover, complete feminization and Leydig cell agenesis occur in males with inactivating mutations of *LHCGR*.[103] Peak production and subsequent waning of fetal hormone production by Leydig cells coincide with their maximal proliferation[18] and subsequent involution, respectively, by the end of the second trimester. Unlike testosterone production, which is acutely responsive to gonadotropin stimulation, *INSL3* expression appears to be largely constitutive, as levels in older males do not respond to gonadotropin stimulation.[102]

Interestingly, recent studies have shown an alternative "backdoor" androgen biosynthesis pathway that exists in the developing testis of tammar wallaby and mouse that leads to the local production of DHT[104] (Figure 68.7). In this pathway, enzymes in the aldo-keto reductase (AKR1C) family synthesize 5α-androstane-3α,17β-diol (androstanediol or 3α-androstanediol) from progesterone and convert it to DHT, bypassing testosterone formation. This pathway is also active in human fetal testis, since individuals with mutations in two enzymes in this pathway, *AKR1C2* and *AKR1C4*, are feminized.

Neonate

A second key period of pituitary and testicular hormone activation occurs in the first 3 months of life, often referred to as "mini-puberty" in males (Figure 68.6). During this

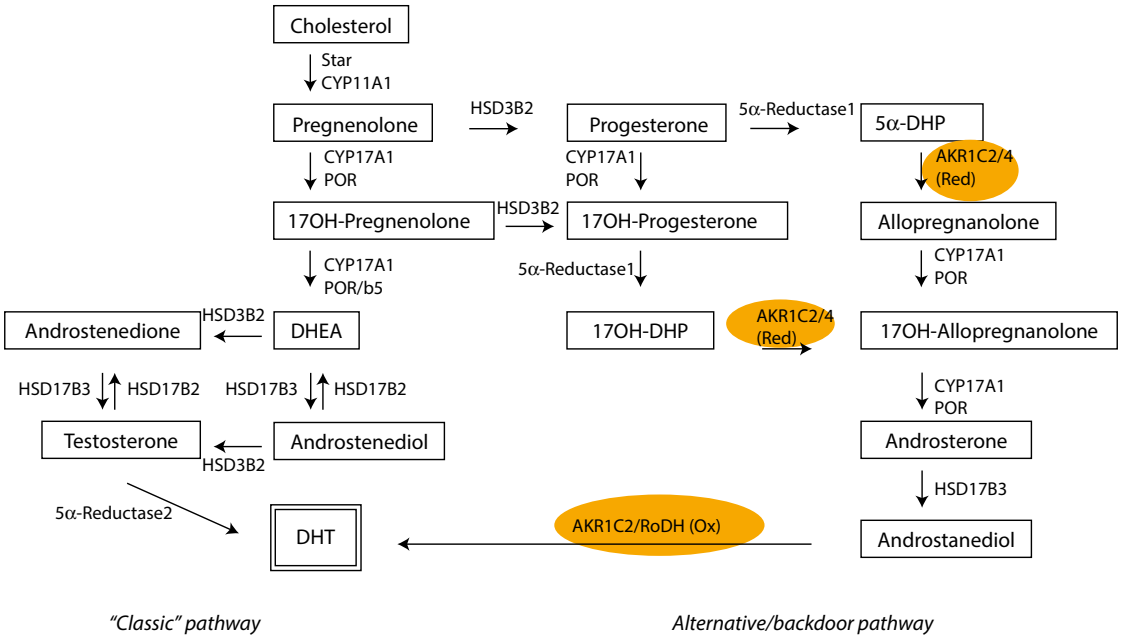

FIGURE 68.7 Synthesis of DHT via the classic and alternative (backdoor) pathways. The *classic pathway* of steroidogenesis (left) includes CYP11A1 (cholesterol side-chain cleavage enzyme, P450scc), StAR (steroidogenic acute regulatory protein), CYP17A1 (17α-hydroxylase/17,20-lyase, P450c17), POR (cytochrome P450 oxidoreductase), HSD3B2 (3β-hydroxysteroid dehydrogenase, type 2), HSD17B3 (17β-hydroxysteroid dehydrogenase, type 3), and 5α-reductase, type 2 (encoded by SRD5A2). The *alternative pathway* is characterized by the presence of additional enzymes: 5α-reductase, type 1 (5α-reductase 1, encoded by SRD5A1), AKR1C enzymes, and RoDH (3-hydroxyepimerase, encoded by HSD17B6). 17OH-allo-pregnanolone (5α-pregnan-3α,17α-diol-20-one or Pdiol) is a key intermediate in this pathway.[104] While the reaction between DHT and 3α-androstanediol (3α-diol) is reversible, DHT is also irreversibly converted to 5α-androstane-3β,17β-diol (3β-androstanediol or 3β-diol), an estrogen receptor β ligand (not shown). (From Fluck CE et al. *Am J Hum Genet* 2011;89(2):201–18.)

time frame, levels of serum LH and FSH surge as early as the first week of life, followed by increases in testosterone, AMH, and inhibin B, while INSL3 levels are high in both cord blood and at 3 months of age.[100,105–108] Evidence from individuals with androgen insensitivity suggests that the postnatal hormone surge is related to the effects of postdelivery androgen withdrawal, with reflex increases in hypothalamic and pituitary activity.[109]

Postnatal maturation and stabilization of the testis and male reproductive tract, respectively, are presumed consequences of the neonatal hormone surge.[109] Data from a recent longitudinal study suggest that the gonadotropin and testosterone surge actually occurs at 1 month of age and is more pronounced in preterm boys.[110] In this series, the percentage growth of the neonatal testis and penis was positively correlated with levels of LH, FSH, and testosterone. The proposal that neonatal testis growth is likely due to seminiferous tubule elongation in response to Sertoli cell proliferation[111] is supported by data showing correlation of testis volume with levels of inhibin B during infancy.[112] In an autopsy series, testes from 1-month-old boys showed greater volume and reduced levels of apoptosis in all cell types than in older boys.[113] In contrast, cohort[114] and longitudinal[110] analyses of living subjects using ultrasound suggest that the peak in neonatal testis size occurs at 5 months of age.

Puberty

Prior to puberty, mean testicular volume based on ultrasound/orchiometer estimations increases slowly from 0.5/1.6 mL at 1 year to 0.8/2.3 mL at 9 years of age.[115] During this period, Leydig cell hormonal activity remains quiescent, but Sertoli cells continue to produce AMH and inhibin B (Figure 68.6). A drop in AMH levels coinciding with an increase in inhibin B levels that may signal Sertoli cell maturation occurs at testis volumes of <2 mL and prior to a rise in serum testosterone, representing the earliest signs of puberty.[100,116] Other early markers of puberty include diurnal variations in urinary gonadotropin levels and an increase in early morning testosterone.[117] Clinically, an orchiometric volume of 3 or 4 mL is used to define the onset of puberty and occurs on average between 10.5 and 11.5 years of age.[117] Active production of spermatozoa occurs at a testicular volume of 6 mL.[117]

The high sensitivity to LH of the emerging adult Leydig cell population and consequent increases in intratesticular testosterone contribute to the rapid increase in germ cell proliferation, tubular diameter, and marked increase in testicular size.[111] With puberty, germ cells now replace Sertoli cells as the main testicular component (Figure 68.8). Complete spermatogenesis requires adequate levels of intratesticular (as opposed to serum) testosterone and multiple sex chromosomal and autosomal genes.[118] INSL3 levels best reflect the LH-stimulated differentiation status of Leydig cells and correlate well with early pubertal increases in LH and FSH.[119] Testosterone levels rise slightly later and reflect the acute Leydig cell response to LH (see above). INSL3 continues to rise after puberty and then falls in aging men, reflecting its usefulness as a marker of Leydig cell status.[119]

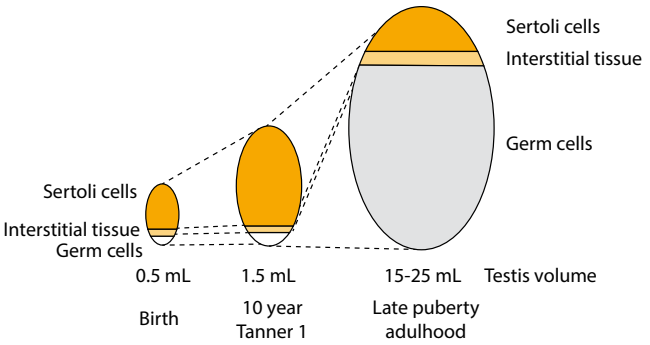

FIGURE 68.8 Schematic ontogeny of the evolution of testicular volume from birth to adulthood. Seminiferous tubules (Sertoli + germ cells) are always the major components of the testis. From birth and during the whole prepubertal period (i.e., until ages 9–14 years, Tanner stage 1), seminiferous tubule volume depends mainly on Sertoli cells, whereas the significant increase in testicular volume during pubertal development (i.e., between Tanner stages 1 and 5) is mainly due to germ cell proliferation. (From Grinspon RP et al. *J Pediatr Endocrinol Metab* 2012;25(1–2):3–11.)

Markers of Testicular Function in Hypogonadism

Activation of the HPG axis provides an opportunity to assess testicular function in neonates with abnormal genital development without the need for stimulation tests. After this period, serum gonadotropin levels fall and secondary increases are not always seen in boys with primary hypogonadism (defined broadly as any reduction in hormonal or spermatogenic function[118]) until puberty. The Sertoli cell markers AMH and inhibin B can be useful in evaluating hypogonadism in childhood as levels remain relatively high and do not require stimulation tests.[120] For example, in boys with hypogonadotropic hypogonadism, AMH and inhibin B levels may be lower than expected in childhood, but at the time of expected puberty, AMH levels are higher than normal for age due to lack of inhibition by testosterone. Inhibin B measurement may be a good first-line diagnostic test for delayed puberty, as very low levels are highly predictive of hypogonadotropic hypogonadism and less likely to reflect constitutional delay of puberty.[121] INSL3 may also be a good marker for pubertal onset,[122] and because it is not directly regulated by LH, levels may be normal in conditions associated with normally differentiated Leydig cells but abnormal steroidogenesis.[123]

In boys with anorchia, gonadotropin levels are abnormally high in infancy and decrease during childhood, but FSH is more likely to remain elevated than is LH, particularly prior to age 3.[124] In contrast, elevated levels of FSH and particularly LH in prepubertal boys with abdominal testes are possible but less common. AMH and inhibin B are also unmeasurable in anorchia but may also be very low or unmeasurable in boys with nonpalpable or abnormal testes, so that discrimination between these diagnoses based solely on hormone levels is not always possible.[124,125] However, when levels of AMH and/or inhibin B are low and FSH is high, hCG stimulation testing may not add additional useful information.[126,127]

Other Regulators of Testicular Function

New data suggest a reciprocal interaction between bone and testis extending beyond the known role of sex steroids on bone remodeling. Osteocalcin, a product of osteoblasts, regulates Leydig cell steroidogenesis by a novel mechanism that involves binding to Gprc6a, a G-protein-coupled receptor expressed in Leydig cells.[128] Interestingly, elevated LH levels do not compensate for reduced testosterone levels in osteocalcin knockout mice.

Hormones in the somatotropic axis also influence the reproductive axis at all levels, linking sexual maturation with physical growth and the availability of energy stores.[129,130] Growth hormone (GH) and IGF1, a mediator of GH signaling, positively impact the release of gonadotropin-releasing hormone from the hypothalamus and gonadotropins from the pituitary. GH and circulating and/or locally produced IGF1 also enhance expression of gonadotropin receptors and steroidogenesis in the testis.[129] The GH secretogogue ghrelin, a hormone activated in response to decreased energy stores, inhibits the HPG axis at the level of the hypothalamus and testis.[131] Ghrelin is expressed in Leydig and Sertoli cells, is a marker of Leydig cell differentiation, and in animal studies, inhibits steroidogenesis and expression of the pro-spermatogenic SCF (kit ligand).[39] Leptin, a hormone activated in response to satiety and complementary to ghrelin in energy homeostasis, has mixed effects in HPG axis regulation that include stimulation of LHRH release and inhibition of steroidogenesis.[132] Balanced ghrelin–leptin signaling is also important for the HPG axis, since unopposed ghrelin signaling appears to be responsible for the reduced steroidogenesis and germ cell apoptosis that occurs in mice with leptin deficiency.[133]

BLOOD–TESTIS BARRIER AND GERM CELL INJURY

With puberty and entry of the testis into meiosis, the BTB develops in order to support and maintain developing sperm in a sequestered environment.[134] The main components of the BTB are the basolateral membrane, apical membrane, and a tight junction complex between Sertoli cells (Figure 68.9) that provide anatomic and

FIGURE 68.9 Components of the BTB. Anatomical barrier: The basal membrane (BM), apical membrane (AM), and tight junction (TJ) form the Sertoli cell barrier. Substances within the circulation enter the interstitial space, but most of them (dots) are prevented from entering the adluminal compartment (thin line) of the testis by the anatomical component of the BTB. Physiological barrier: At the adluminal (thin line) and basal (thick line) membranes are the sites of specific transporters that control the movement of molecules (dots and stars) between the compartments, creating unique microenvironments for germ cell development and maturation in the testis. S, Sertoli cell; GC, germ cell, L, Leydig cell; B, blood vessel. (From Mital P et al. *Biol Reprod* 2011;84(5):851–8.)

physiologic barriers. The latter is determined by active transport across the basolateral and apical membranes. Proteins important for assembly of the BTB include testosterone, cytokines, TGFβs, RA, and junctional and cytoskeletal proteins.[135–137] Complex restructuring consisting of temporary disruption followed by reassembly is required for transport of preleptotene spermatocytes across the BTB at the appropriate stage of the spermatogenic cycle.[135]

The testis is an immunologically privileged site because normal fertility requires protection of spermatogenic cells from the host immune response. Immune privilege exists because multiple testicular cell types express regulatory factors that actively suppress this immune response and is not due to existence of the BTB per se.[138] However, the BTB limits passage of germ cell antigens from the tubule to immune cells in the interstitium (including macrophages, dendritic cells, and T cells) and transfer of antibodies into the tubule.[139] Failure of normal immunosuppression can occur as a result of trauma, infection, or other pathology and lead to testicular autoimmunity characterized by activation of immune cells, production of cytokines, germ cell apoptosis, and infertility.

Oxidative stress is a common testicular response to many types of injury or disease, including developmental disorders, genetic abnormalities, and environmental toxicants, and leads to excess germ cell apoptosis.[140] Oxidative stress occurs whenever there is an imbalance of production and removal of reactive oxygen species (ROS). For example, ischemia–reperfusion injury associated with testicular torsion initiates expression of inflammatory mediators, such as TNF-α and interleukin 1β (IL-1β). These activate mitogen-activated protein kinase (MAPK) pathways, neutrophil recruitment, and ROS production with resultant germ cell apoptosis.[141] Other sources of oxidative stress include heat stress related to varicocele and untreated cryptorchidism; exposure to toxicants such as phthalates, BPA, pesticides, and industrial chemicals; ionizing irradiation, chemotherapy; and genetic abnormalities.[140,142] The apoptosis pathways triggered by oxidative stress vary based on the source of injury but include the intrinsic pathway, mediated by members of the Bcl-2 (B-cell lymphoma 2) family of apoptotic regulators in mitochondria, and the extrinsic pathway, mediated by the cell death surface receptor Fas, expressed by germ cells and Fas ligand, secreted by Sertoli cells.[140,142] Heat and oxidative stress also cause DNA damage, which alters chromatin integrity and the potential for altered fertility and pregnancy outcomes.[143,144]

MAPK signaling, a common response pathway for potentially harmful cellular stimuli, is a key participant in the pathologic effects of oxidative stress that include apoptosis and the disruptive effects of toxicants on the BTB.[145] However, the MAPK pathway also responds to hormonal signaling by FSH and testosterone during spermatogenesis.[142] Normally, these hormones and physiologic levels of estrogen promote germ cell survival, while pharmacologic levels of androgen or estrogen can induce germ cell apoptosis.[142] These observations illustrate the dynamic balance between cellular proliferation and apoptosis required for healthy spermatogenesis, and therefore its susceptibility to disruption by diverse stimuli.

CHAPTER
69

Gonads, Genital Ducts, and Genitalia

Steven E. Lerman, Irene M. McAleer, Alan L. Kaplan, and George W. Kaplan

Sex determination is the phenotypic expression of genotypic sex as defined by the presence or absence of a Y chromosome. The SRY gene, the testis-determining factor located on the Y chromosome, is responsible for male gonadal sex determination and subsequent male external and internal genitalia, testicular descent, regression of Müllerian ducts, and male gender identity. The absence of SRY expression results in female external and internal genitalia and a regression of the Wolffian ducts.[1]

Formation of the gonads begins during the first 3 weeks.[2–4] Approximately 30–50 germ cells become recognizable among the endodermal cells of the caudal portion of the yolk sac near the allantoic stalk. These begin to migrate by ameboid motion toward the genital ridge.

The hindgut begins to develop during this same time frame. Its development was described in Chapter 49. To briefly recapitulate, the hindgut, which is endoderm, sends a blind extension caudally, which meets the ectoderm of the body wall at the cloacal membrane. The cloacal membrane initially extends from the tail bud to the body stalk, but as the mesoderm grows, the extent of the cloacal membrane becomes smaller.

The gonads continue to develop during the fourth week but remain in an indifferent stage. At this time, it is impossible to determine the sex of an embryo by examination. The ventromedial surface of the urogenital ridge begins to thicken and bulge into the coelom as a separate genital ridge, which lies medial and parallel to the mesonephric ridge.

The germ cells, which have been migrating dorsally in the wall of the yolk sac and gut, reach the gonadal ridge by the middle of the fifth week (Figure 69.1). It is during this time that the genital tubercle appears on the ventral midline between the umbilical cord and the tail bud. The tubercle has a thin urogenital groove caudally, the floor of which is the cloacal membrane, and the sides are the urogenital folds. At this same time, the cloaca is divided into an anterior urogenital sinus and a posterior rectum by the urorectal septum.

During the sixth week, an indifferent gonad is recognizable in both sexes and consists of superficial germinal epithelium and an internal blastema derived from ingrowth of coelomic epithelium. The blastema forms into primary or medullary sex cords, and the germ cells and mesenchyme come to lie between these cords. The urogenital ridge is attached broadly near the root of the mesentery. In both sexes, a groove appears in the urogenital ridge located laterally on the mesonephros near the cephalic end. The cranial end of this groove remains open, while caudally it begins to close into a tube (the Müllerian duct) (Figure 69.2). There is progressive caudal growth of the solid, blind end of the Müllerian duct, guided by the mesonephros. Near the cloaca, the urogenital ridges swing mesiad into the genital cord. The cranial end of the Müllerian duct is forced laterally by the enlarging suprarenal glands and kidneys. Hence, each Müllerian duct has two bends, a cranial one and a caudal one (Figure 69.3).

During the seventh week in the male, the attachment of the gonads to the mesonephros becomes the mesorchium. The medullary sex cords fuse with mesonephric tubules to form ductuli efferentes (Figure 69.4). Some mesonephric tubules cephalad to this area persist as vestigial structures associated with the epididymis and spermatic cord (the appendix epididymis, the superior and inferior vasa aberrantia, and the paradidymis). The sex cords become separated from the surface epithelium of the gonad by small cells that eventually form the tunica albuginea. The primordial germ cells become incorporated into the testis cords, and these cords become arranged radially, separated by a proliferation of mesenchyme. The cords eventually converge toward the blastemal mass, emerging as the primordia of the rete testis. In the female, at this time the round ligament begins to form. There are known teratogens that disrupt normal embryogenesis resulting in abnormalities of the genitalia (Table 69.1).

The genital tubercle elongates into a phallus, and its tip rounds into the glans (Figure 69.5). The Sonic hedgehog (SHH) signaling pathway, important in genitourinary tract development, has been shown to be indispensible for the establishment of male external genitalia, and likely facilitates the masculinization process.[5] Genital swellings appear lateral to the phallic base. The urogenital sinus opens at the base of the phallus by rupture of the cloacal membrane. In the male, the corpora cavernosa begin to appear from mesenchymal columns in this area (Table 69.1).

The upper five-sixths of the mesonephric ridge is lost by the eighth week and becomes the diaphragmatic ligament of the mesonephros, which eventually will become the suspensory ligament of the gonad.

In the male, the tunica albuginea has formed a definite encapsulating layer on the gonad, and the gubernaculum begins to form. The phallus elongates, as does the urethral groove, and the genital swellings rotate caudad.

In the female, clusters of indifferent cells and primordial germ cells appear. These fall into a dense primary cortex and a looser primary medulla. A mass bulges from the medulla into the mesovarium to form the rete ovarii (Figure 69.6). The suspensory ligament of the ovary is formed from the cephalic end of the genital ridge, while the proper ligament of the ovary is formed from the terminal part of the genital

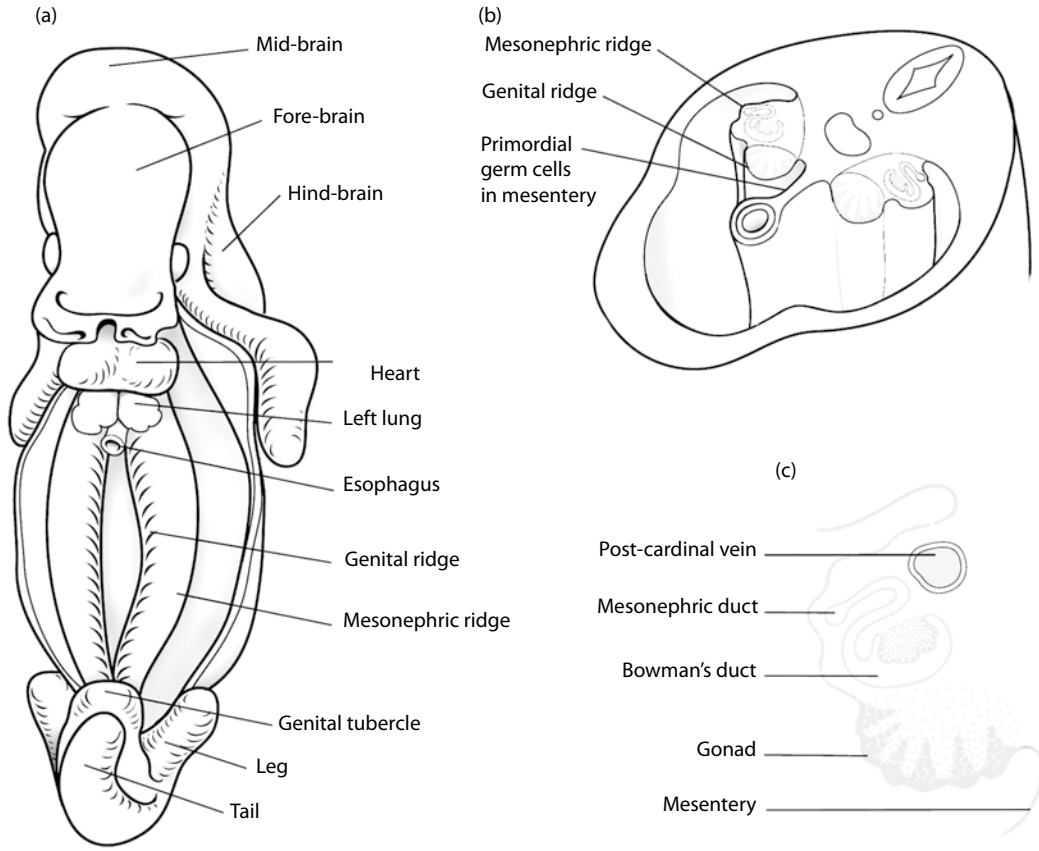

FIGURE 69.1 Urogenital ridge in the human: (a) 9 mm ventral view; (b) 7 mm transverse view; and (c) 10 mm transverse view. (Reproduced from Arey LB. *Developmental Anatomy*, 6th edn. Philadelphia: WB Saunders, 1974. With permission.)

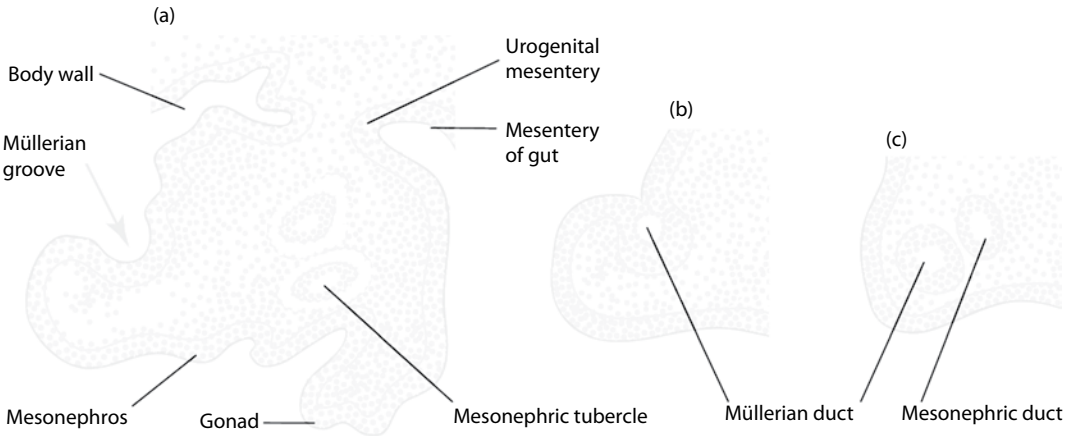

FIGURE 69.2 Origin of the human Müllerian duct at the 12 mm stage: (a) through the open groove; (b) slightly lower level, showing closure; and (c) still lower, showing a tube. (Reproduced from Arey LB. *Developmental Anatomy*, 6th edn. Philadelphia: WB Saunders, 1974. With permission.)

ridge and unites the caudal end of the ovary to the transverse bend of the Müllerian duct and eventually to the uterus.

The mesonephros consists of 34 pairs of tubules by the ninth week, but half of them are nonfunctional. This is the end of the stage of maximal mesonephric development. The cranial 8–15 pairs project against the rete testis or rete ovarii. The caudal ends of the Müllerian ducts have now fused medially and end blindly at Müller's tubercle. The mesonephric ducts are now lateral to the Müllerian duct caudally.

Cowper's gland in the male and Bartholin's gland in the female, which are homologs, arise as a pair of solid buds from the endodermal epithelium of the urogenital sinus distal to Müller's tubercle. In the male, they extend backwards, paralleling the urogenital sinus, and penetrate the mesenchyme of the corpus cavernosum urethrae and become glandular. They open into the bulbus urethrae. In the female, they open into the vestibule near the hymen.

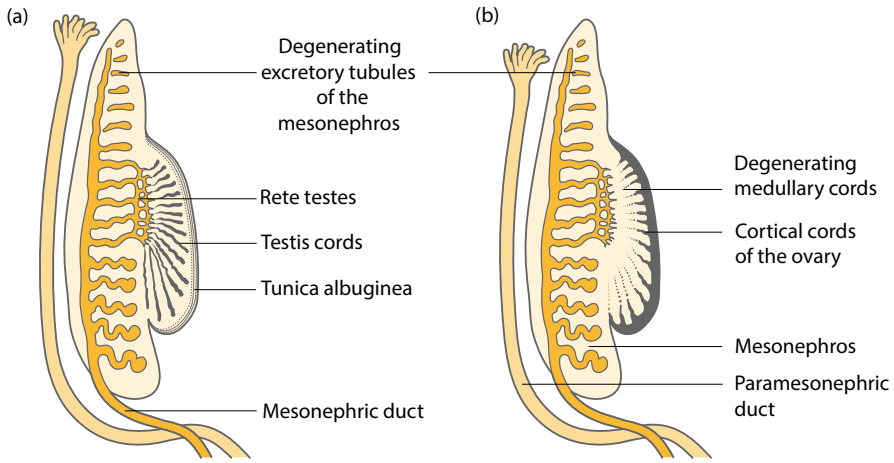

FIGURE 69.3 Diagram of the genital ducts in the 6th week of development in the male (a) and female (b). The mesonephric and Müllerian ducts are present in both. Note the excretory tubules of the mesonephros and their relationship to the developing gonad in both sexes. (Reproduced from Sadler TW. *Longman's Medical Embryology*, 7th edn. Philadelphia: Williams & Wilkins, 1995. With permission.)

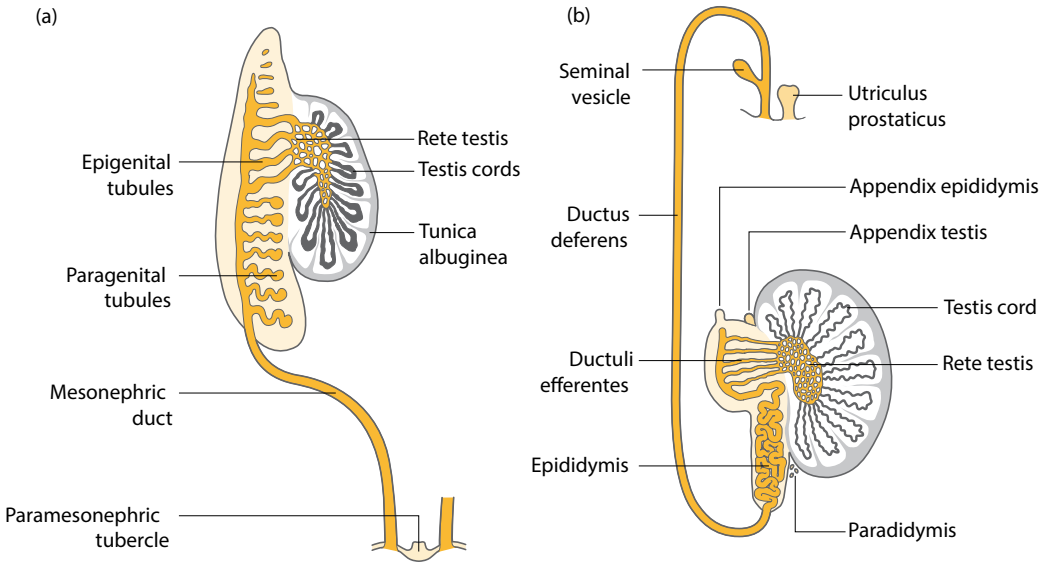

FIGURE 69.4 (a) Diagram of the genital ducts in the male in the 4th month of development. Cranial and caudal (paragenital tubule) segments of the mesonephric system regress. (b) Diagram of the genital ducts after descent of the testis. Note the horseshoe-shaped testis cords, rete testis, and efferent ductules entering the ductus deferens. The paradidymis is formed by remnants of the paragenital mesonephric tubules. The müllerian duct has degenerated except for the appendix testis. The prostatic utricle is an outpocketing from the urethra. (Reproduced from Sadler TW. *Longman's Medical Embryology*, 7th edn. Philadelphia: Williams & Wilkins, 1995. With permission.)

By the 10th week, all the mesonephric tubules have become discontinuous. The gonads in both sexes lie at the boundary of the pelvis and the abdomen. In the male, the external genitalia are becoming visible as male structures as a result of secretion of testosterone by the fetal testis. The phallus has become the penis. The edges of the urethral folds begin to fuse progressively from posterior to anterior, forming the urethra and the median raphe. The genital swellings become scrotal swellings, which fuse, forming a scrotal septum and raphe.

In the 11th week, the prostate arises as multiple outgrowths of endoderm both above and below the mesonephric ducts. These outgrowths arise in five different groups, each of which corresponds to a future prostatic lobe. The buds grow into the surrounding mesenchyme, which in turn provides both connective tissue and smooth muscle. In the female, the homologs of the prostate are the urethral glands, which are drained by Skene's ducts on each side.

Littre's glands bud from the male urethra in the 12th week. In the female, homologs of Littre's glands bud into the vestibule. In the male, the processus vaginalis appears as an outpouching at the internal inguinal ring, and the testis lies nearby. The gubernaculum has already formed. The Müllerian ducts degenerate owing to the secretion, by Sertoli cells, of Müllerian inhibiting factor (MIF). Müllerian remants in the male are the appendix testis

TABLE 69.1 Genitourinary (GU) tract teratogens

Teratogen	Potential GU defect
Maternal hyperthermia	Micropenis
Rubella virus (congenital rubella)	Hypospadias, cryptorchidism
Progestational agents	Ambiguous genitalia
Oral contraceptives	Hypospadias
ACE inhibitors	Renal dysplasia
Ethanol (fetal alcohol syndrome)	Hypospadias, hydronephrosis
Anticonvulsants	Hypospadias, ambiguous genitalia, cryptorchidism
Cocaine	Eagle–Barrett syndrome, hypospadias, hydronephrosis
Vitamin A (excessive)	Hydronephrosis, hypospadias

Abbreviation: ACE, angiotensin-converting enzyme.

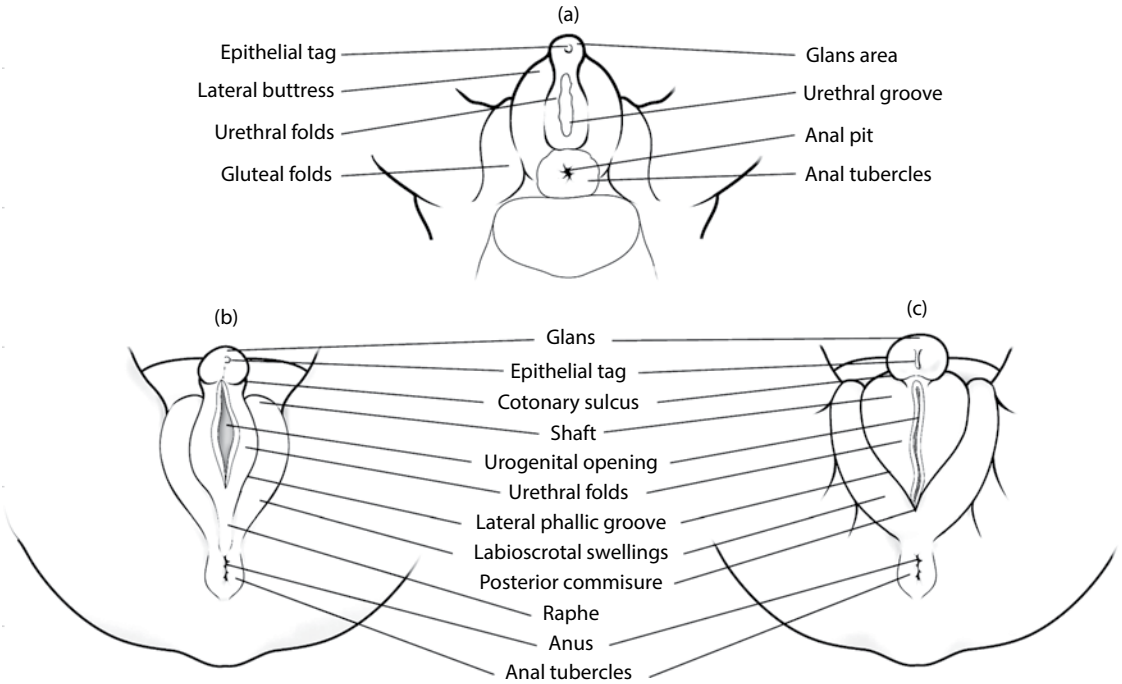

FIGURE 69.5 Developing external genitalia of the human: (a) 7th week; (b) male, 10th week; and (c) female, 11th week. (Reproduced from Gray SW, Skandalakis JE. *Embryology for Surgeons*. Philadelphia: WB Saunders, 1972, 496. With permission.)

from the cranial end and the prostatic utricle from the caudal end of the Müllerian duct (Table 69.2).

In the female, the secondary ovarian cortex begins to form in the 12th week by division of cells of the ovarian blastema and by new growth of germinal epithelium. The early ova regress and form the medulla. The ovaries at this time lie at the pelvic brim. The round ligament is complete. Vaginal and uterine musculature appears from the mesenchyme surrounding the Müllerian ducts. The distal portions of the Müllerian ducts have fused below the caudal bend (Figure 69.7).

In the 13th week, in the male, the seminal vesicles develop as lateral branches off the mesonephric duct. Branching of these seminal vesicles is evident by the fourth month of fetal life, and eventually a muscular coat is gained from the mesenchyme. In the female, the mesonephric ducts begin to regress. Elongation of the fetal pelvis causes a solid epithelial cord to form between the end of the Müllerian ducts and the urogenital sinus; this cord will become the upper vagina.

During the 14th week, the penile shaft continues to elongate in the male, and the urethra has fused to the base of the glans penis. The penile shaft has a ventral deflection.[6] The prepuce now begins to form as a fold of skin that grows distally. By 5 months of gestational age, preputial formation is complete. The prepuce then fuses to the glans and reseparates from it under the influence of testosterone by the formation of small clefts in the preputial sac. This procedure of separation is incomplete at birth and continues for several years thereafter.

By the 16th week, maximal degeneration of the mesonephric tubules has been attained. The muscles of the perineal floor are visible. The epithelium of Cowper's and Bartholin's glands is glandular in nature. In the

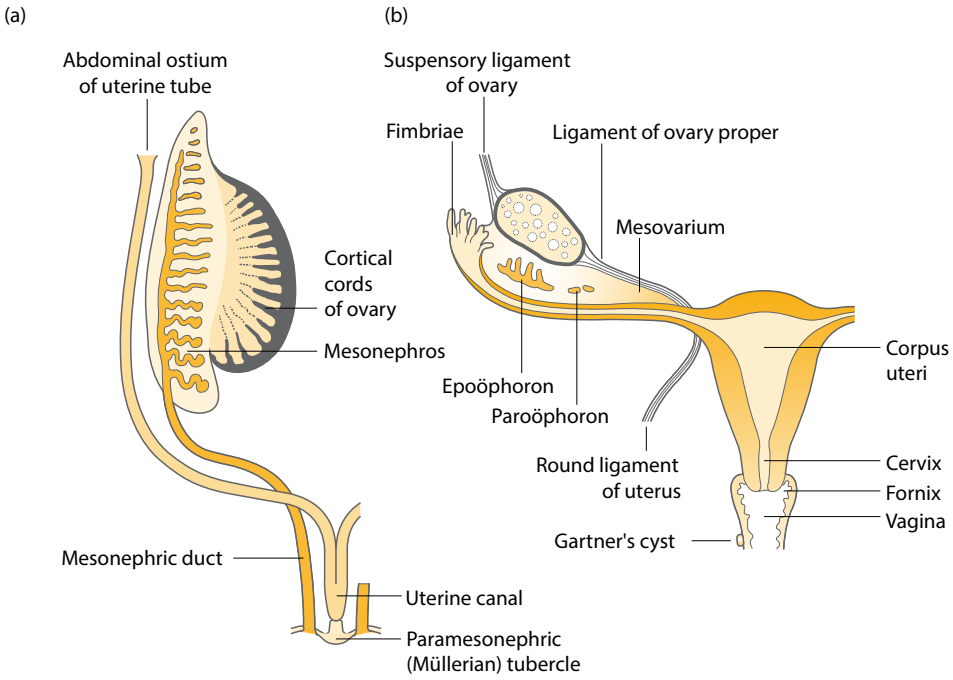

FIGURE 69.6 (a) Drawing of the genital ducts in the female at the end of the 2nd month of development. Note the müllerian tubercle and formation of the uterine canal. (b) Drawing of the genital ducts after descent of the ovary. The only parts remaining from the mesonephric system are the epoöphoron, paroöphoron, and Gartner's duct. Note the suspensory ligament of the ovary, ligament of the ovary proper, and round ligament of the uterus. (Reproduced from Sadler TW. *Longman's Medical Embryology*, 7th edn. Philadelphia: Williams & Wilkins, 1995. With permission.)

TABLE 69.2 Embryologic remnants

Male	Müllerian remnants	Appendix testis
		Prostatic utricle
Female	Wolffian remnants	Epoophoron
		Paraoophoron
		Gartner's duct

testis, interstitial cells are very abundant. In the female, the vagina begins to form a lumen, as the fornices appear as clefts in the solid epithelial cord distal to the fused Müllerian ducts. The uterus forms as a fusion of Müllerian ducts as they move ventrally and medially. Inappropriate fusion can result in uterine structural abnormalities, such as bicornuate uterus (Figure 69.8). During this fusion, the broad ligaments are formed. The cervix and the fallopian tubes are now evident.

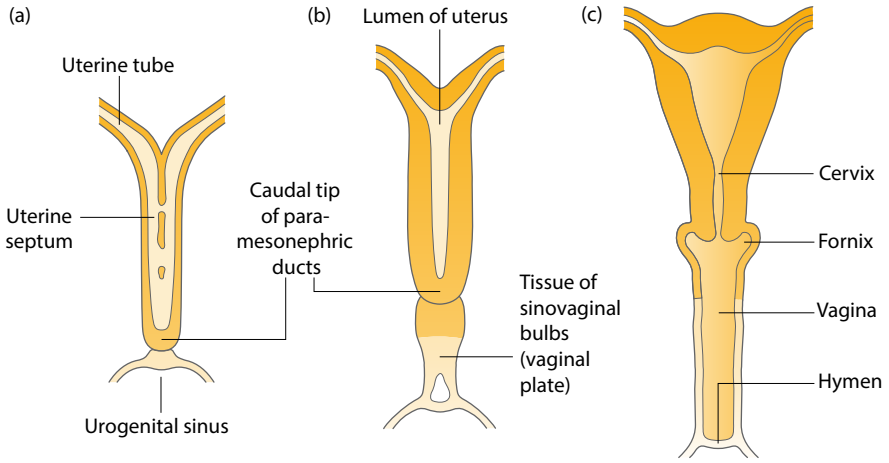

FIGURE 69.7 Schematic drawing showing formation of the uterus and vagina: (a) at 9 weeks, note the disappearance of the uterine septum; (b) at the end of the 3rd month, note the tissue of the sinovaginal bulbs; and (c) in the newborn, the fornices and the upper portion of the vagina are formed by vacuolization of the Müllerian tissue and the lower portion of the vagina is formed by vacuolization of the sinovaginal bulbs. (Reproduced from Sadler TW. *Longman's Medical Embryology*, 7th edn. Philadelphia: Williams & Wilkins, 1995. With permission.)

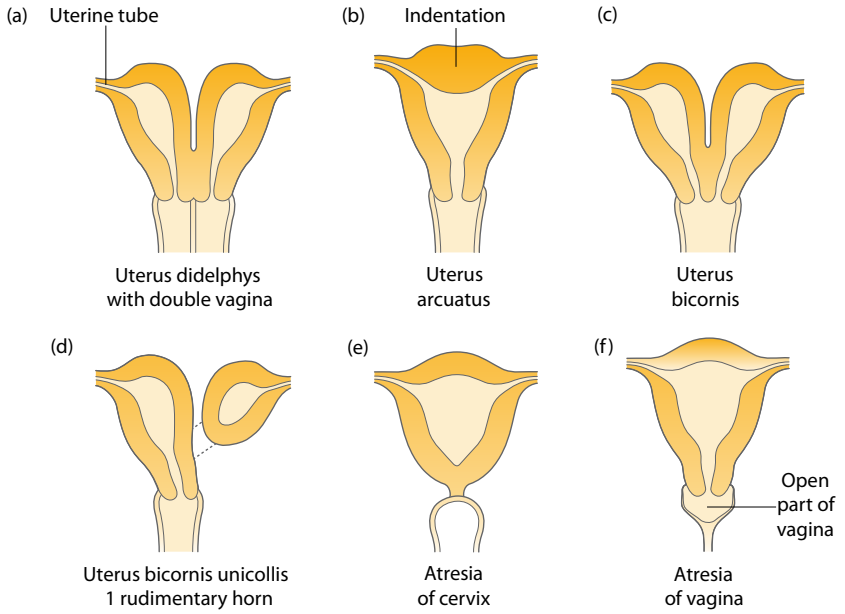

FIGURE 69.8 Schematic representation of the main abnormalities of the uterus and vagina, caused by persistence of the uterine septum or obliteration of the lumen of the uterine canal. (Reproduced from Sadler TW. *Longman's Medical Embryology*, 7th edn. Philadelphia: Williams & Wilkins, 1995. With permission.)

The vaginal lumen and the prepuce are completely formed by the 20th week. The penile shaft is now straight.[6] Homologous structures between males and females and their embryologic origin are listed in Table 69.3.

The tunica albuginea of the ovary forms during the 24th week. In the male, the lumens of the rete tubules and cranial mesonephric tubules become continuous and form the efferent ductules of the epididymis. The cranial end of the mesonephric duct convolutes, forming the body of the epididymis. The caudal end remains straight, forming the ductus deferens. The terminal end of the mesonephric duct forms the ejaculatory duct. The ampulla of the vas deferens forms from dilation of the ejaculatory duct. The processus vaginalis in the male now begins to move through the inguinal canal.

Formation of the seminal vesicles in the male is complete by the 28th week. The processus vaginalis has herniated through the abdominal wall, formed the inguinal canal, and reached the scrotum. The testis then begins to descend toward the scrotum. Several factors are hypothesized to influence testicular descent. These include gubernacular guidance, increased intra-abdominal pressure,[7] and possibly the release of a substance, descendin, from the normal testis.[8] In addition, the genitofemoral nerve has been studied as a potential factor in inducing testicular descent.[9] With normal factors intact, the testicle will reach the ipsilateral scrotum during the third trimester. Testis descent occurs in 60% of males by 30 weeks and 93% of males by 32 weeks.[10] Cryptorchidism is a frequent anomaly whose etiology has been extensively studied but is still incompletely understood. Some instances appear to be due to intrauterine endocrine failures, whereas others seem mechanical. Intra-abdominal testes might result if the processus vaginalis did not form.

TABLE 69.3 Embryologic homologs

Embryologic structure	Male	Female
Urogenital sinus	Prostatic urethra, prostate	Urethra, upper vagina
Genital tubercle	Glans penis	Clitoris
Genital folds	Urethra, penile shaft	Labia minora
Genital swellings	Scrotum	Labia majora
Mesonephric duct	Appendix epididymis	Appendix vesiculosa
	Duct of epididymis	Duct of epoophoron
	Ductus deferens	Gartner's duct
	Ureter, pelvis, collecting tubules	Ureter, pelvis, collecting tubules
	Ejaculatory duct, seminal vesicles	
Paramesonephric duct	Appendix testis	Hydatid of Morgagni
		Uterus, fallopian tubes

Ectopic testes might result if the path of descent were obstructed or if the gubernaculum went astray, failing to define a path for the testis to follow into the ipsilateral scrotum. The descent of the ovary is quite comparable to that of the testicle, but the gubernaculum fuses with the lateral margin of the uterus, which therefore arrests descent of the ovary in the pelvis. Failure of fusion of the gubernaculum to the uterus may allow the ovary to descend into the labia majora.

Major anomalies of these genital organs are frequent, including intersex, hypospadias, and cryptorchidism. If the testis-determining factor is present, a testis will develop. In the presence of the testis, the MIF will be released by Sertoli cells and lead to regression of the Müllerian ducts. In addition, elaboration of testosterone from Leydig cells will cause development of the mesonephric ducts and masculinization of the internal ducts. Masculinization of the external genitalia is dependent on the conversion of testosterone to 5-dihydrotestosterone. Failure of this conversion helps to explain some cases of ambiguous genitalia. In the absence of a testis, an ovary (or streak gonad) forms, the Müllerian structures persist, and the external genitalia are feminine.

Hypospadias represents arrested formation of the phallus and phallic urethra. In many instances, the distal hypospadiac urethra is dysplastic, as is the surrounding corpus spongiosum.[11] With severe forms of hypospadias, a small Müllerian remnant may persist as a diverticulum off the prostatic utricle.

CHAPTER 70

Disorders of Sex Development

Joao Luiz Pippi Salle and Rodrigo L. P. Romao

INTRODUCTION

The term *disorders of sex development* (DSDs) is a relatively recent addition to pediatric urology practice. It was forged in 2006 as part of a consensus statement elaborated on following a multidisciplinary meeting involving endocrinologists, urologists and pediatric surgeons, geneticists, psychologists, and representatives from advocacy groups.[1,2] The consensus postulated that any expression that could give rise to an idea of an intersex state, hermaphroditism or "third gender" should be abandoned. Classical terms such as *male and female pseudohermaphroditism* were thus banished (Table 70.1). DSD was purposely picked as a broad term defined as a congenital condition where the development of chromosomic, gonadal, or anatomical sex is atypical.[2,3] Hence, it widens the scope of the previous terminology (*intersex*), which included only conditions associated with some sort of genital ambiguity, and incorporates, for example, patients with abnormalities in the sexual chromosomes (such as Turner or Klinefelter syndromes) or others with discordance between genetic and phenotypic sex (e.g., complete androgen insensitivity syndrome [CAIS]). For that reason, establishing the true incidence of DSDs is impossible.

Despite some criticism on the suitability of the term *disorders*, with some suggesting that a nonpathological nomenclature should be sought, such as "atypical sex anatomy,"[4] the consensus statement has been well accepted by the medical and patient community worldwide;[5–8] the vast majority of publications related to this subject after 2006 have adhered to the classification and nomenclature proposed therein. Therefore, it is used throughout this chapter.

The first section of this chapter is a detailed description of the normal development of the external and internal genitalia, outlining the most recent discoveries in terms of genetic mechanisms associated with it. Second, the approach to the newborn or young infant with genital ambiguity is presented, following a detailed explanation of the DSD classification. Finally, each diagnosis is presented separately, along with specific medical and surgical management.

GENITAL DEVELOPMENT

Primordial germ cells are initially seen at the outer ectodermal layer of the embryo and undergo migration until they settle in the urogenital ridge, which is the site of development of the future gonad, kidney, and adrenal gland. The cornerstone of sex determination in humans is gonadal function.[9] The gonads regulate all changes that will eventually lead to the definition of the phenotypic sex. The gonads are undifferentiated initially and develop into a testicle or ovary around the sixth week of embryogenesis. In DSD patients, two other types of gonads can be seen: streak gonads, consisting of ovarian stroma without follicles, or germ cells and ovotestis, comprising a mixture of normal ovarian and testicular tissues.

In the past, it was widely accepted that internal and external female development were the "default" pathway, which would only be altered by the presence of a testicle. That concept was largely based on Jost et al.'s experiments with castrated rabbits.[10] Recent discoveries regarding the genetic basis of sexual development and differentiation have cast shadow on this theory and suggested that both male and female phenotypes are induced individually by a specific genetic makeup. Currently, the gene known as SRY (sex-determining region mapped to the short arm of the Y chromosome) is regarded as the male-defining factor in humans; however, the presence of this gene does not seem to be sufficient for testis induction; i.e., SRY is not the immediate inducer of testis formation. Rather, it appears to upregulate an ultimate testis-inducing gene (mechanism not totally elucidated, possible role for R-spondin 1) called SOX9, mapped to chromosome 17, which in turn upregulates PGD2 and FGF9. Both genes maintain SOX9 expression through a positive feedback loop, establishing the male pathway.[11]

Despite also playing a role in testicular development, DAX1 has been implicated as a likely X-linked female-determining gene.[12] WNT4 could be the female counterpart of SOX9, since it has also been implicated in suppression of both male sexual differentiation and gonadal androgen production in females.[13] Overexpression of either DAX1 or WNT4 antagonizes testis formation. In XX gonads, WNT4 induces beta-catenin, which results in silencing of FGF9 and SOX9.[11] The WNT4 signaling pathway plays a role in ovarian development and maintenance, whereas FOXL2 is involved in granulosa cell differentiation and follicle development,[11] thus acting as an ovarian-inducing gene as well.[12] Finally, RSPO1 is also a suppressor of the SOX9 gene.[11]

Internal Genitalia

Once the gonad differentiates into a testicle, two hormones drive differentiation of the internal genitalia: testosterone and anti-Mullerian hormone (AMH). The former is

TABLE 70.1 Comparison of current nomenclature with previous ones

Previous	Proposed by 2006 consensus
Intersex	Disorder of sex development (DSD)
Male pseudohermaphroditism	46 XY DSD
Female pseudohermaphroditism	46 XX DSD
XX male	46 XX testicular DSD
True hermaphroditism	Ovotesticular DSD
Any situation with chromosome mosaicism	Sex chromosome DSD

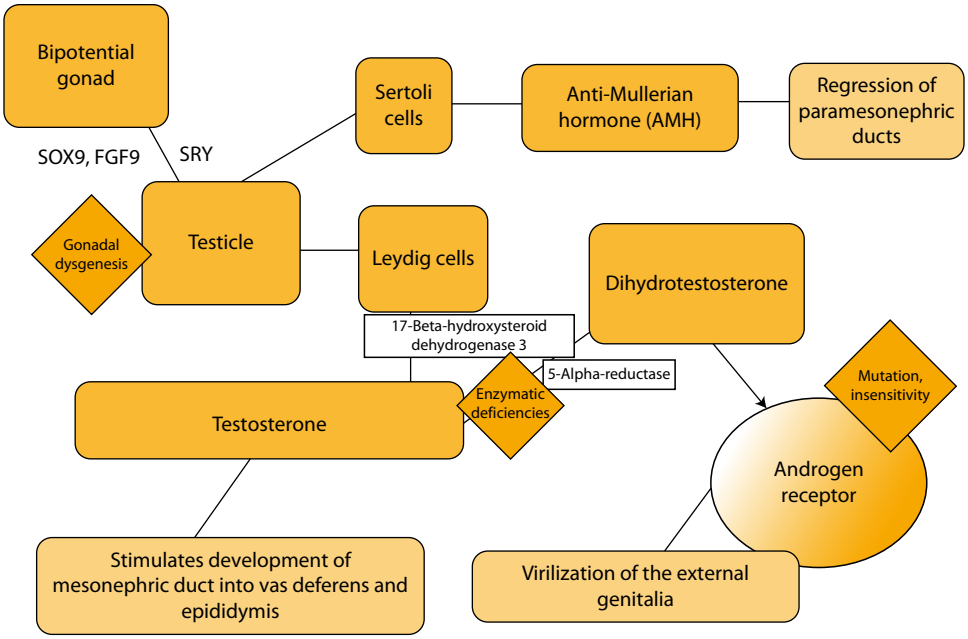

FIGURE 70.1 Schematic representation of steps modulating internal and external male genitalia differentiation. The diamond-shaped boxes depict potential areas for disruption, leading to DSDs.

produced by Leydig cells and binds to the nuclear androgen receptor (AR) of the fetus, thus stimulating the development of the Wolffian (mesonephric) ducts into male structures, such as the vas and epididymis; the latter is synthesized by Sertoli cells and causes regression of the Mullerian (paramesonephric) ducts, thereby inhibiting their differentiation into a uterus, fallopian tubes, cervix, and upper third of a vagina (Figure 70.1).

External Genitalia

Virilization of the external genitalia, characterized by fusion of labioscrotal folds forming the scrotum, urethral plate tubularization, and development of the genital tubercle into a penis, is the result of the action of dihydrotestosterone (DHT) on the AR present on genital skin. DHT is converted from testosterone (which in turn is synthesized by the Leydig cells from cholesterol) by 5-alpha-reductase type 2 (SRD5A2) and represents a much more potent androgen. Recently, it has been demonstrated that the fetal testis can also produce DHT directly through the so-called backdoor pathway;[14] the same authors have postulated that both the classic (from testosterone) and alternative pathways are essential for normal human male development. In the absence of DHT, the genital tubercle will become the clitoris and the labioscrotal folds will form the labia majora and minora. It should be noted that the development of a normal female phenotype is contingent on normal levels of estrogen produced by the ovaries (for example, patients with Turner's syndrome, who have bilateral streak gonads, depict an infantile external genitalia and lack of breast development), and therefore it should not be seen as the "basic" or default phenotype.[12]

Most DSD conditions will result from gonadal dysfunction (dysgenesis) or inadequate hormonal (androgen) action (either excessive or insufficient), which clinically will translate into either virilization of the female fetus or undermasculinization of the male one.

Studies using knockout mice, as well as research involving families affected by variable types of DSDs, have elucidated some genetic mechanisms associated with the development of gonadal dysfunction, as detailed below.

The urogenital ridge develops from the intermediate mesoderm. Some genes have been identified as critical in the formation of the urogenital ridge, which explains why they are associated not only with gonadal but also

TABLE 70.2 Genes and genetic syndromes known to be associated with DSDs

Disorder of sex development	Gene	Locus	Genetic syndrome/associated disorders
CAH	CYP21A2 (21-hydroxylase deficiency)	6q	n/a
	CYP11B1 (11-beta-hydroxylase deficiency)	8q	
	HSD3B2 (3-beta-hydroxysteroid dehydrogenase type 2)	1p	
CAIS or PAIS	AR	Xq	n/a
5-Alpha-reductase deficiency	SRD5A2	2p	n/a
17-Beta-hydroxysteroid dehydrogenase deficiency	HSD17B3	9q	n/a
Persistent Mullerian duct syndrome	AMH AMH receptor	19p 12q	n/a
Ovotesticular DSD, testicular DSD, and dysgenetic testicle	SRY	Yp	n/a
Dysgenetic testicle	WT1	11p13	WAGR, Denys–Drash, and Frasier syndromes
Dysgenetic testicle	ATRX	Xq	Alpha-talassemia and mental retardation
XY DSD (inborn error of cholesterol synthesis)	DHCR7	11q	Smith–Lemli–Opitz syndrome
Dysgenetic testicle	SOX9	17q	Camptomelic dysplasia

with renal or adrenal problems. Wilms' tumor suppressor gene (WT1) is crucial for gonadal and renal development. Frasier and Denys–Drash syndromes are caused by a WT1 mutation that will affect both the gonads and the kidneys, leading to DSDs. Steroidogenic factor 1 (SF1 encoded by NR5A1) and the "duplicated in adrenal hypoplasia congenital on the X chromosome (DAX1) proteins" are essential for gonadal and adrenal development.[9] Mutations in NR5A1 have been identified not only in patients with 46 XY gonadal dysgenesis, but also with isolated hypospadias and ovarian insufficiency.[15,16] Recently, another gene associated with intermediate mesoderm formation, GATA4, has been implicated in human testicular development, and a mutation was identified in a patient with 46 XY DSD and a congenital cardiac anomaly.[17] A recent genome-wide study in individuals with 46 XY gonadal dysgenesis identified copy number variations in many of the aforementioned genes, further supporting their role in the intricate process of gonadal development and differentiation.[18] Analysis of two families with cases of 46 XY DSD underlined a causative effect of mutations in MAP3K1.[19]

Molecular mechanisms of excessive or insufficient androgen action will be highlighted in the respective sections. Table 70.2 summarizes genes and genetic syndromes that have been demonstrated to be associated with DSDs.

CLASSIFICATION

The current DSD classification follows the patient's karyotype, and three main groups are recognized: 46XY DSD, 46XX DSD, and sex chromosome DSD (mosaic karyotype, most commonly 45X/46XY). Further identification of the source of the problem, i.e., gonad structure or function, androgen pathway and receptor, etc., will lead to a specific diagnosis.[1,2] Most common causes of DSDs divided by karyotype are depicted in Table 70.3.

Most patients with a DSD present in the neonatal period with genital ambiguity. Clinical scenarios that should trigger evaluation for DSDs are overt genital ambiguity, female external genitalia that appears virilized (i.e., enlarged clitoris, posterior labial fusion, and inguinal or labial mass), or male external genitalia that appears undervirilized (bilateral nonpalpable testicles, micropenis, association of hypospadias, and undescended testicles).

A significant proportion (10%–20%) of patients can present later in life (childhood or even young adulthood), and for those, the absence of ambiguity is the rule. Reasons for referral of female patients include palpable gonad within an inguinal hernia; absent, delayed, or incomplete puberty; virilization; and primary amenorrhea. In males, breast development, gross cyclic hematuria, and sometimes simply infertility flag the possibility of a DSD. In pediatric medicine, as karyotype has become more common, discordance between genital appearance and karyotype ordered for issues unrelated to gender assignment is another reason for referral to DSD clinics.[20,21]

APPROACH TO THE NEWBORN WITH GENITAL AMBIGUITY

Newborns with genital ambiguity should be evaluated on an urgent basis for two reasons: to rule out congenital adrenal hyperplasia (CAH), since the salt-wasting form of the disease can be life threatening, and to provide a male or female gender assignment after a thorough, timely investigation. The first challenge is to define which patients in fact have ambiguous genitalia, as opposed to minor genital abnormalities (e.g., mild clitoral enlargement or isolated

TABLE 70.3 Most common DSD diagnoses divided by karyotype

	XX DSD	XY DSD	Sex chromosome DSD
Disorders of gonadal development	• Ovotesticular DSD • XX sex reversal (testicular DSD) • Gonadal dysgenesis	• Pure gonadal dysgenesis • Partial gonadal dysgenesis • Ovotesticular DSD • Gonadal regression or vanishing testis syndrome	• 45 X/46 XY—Mixed gonadal dysgenesis or ovotesticular DSD • 47 XXY—Klinefelter syndrome • 45 X—Turner syndrome
Disorders related to androgen synthesis or action	**Androgen excess**	**Androgen action**	
	a) Maternal • Luteoma • Exogenous (medications)	Androgen insensitivity syndrome (complete or partial)	
	b) Fetoplacental • Aromatase deficiency	Androgen synthesis	
	c) Fetal • Congenital adrenal hyperplasia (21-hydroxylase deficiency most common)	• LH receptor mutation • 17-Beta-hydroxysteroid dehydrogenase deficiency • 5-Alpha-reductase deficiency • Male CAH (e.g., 3-beta deficiency)	

distal hypospadias), and therefore avoid overinvestigation. After identifying one of the scenarios listed in the section above, the first step is to request an evaluation by an expert in DSDs, who works as part of a multidisciplinary team. Even before the first assessment is initiated, some general principles should be kept in mind: one should refrain from making comments or statements based on the appearance of the external genitalia alone; a long-term care plan should be discussed in the setting of a multidisciplinary, holistic, patient-centered clinic using the best level of evidence available; family concerns should be addressed promptly, openly, and confidentially by professionals with the best communication skills, without withholding detailed information.[22]

Prenatal Diagnosis

The second-trimester ultrasound has an accuracy of 98% for determining the fetal sex. The presence of ambiguous genitalia is amenable to sonographic detection. Following such detection, a detailed scan seeking associated anomalies (renal are the most common) should be performed. Cell-free DNA (cfDNA) from the fetus is detectable in maternal blood 4–6 weeks after fecundation;[23] therefore, Y material could be identified offering insight into the possible diagnosis. In the presence of a Y chromosome, undervirilized genitalia (hypospadias, penoscrotal transposition, etc.—see below for details), and sonographic signs of placental insufficiency (such as intrauterine growth retardation), no additional tests are required, since this association has been well documented[24,25] and is known not to be coupled with added abnormalities.

In fetuses with abnormal genitalia, normal intrauterine growth, and no evidence of Y DNA, amniocentesis could be offered to confirm female gender with a karyotype and assess the steroid profile (see "Diagnostic Tests" section below), hence allowing an early diagnosis of an otherwise unsuspected CAH case. Prenatal treatment of CAH will be discussed in detail in the corresponding section.

In a series of 140 individuals followed by a multidisciplinary DSD clinic, 24% were identified prenatally, and the most common diagnoses were penoscrotal hypospadias associated with transposition of the scrotum and no specific genetic cause (17%) and CAH due to 21-hydroxylase deficiency (14%),[26] thus highlighting the limited but still valid role of prenatal diagnosis for genital ambiguity.

Discordance between the sonographic appearance of the genitalia and karyotype performed by amniocentesis for an unrelated reason is another contemporary source of DSD diagnosis. Hence, male-appearing external genitalia in XX patients and vice versa may trigger a suspicion for a DSD. Furthermore, the finding of a 45X/46 XY karyotype prenatally is not necessarily associated with genital ambiguity, since the phenotype in patients with such abnormality is highly variable,[27] and some publications have suggested that up to 90% of patients detected prenatally can be phenotypically normal.[28,29] Figure 70.2 depicts a suggested algorithm for the investigation of prenatally detected genital abnormalities.

History

A detailed history should focus on family history of DSDs, parental consanguinity, unexplained previous infant deaths, maternal ingestion of drugs (particularly progestagens and steroids), use of assisted reproductive technologies, and results of prenatal tests. A history of maternal virilization or severe acne during pregnancy is also valuable. During the first interview, care should be taken to ascertain the degree of knowledge parents might already have about their baby's condition and DSDs. A careful perinatal history focused on evidence of prematurity, intrauterine growth retardation, or other signs of placental insufficiency should also be obtained because of the aforementioned association of those conditions with undervirilization of the male genitalia.[24,25] As the parents may not know details of a family history of DSDs, it is important to ask about a history of hypospadias, amenorrhea, and infertility.

Physical Examination

Physical examination should initially focus on general findings and potentially life-threatening problems, like the

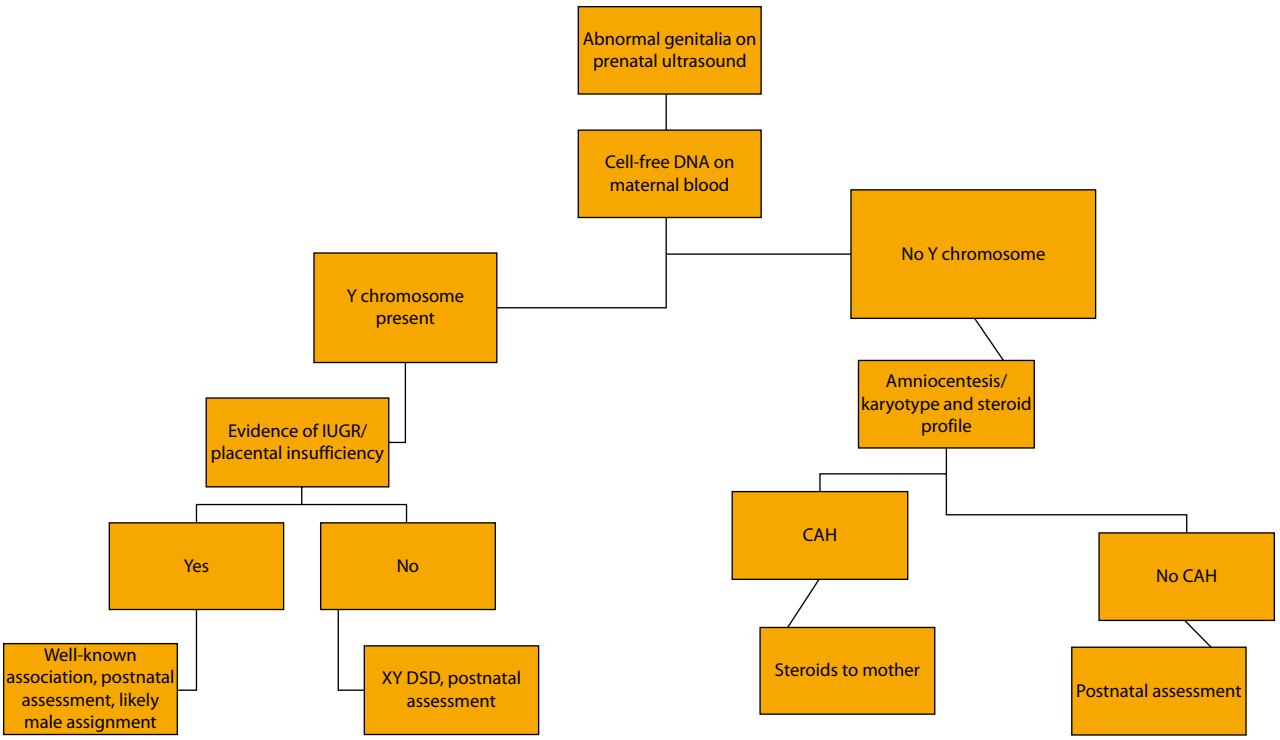

FIGURE 70.2 Suggested algorithm for the pre- and postnatal investigation of patients with genital abnormalities on ultrasound.

presence of severe dehydration that can be associated with salt-wasting CAH (which usually happens after 1–2 weeks of life), followed by inspection for signs of dysmorphic features or associated anomalies. Examination of the genital tubercle starts with careful inspection of the phallic structure, noting length, breadth, and amount of erectile tissue; number of orifices in the perineum and their topography; rugation; pigmentation and fusion of the labioscrotal folds; and position and patency of the anus (females with cloacal anomalies often have some degree of genital ambiguity). Asymmetry is also an important sign to look for, since the degree of virilization will usually follow the ipsilateral gonad; hence, some DSD conditions, like ovotesticular DSD and mixed gonadal dysgenesis (MGD), will produce virilization on only one side of the genitalia.[30] Palpation of gonads is a key step in the initial assessment. Gonads can be palpated within the scrotum or labioscrotal folds, or in the inguinal canal, or be nonpalpable. The status of the gonads on palpation bears a particularly important weight on the initial diagnostic thought process.

An accurate description of the genital tubercle is usually hampered by subjective criteria and lack of standardization. Most authors refer to the external genitalia of patients with genital ambiguity as displaying a virilized female or undervirilized male appearance, as depicted in Figure 70.3.

In either case, it is important to palpate the phallus for the presence of corpora (erectile tissue) and measure its stretched dorsal length, which can be compared with normatized data.[31]

Virilized female genitalia will usually exhibit variable degrees of clitoromegaly, pigmentation, and rugation of the labial skin and labial fusion; depending on the degree of virilization, only one opening other than the anus will be visible in the perineum, representing an urogenital sinus (UGS). The UGS represents a common channel of variable length for the urinary and genital tracts. The terms *low* (closer to the perineum) and *high* (closer to the bladder neck) are used to describe the level of the confluence between the urethra and vagina. In cases with a high confluence, the urethra is usually very short (<1.5 cm). Traditionally, the Prader classification has been widely used in an attempt to standardize such findings. It ranges from 1 (mild clitoromegaly) through to 5 (complete virilization with UGS opening up at the tip of the phallus). Figure 70.4 depicts a schematic illustration of the Prader

FIGURE 70.3 Examples of the most common DSD clinical presentations—undervirilized male or virilized female.

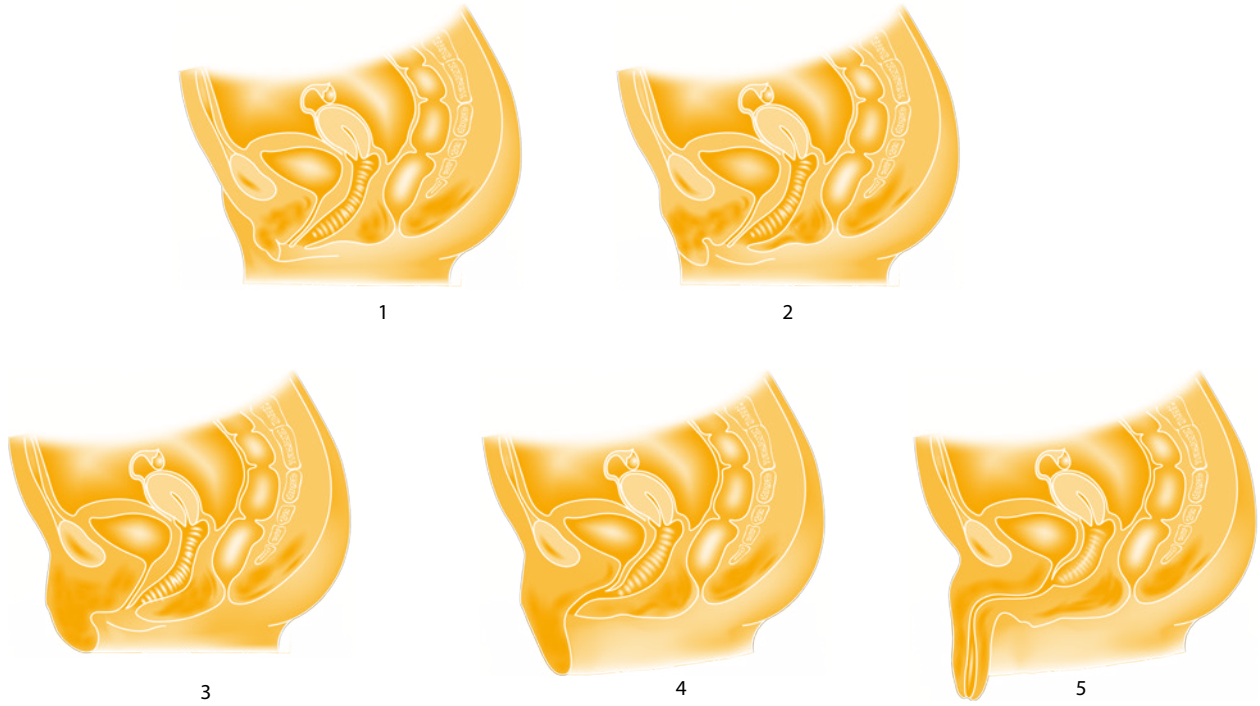

FIGURE 70.4 Schematic illustration of the Prader classification.

classification, and Figures 70.5 through 70.8 provide clinical examples of the Prader scale. The disadvantage of the Prader classification is the assumption that there is a fixed association between the external appearance of the genitalia and the internal anatomy. In other words, sometimes a severely virilized genital tubercle can be associated with a low UGS and vice versa. An alternative standardization for the description of the virilized genital tubercle, known as PVE, has been suggested. P refers to the length and width of the phallus, V relates to the distance between the entry point of the vagina in the UGS and the bladder neck and the length of the common channel measured by endoscopy, and E is the Prader number.[32] Albeit more objective, this classification has not been incorporated into clinical practice by many centers.

FIGURE 70.5 Prader 2: Mild clitoromegaly with urethral and vaginal openings clearly separate on inspection.

FIGURE 70.6 Prader 3: Moderate clitoromegaly, but separate urethral and vaginal openings are still visible or the confluence is very low (close to the perineum).

Male undervirilization is portrayed by variable degrees of hypospadias (urethral opening in the ventral aspect of the penile shaft), which can also be associated with bifid scrotum, penile ventral curvature, and penoscrotal transposition. Similarly to the PVE system described above, a score system has been proposed for cases of undervirilization in order to standardize reports and allow comparisons between different centers. According to this system, external and internal masculinization scores (EMS and IMS, respectively) are generated, taking into account all the physical examination findings that have been mentioned.[33]

FIGURE 70.7 Prader 4: More significant clitoromegaly, labial fusion, and single perineal opening.

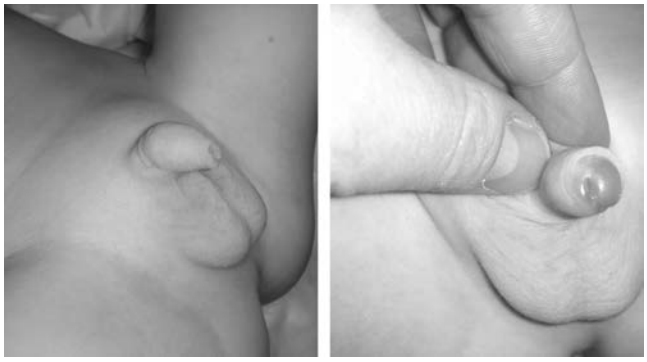

FIGURE 70.8 Prader 5: Note the undistinguishable appearance from male external genitalia and the UGS opening at the tip of the phallus.

Even in patients with normal-appearing male genitalia, a stretched penis shorter than 2–2.5 cm with a narrow breadth should be considered a micropenis and warrants further investigation.

In recent years, a rather simple measurement has been increasingly incorporated into clinical practice, the anogenital distance (AGD). It is regarded as a surrogate of androgen action and a permanent readout of the virilization process that occurred during fetal life. AGD is measured from the center of the anus to the base of the scrotum in males and to the posterior fourchette in females, and the normal male-to-female ratio is 2:1. Normative data for males and females up to 2 years old are available.[34] AGD has been demonstrated to be significantly lower in boys with hypospadias and adult men with infertility than in controls.[35,36] In females, a ratio between AGD and the distance between the anus and the base of the clitoris larger than 0.5 has been associated with severe virilization.

Diagnostic Tests

The most important initial diagnostic tests in the DSD workup are karyotype, pelvic ultrasound to evaluate the presence of Mullerian structures, and serum levels of sodium, potassium, and 17-hydroxyprogesterone (17OHP) after day 3 of life. A thorough history and physical examination (especially gonad palpation) coupled with the results of the aforementioned tests will allow the patient to be situated within the DSD umbrella, as well as receive a final diagnosis based on pathophysiology in the majority of cases. Other serum biochemistry tests frequently employed are androgen (testosterone, dihydrotesterone, and androstenedione), cortisol, gonadotropin, and AMH levels. In infants older than 3–6 months of age or if a defect of androgen production is suspected, it may be necessary to perform a stimulation test with human chorionic gonadotropin (hCG) to reliably estimate gonadal production of androgens. The availability of more advanced genomic technologies, such as genome-wide arrays to detect copy number variations and DNA sequencing at affordable prices, has exerted a positive impact on the assessment of patients with a suspected DSD, and this trend is likely to rise in the near future.[37]

Pathology reports from gonadal biopsies or removal may be helpful in formulating a more complete diagnosis, but such procedures are rarely performed in young newborns or infants right from the outset.

In the next sections, as each diagnosis is addressed individually, the constellation of clinical, genetic, and biochemical findings is detailed as well.

XX DSD (FORMER FEMALE PSEUDOHERMAPHRODITISM)

The XX DSD group can be further subcategorized into situations with androgen excess, disorders of gonadal development, and other problems (Figure 70.9).

Androgen Excess

Clinical situations where there is androgen excess leading to virilization of the female fetus can be divided according to the source of hormonal production into fetal, maternal, and placental. CAH remains by far the most common 46 XX DSD and the most frequent DSD overall.[2,20,38–40]

Congenital Adrenal Hyperplasia

CAH happens with an incidence of 1:10,000 to 1:20,000, live births.[41] The pathophysiology of CAH involves an enzymatic defect in the adrenal cortisol synthesis pathway, which leads to accumulation of precursors and excessive production of androgens (Figure 70.10). The most common enzymatic defect, which accounts for 95% of the cases, affects 21-alpha-hydroxylase (CYP21), following an autosomal recessive inheritance.[42] CYP21 has been mapped to chromosome 6. The genital tubercle shows variable degrees of virilization with bilateral *nonpalpable* gonads. Identification of Mullerian structures on US and 17OHP elevation confirm the diagnosis. Boys with this enzymatic defect do not present with genital ambiguity.

Three clinical forms of the disease are recognized. About 75% of the patients will have salt-wasting CAH, which can present with a life-threatening salt-losing crisis in the first or second week of life,[22,43] characterized by severe hyponatremic dehydration secondary to mineralocorticoid deficiency. In the simple virilizing form, residual enzymatic activity is enough for mineralocorticoid production, and nonclassic CAH is characterized by normal genitalia at

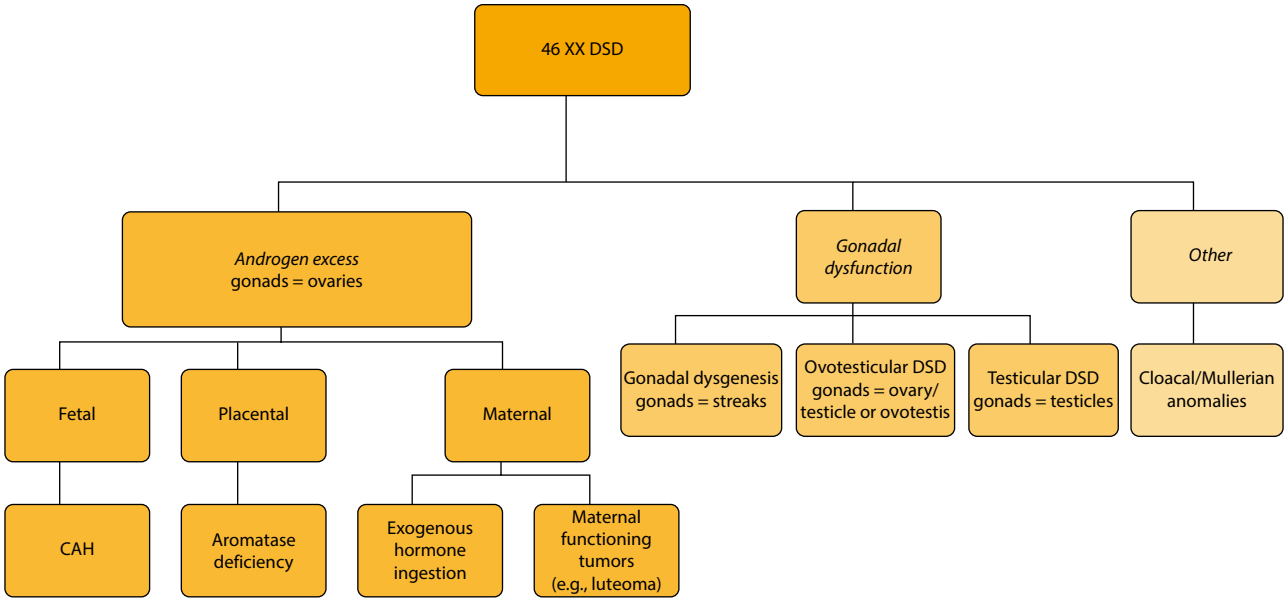

FIGURE 70.9 Diagram illustrating different causes of 46 XX DSD and the respective gonads seen with each cause.

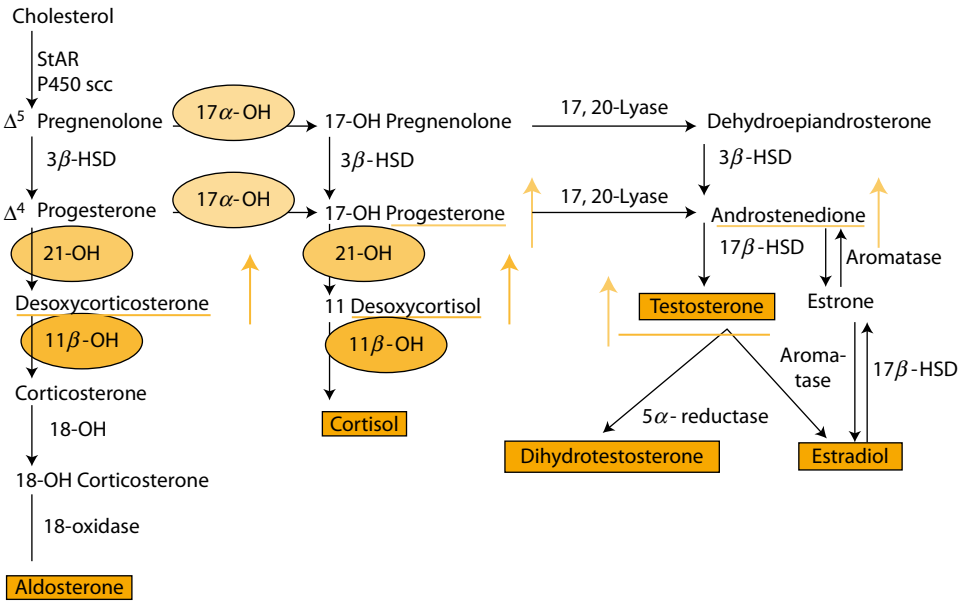

FIGURE 70.10 Cortisol synthesis pathway. The possible enzymatic defects seen with CAH are highlighted, as well as the precursors that accumulate, allowing for accurate diagnostic suspicion to be made.

birth and the onset of virilization at puberty. Although accurate determination of the type of CYP21 mutation in CAH often demands quite extensive genetic analysis due to rather complex genetic variations,[44] a high concordance rate between genotype and phenotype has been suggested; i.e., patients who are completely homozygous for a mutation (null genotype) usually have no enzyme activity whatsoever and present with severe virilization and salt-wasting disease. Conversely, patients who are compound heterozygotes for the mutations have variable degrees of residual enzymatic activity, which correlates with a milder phenotype (simple virilizing or nonclassical CAH). Interestingly, the salt-wasting form of CAH is usually associated with both the null genotype or the less severe I2 splice mutations; whereas the clinical presentation is similar for patients with either genotype, it has been demonstrated that patients with the null genotype are unique and significantly different from all the other groups in terms of gender role, sexual orientation, and psychosocial aspects (see below).[42,45] Newborn screening for 21-hydroxylase deficiency is available in many countries and allows diagnosis of CAH prior to a significant salt-wasting event.

Prenatal Treatment

Prenatal treatment of fetuses at risk for salt-wasting and simple virilizing CAH with dexamethasone remains highly controversial. The discussion does not apply to the nonclassic form of the disease. The possibility of reliably

determining fetal sex with noninvasive techniques (cell-free fetal Y DNA detected in maternal blood) as early as 4 weeks postconception holds promise, since it could allow significant reduction in unnecessary exposure to dexamethasone from seven in eight to three in four (female only) fetuses.[23] Yet, in the best-case scenario with the availability of early determination of fetal sex and amniocentesis for diagnostic confirmation at 14 weeks of gestation, three girls would be exposed to dexamethasone unnecessarily for 9–10 weeks. A recent systematic review[46] concluded that most studies on prenatal treatment are observational with low methodological quality. While the data suggest that prenatal treatment is successful in reducing virilization with no significant short-term side effects to the fetus or the mother, some degree of behavioral changes in children exposed to dexamethasone during pregnancy have been suggested and need to be investigated further before making any firm recommendations.[47] Prenatal treatment for CAH should still be regarded as experimental and discussed with families on an individual basis, with clear explanation of risks and benefits.[43]

Medical Management

Glucocorticoid replacement with the goals of replenishing the lack of cortisol and suppressing excessive androgen production by means of negative feedback on adrenocorticotropic hormone (ACTH) release remains the mainstay of medical therapy for CAH. Hydrocortisone is the preferred drug in children due to its short half-life, and it should be administered as crushed tablets.[41,43] Typical doses are in the range of 10–15 mg/m^2/day, with lower-range doses in toddlers and higher ones in adolescents.

Approximately three-fourths of the CAH population will have the classic salt-wasting form of the disease and also require mineralocorticoid replacement, in the form of fludrocortisone.

In adults, longer-acting and more potent drugs, such as dexamethasone or prednisone, are favored, since growth-suppressive effects are less relevant.

Currently, bilateral adrenalectomy is not part of the standard of care and should be considered only in cases of failed medical management, particularly in adult females with salt-wasting CAH and infertility, where compliance to medical treatment is not an issue.

Therapy is monitored through determination of morning blood levels of 17OHP and androstenedione. 17OHP reflects ACTH suppression, and complete normalization usually reflects overtreatment leading to hypercortisolism, which is also deleterious. In children, height and weight should be recorded in each follow-up visit, and a bone age should be performed yearly.[41,43] Patients with salt-wasting CAH also require Na, K, and renin monitoring.

A stress dose of steroids should be given in cases of febrile illness, dehydration, surgery, and trauma. Emotional or mental stress, as well as minor illnesses, does not require a stress dose.[43]

Gender Assignment

The DSD consensus supports female gender assignment for XX CAH patients, since more than 90% of those patients identify themselves as females[1,2] and the presence of normal female internal genitalia offers the potential for fertility. Furthermore, the incidence of gender dysphoria in adult CAH females was shown to be around 5%, which despite being a higher rate than what is found in the general population, was deemed to be acceptable to support a uniform female sex of rearing assignment in this population.[48] However, recent publications have questioned this practice for markedly virilized patients (namely Prader 5 and some Prader 4) and suggested that male gender assignment should be entertained in this particular situation.[49] A series of 12 XX CAH patients referred later in life assigned male gender demonstrated satisfactory male sexual function.[50] The topic is controversial, and at this stage, it is reasonable to state that the vast majority of XX CAH patients should be assigned females.

Timing of surgery

The timing and magnitude of surgical treatment for CAH have been a subject for intense debate in recent years. Surgical treatment for females with CAH involves feminizing genitoplasty, in the form of clitoroplasty and labioplasty, and vaginoplasty, which may be performed concomitantly or not, with the goal of exteriorizing the vagina and creating two separate openings for urethra and vagina.

Controversies surrounding the ideal timing for surgery (early infancy, i.e., first 6 months of life, vs. postpubertal) on the external genitalia have been raised and are truly unsettled. The DSD consensus, as well as the Endocrine Society CAH guidelines, recommends that for severely virilized females (Prader 3 and above), clitoral and perineal surgery should be offered in infancy, as long as performed by an experienced surgeon in a center where multidisciplinary care and psychosocial support to parents are available.[1,43]

A pro of early infancy surgery is normalization of the appearance of the external genitalia in accordance with the assigned female gender, which is the main reason driving parents to decide for this option. There is a perception that the girl left with a nonoperated virilized genitalia may go through unwarranted social interactions with her peers, leading to embarrassment and social withdrawal. Furthermore, the idea of "doing nothing" sometimes represents a stressful concept for some parents who have difficulties coping with the appearance of their child's genitalia. Lastly, notwithstanding the limited experience, some surgeons perceive feminizing genitoplasty in postpubertal girls as being technically more demanding.[51]

The main disadvantage of early surgery is that it excludes the patient from the decision to intervene and provide her own informed consent;[52] also, it is inherently associated with potential complications that are not amenable to diagnosis until later in life, such as decreased clitoral sensitivity and vaginal stenosis.

Scientific evidence supporting one or the other is faint.[3] Studies comparing parental anxiety or surgical results and perceptions by patients operated on early versus late have not been done, and the long time span needed to be able to measure outcomes poses an important methodological challenge. Long-term outcome studies of surgical intervention for CAH are scarce and often refer to surgical procedures that are outdated. Some reports suggest poor cosmetic and functional results of genitoplasty done in infancy,[53,54] with a high reintervention rate in adulthood

(especially due to vaginal stenosis[55]). A few publications have demonstrated that psychosexual outcomes in CAH patients are worse than in controls.[42,56] However, they do not seem to be necessarily related to surgical interventions, since the presence of a null genotype has been associated with poorer outcomes regardless of type of surgical treatment;[45] interestingly, most women in such reports, when questioned about the ideal timing for surgery, favor having surgery performed early in life.[45,56–58]

The authors favor that feminizing surgery should *not* be offered to girls with mild virilization (Prader 1 or 2 and some Prader 3). For those with Prader 4 or 5, surgery should only be performed after extensive discussion with the multidisciplinary team and active participation by families in the decision-making process. Regardless of the decision to perform surgery or not, parents should be under solid and continuous psychosocial support.

Since the vagina has no function in early childhood, vaginoplasty could be postponed until after puberty. The advantages of such an approach would be the inclusion of the patient in the informed consent process and assurance of cooperation for vaginal dilatations, if necessary. In addition, manipulation of the vagina is easier in the setting of higher estrogen levels. On the other hand, by not performing vaginoplasty at the time of clitoroplasty, the flaps from the UGS and prepuce would be discarded, and therefore would no longer be available for reconstruction of the distal vagina, which could represent a problem, especially in cases of high UGS or very small vaginas.

Technique

From a technical standpoint, feminizing surgery includes clitoroplasty or labioplasty and vaginoplasty. Procedures have evolved significantly in the past decade. In general, higher degrees of external virilization (Prader 4 and 5) are associated with a longer UGS and a higher insertion of the vagina. Occasionally, patients with severe virilization will have a low confluence and vice versa, so the surgeon should gather as much information as possible preoperatively to avoid surprises. That can be achieved through a genitogram performed with contrast injection in a retrograde fashion through the UGS and pan-endoscopy (cystoscopy or vaginoscopy) in the operating room to assess the length of the common channel and the level where the vagina enters the UGS.

CLITOROPLASTY

The first report of clitoroplasty (as opposed to clitoral amputation) for patients with enlarged clitoris dates back to the 1960s.[59] Later on, more elaborate techniques aimed at preserving the dorsal neurovascular bundle, and thus sensation, were described.[60,61] The procedure starts with a circumcision, followed by degloving that mirrors what is done for hypospadias repairs (Figure 70.11). The dorsal foreskin is split longitudinally, and the flaps obtained are used for labia minora reconstruction. Most authors suggest subtunical removal of erectile (corporal) tissue ventrally, sparing the glans with its neurovascular supply (Figure 70.12). After dissection is completed, the proximal aspect of the corporal bodies at the level of the crura

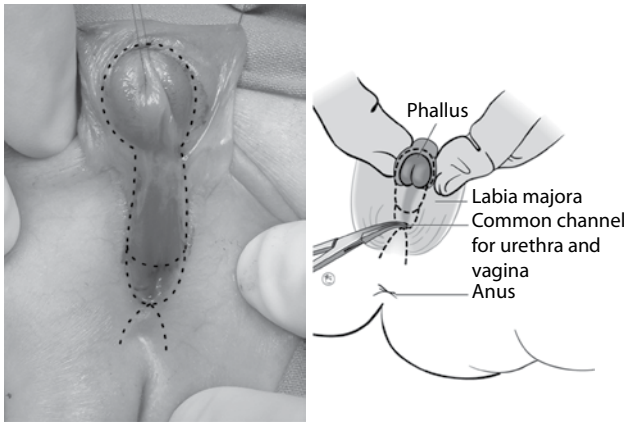

FIGURE 70.11 Outline of the initial incision for feminizing genitoplasty.

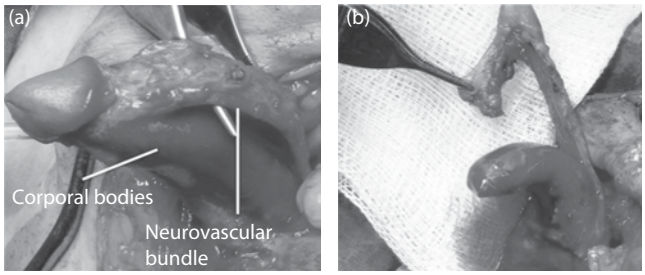

FIGURE 70.12 (a and b) Dissection of the clitoral corporal bodies from the dorsal neurovascular bundle.

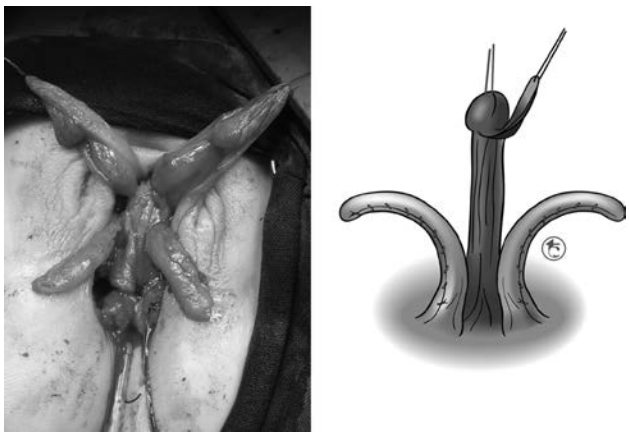

FIGURE 70.13 Dissection is complete. Neurovascular bundle and glans and corporal bodies are independent units.

is controlled with suture ligation for hemostasis, and the clitoris is receded with a stitch to the periosteum of the pubic bone. Maintenance of the dorsal clitoral skin is crucial since it has been demonstrated in healthy women that the clitoris and area above it are the key areas to achieve orgasm.[62] The scrotal-type skin is used for labia majora reconstruction. A corporal-sparing clitoroplasty where no tissue is ablated from the clitoris has been described, with the goal of preserving all sensation-bearing structures,[63] where the corporal bodies are separated and kept in a subcutaneous pouch after labial reconstruction (Figures 70.13

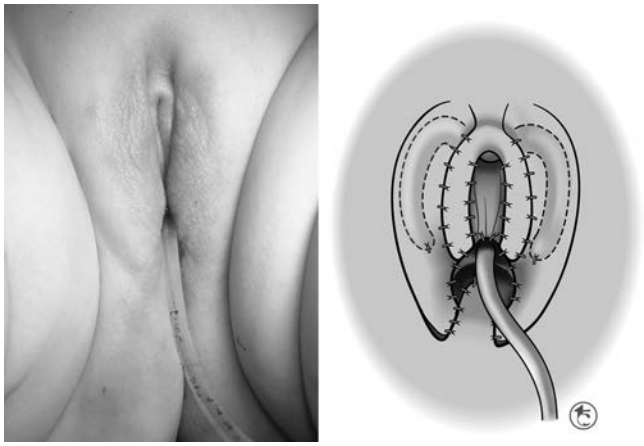

FIGURE 70.14 Final aspect of a feminizing genitoplasty. Note the schematic representation of corporal bodies spared and tacked to a subcutaneous pouch on either side.

and 70.14). In instances where the glans is too prominent, glans reduction can be done either by wedge resection or by deepithelization.[64]

VAGINOPLASTY

The choice of technique for vaginoplasty is contingent on the site where the vagina opens into the UGS. Some reports have suggested that a common channel of ≤3 cm would be the cutoff between a high and a low vaginal opening.[65] Others (including the authors) have implied that the distance between the urethrovaginal confluence and the bladder neck is in fact more important than the length of the common channel.[66,67] Figures 70.15 through 70.17 exemplify possible relationships between the urethra and vagina in a UGS. From a surgical perspective, techniques range from flap vaginoplasties (Fortunoff and Passerini–Glazel) to vaginal pull-through after complete separation from the UGS, going through total and partial urogenital mobilization.

With the flap techniques, a perineal skin flap is used to bridge the gap between the vagina and the perineum. The Fortunoff flap was described in 1964 and consists of an inverted U-shaped incision in the perineum that is elevated as a flap and sutured to the posterior wall of the vagina.[68] In the Passerini–Glazel technique, the vagina is disconnected from the UGS and the so-called mucocutaneous plate from the UGS is tubularized and anastomosed to the vagina.[69] When flap techniques are utilized, only the posterior vaginal wall is mobilized. The actual anterior vaginal wall is never mobilized, and a mucocutaneous flap of UGS is required to bridge the gap between the hypospadiac urethra and the perineum; the result is a simple augmentation of the UGS diameter. For a long time, flap vaginoplasties were widely employed even for the high UGS, since they were the only available alternatives, which probably explains the high reported incidence of vaginal stenosis requiring reintervention in some series.[42,55]

In the last two decades, total and partial urogenital sinus mobilization (TUM and PUM, respectively) have been introduced to the surgical armamentarium

FIGURE 70.15 Genitogram demonstrating an intermediate confluence between the urethra and vagina—the common channel extends until the midportion of the urethra where the vagina enters.

FIGURE 70.16 Genitogram demonstrating a very low UGS. It is likely that upon inspection of the genitalia with gentle traction of the labia, one would be able to visualize separate openings.

FIGURE 70.17 Example of a very high UGS. The vagina enters the common channel almost at the level of the bladder neck. Note that the UGS resembles the male urethra.

of vaginoplasties as a technical variation of the surgical approach to cloacal repairs described by Peña.[70] He observed that patients with cloacal anomalies that underwent extensive repairs where separation of the rectum, vagina, and urethra was attempted commonly developed complications related to the urogenital portion of the procedure, namely, urethrovaginal fistulas. He described total mobilization of the UGS as a unit (TUM) in order to minimize those complications, and following that, other authors expanded on the indication to include vaginoplasty in CAH patients.[65] TUM seems to produce better results than flap vaginoplasties, especially in low UGS.[71] Nonetheless, the problem of high vagina remains, due to the need of extensive mobilization, which is concerning for the possibility of disrupting the urinary continence mechanism by placing undue traction on the bladder neck. To limit such potential disruption, PUM was devised, where the same principles of TUM are followed, except that the pubourethral ligaments are not incised.[72,73] A recent comparison between the two techniques in terms of urinary continence showed no difference after 4 years of follow-up.[74] However, long-term follow-up is definitely warranted, especially after situations like pregnancy and delivery, to ensure no urinary functional issues will arise. In both techniques, the excess mucosa from the UGS after mobilization can be used to create a mucosa-lined vestibule.[66]

As outlined above, the most challenging aspect of the surgical treatment of CAH is the vagina with high insertion in a long UGS. Although flap vaginoplasties have been widely employed even in this scenario, in our view, the best approach for such cases is a vaginal pull-through, where the vagina is disconnected from the UGS, which in turn will be kept as a urethra, and mobilized to the perineum. This technique was initially described using an anterior perineal approach,[75] which proved to be quite technically demanding and was later replaced by a posterior sagittal approach, similarly to what is done for anorectal malformations, with a protective colostomy.[76] In recent years, the anterior sagittal transrectal approach (ASTRA) was introduced;[77] in this technique, only the anterior wall of the rectum is opened longitudinally, with the patient in the prone position, allowing the high vagina to be separated from the urethra and mobilized to the perineum with improved exposure in a more ergonomic way for the surgeon (Figure 70.18a and b). In our view, the ASTRA approach offers better exposure, facilitating the dissection and separation of the vagina from the UGS[67] without the need for a colostomy or extensive bowel preparation. Others have suggested that the vaginal pull-through can be performed without opening the rectum, as long as the patient is placed in a prone position.[66] Despite the improved exposure, dissection and mobilization of the vagina in the infant can be challenging given its inherent friability. The use of topical estrogens on the genitalia

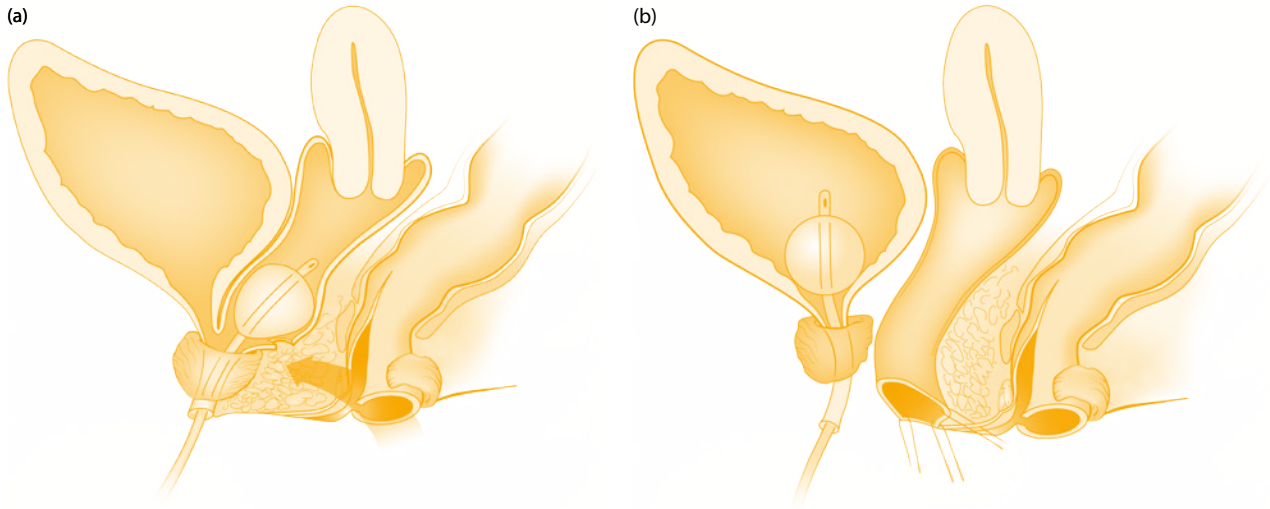

FIGURE 70.18 (a and b) Schematic illustration of the transrectal approach for the high vagina (ASTRA).

4 weeks before surgery in this age group, with the goal of increasing the robustness of the genital structures for surgical manipulation, has produced encouraging preliminary results. Many patients undergoing vaginoplasty in infancy will require dilatations or minor procedures after puberty; however, repeated interventions in the prepubertal patient should be avoided.

Maternal and Placental Causes of Androgen Excess

The most common maternal cause of virilization is exogenous administration of androgenic drugs. Whenever there is a history of maternal virilization (development of acne, voice changes, and clitoromegaly) during pregnancy, the possibility of placental aromatase deficiency and, rarely, maternal androgen-secreting tumors, such as luteomas, should be entertained.[1,22,78] In these situations, maternal testosterone is usually high and estradiol low. After birth, withdrawal of the androgenic stimulus may lead to significant reduction in clitoral size, which justifies taking an initial conservative approach in such cases.

Disorders of Gonadal Development

This category encompasses problems of ovarian development. Included in this subcategory are ovotesticular DSD, gonadal dysgenesis, and testicular DSD. 46 XX gonadal dysgenesis is exceedingly rare and not seen in infancy, since there is no genital ambiguity. Testicular and ovotesticular DSDs can share common genetic features, and the concomitant reported occurrence in monozygotic twins suggests a possible common origin.[79] In more than 80% of the testicular DSD patients, a translocated copy of the SRY gene is identified in the X paternal chromosome;[80] in contrast, only 10% of ovotesticular DSD patients are SRY+.[81]

Ovotesticular DSD

Ovotesticular DSD replaced the term *true hermaphroditism* and is defined by the presence of normal ovarian tissue containing follicles and normal testicular tissue containing tubules in the same individual. The tissues can be present within the same gonad (ovotestis) or independently (ovary and testicle). The most common gonadal combination is ovotestis–ovary, followed by ovotestis–ovotestis, ovary–testis, and less frequently, ovotestis–testis.[81] The occurrence of ovotesticular DSD is quite rare.[20,21] Patients with this entity usually present with genital ambiguity and marked asymmetry of the external genitalia (Figure 70.19). Associated inguinal hernia is common. The most common karyotype is 46 XX (about 60% of the cases), followed by mosaicism containing a Y chromosome (25%) and XY (15%). Gender assignment decisions are individualized based on the appearance of the external genitalia, hormonal profile, and response to hCG and are usually split equally between male and female gender.[82,83] Surgical treatment will entail removal of discordant gonadal tissue and other structures to the sex of rearing. The same controversy presented before in terms of timing of genital surgery exists, and psychosocial support to patients and families is paramount, as in any other type of DSD.

FIGURE 70.19 Example of significant asymmetry of the external genitalia on inspection.

Testicular DSD

Most patients (80%) with 46 XX testicular DSD (formerly called "XX male") present after puberty with normal genitalia, pubic hair, small testes, and gynecomastia. They are usually infertile men due to azoospermia that demonstrate hypergonadotropic hypogonadism biochemically. The remainder usually present at birth with ambiguous genitalia.[80]

Other Causes

Miscellaneous rare conditions, also called nonhormonal DSDs, are included in this subcategory. Examples are cloacal and Mullerian anomalies. Cloacal anomalies, including cloacal exstrophy, will be covered in Chapter 73. It should be kept in mind that a newborn baby with an ambiguous genitalia and a single perineal opening is a female with a cloacal anomaly until proven otherwise (Figure 70.20).

FIGURE 70.20 Newborn with cloacal anomaly and virilized appearance of external genitalia.

XY DSD (FORMER MALE PSEUDOHERMAPHRODITISM)

XY DSD is a more diverse and heterogeneous group than XX DSD. The success rate in establishing the precise pathophysiology and etiology of 46 XY DSD is far lower than that in XX DSD (Figure 70.21).[2] Furthermore, this category encompasses a wider range of diagnoses where genital ambiguity is not necessarily present. Finally, gender assignment discordant to karyotype (i.e., female assignment) is prevalent in this group. Similarly to XX DSD, the XY group can be subcategorized in disorders of gonadal (testicular) development, androgen synthesis, androgen action, and other problems (Figure 70.1).

Disorders of Androgen Action

Partial Androgen Insensitivity Syndrome

The vast majority of patients in the XY DSD group will present with variable degrees of undervirilization despite normal androgen production by the pituitary–gonadal axis, normal AMH function (depicted by the absence of Mullerian structures), and normal testicular histology. Several mutations in the AR have been identified that can lead to variable degrees of androgen insensitivity syndrome;[84] however, the most optimistic reports estimate that no more than 50% of cases of undervirilization will have an identifiable AR mutation,[8] and a precise etiology remains undefined for most of them. Although the term *partial androgen insensitivity syndrome* (PAIS) is used interchangeably both for patients with and those without a proven AR mutation, most authors agree on the inadequacy of the term PAIS when the mutation is not confirmed. Recent studies have pointed out mutations in the Mastermind-like domain containing 1 (MAMLD1) as an additional possible etiology for PAIS-like phenotypes with a normal AR.[8,85]

Environmental endocrine disruptor chemicals (EDCs) have also been related to the rising incidence of hypospadias, cryptorchidism, and male infertility in the general population.[86]

Since the yield of diagnostic studies is so low and potentially costly, a question that is pertinent to the pediatric urologist is, which patients deserve to be investigated? Patients that are not considered to have ambiguous genitalia per se, with common conditions such as hypospadias or bilateral undescended testicles, will commonly be referred for surgical treatment, and drawing the line of which patients will truly benefit from additional genetic and biochemical testing can be rather challenging. Traditionally, the 2/3 rule has been taught, where the phallus and each gonad represent a unit and abnormalities in two out of three (e.g., hypospadias and one undescended testicle, or normal phallus with two nonpalpable testicles) would warrant further investigation. Approximately 1/3 of patients with proximal hypospadias and at least one undescended testicle have an abnormal karyotype, but the yield is lower if patients with distal hypospadias are included.[87] Furthermore, it seems that a nonpalpable gonad is more predictive than a palpable one when the association of hypospadias and undescended testicle is studied for the presence of a DSD condition.[88] Albeit the consensus advocates for a full DSD workup for patients with perineal hypospadias and bilateral descended testicles,[1,2] a review of the authors' data showed that the large cohort of such patients with well-developed phallus and scrotum with 46 XY karyotype was uniformly assigned male and found not to harbor any Mullerian structures. Therefore, it seems that labeling such patients as having "ambiguous genitalia" is inappropriate, and lengthy delays in sex assignment for such patients should be avoided, as this is a significant source of stress for parents and has no impact on the management.[89]

Gender Assignment

In patients with PAIS and PAIS-like phenotypes, gender assignment can be rather challenging in the setting of significant undervirilization and a small phallus. Recent studies have documented the existence of a masculinization

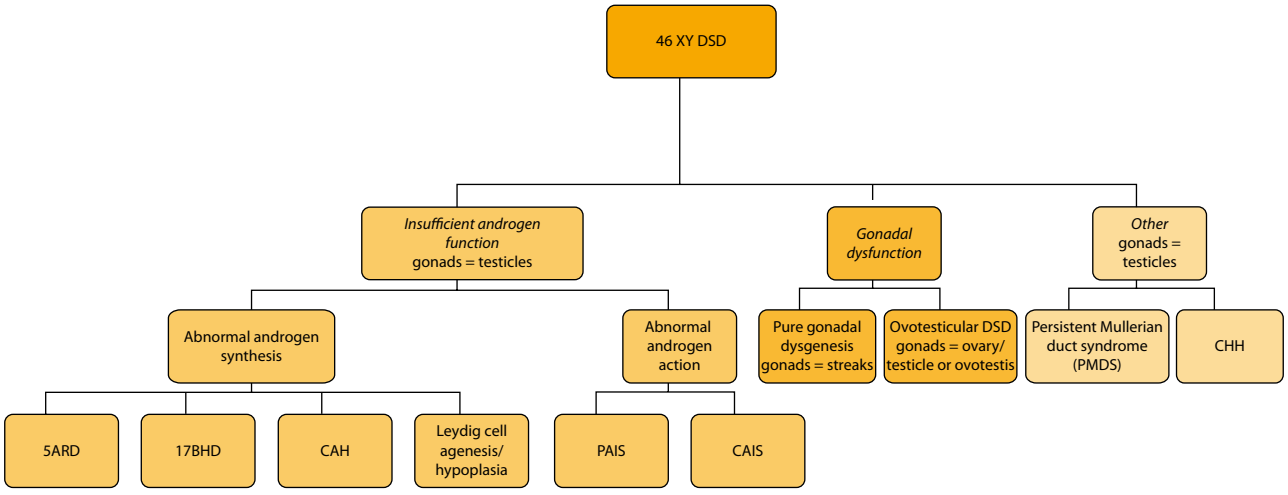

FIGURE 70.21 Diagram illustrating differential diagnoses for XY DSD. 5ARD, 5-alpha-reductase deficiency; 17BHD, 17-beta-hydroxysteroid dehydrogenase deficiency.

programming window, i.e., a critical moment of androgen exposure prenatally; interestingly, although this window, believed to take place between 8 and 12 weeks of gestation, seems vital for penile development and growth, at 14 weeks there is not a significant difference between the size and appearance of the clitoris and the penis. Therefore, it has been hypothesized that the masculinization window is key for brain imprinting and development of a male identity.[90] In fact, it could explain the male gender role adopted by some CAH patients with severe virilization (possibly the ones bearing the null genotype), i.e., early exposure to androgens during development. Postnatally, there is another period of surge in luteinizing hormone (LH) and testosterone that seems important to ensure penile growth to full potential.

In the past, severely undervirilized XY patients were offered feminizing surgery, gonadectomy, and hormonal replacement as part of the "optimal gender approach," which was based on the assumption that sex of rearing would overrule chromosomal or gonadal sex ("nurture over nature").[30,91] This concept has been challenged in face of long-term outcomes studies suggesting that XY DSD patients are usually satisfied and lead a well-adjusted sexual life regardless of their sex assignment.[91,92] Partially virilized XY females demonstrate the highest rates of gender dysphoria and need for reassignment among all patients with a DSD, as well as dissatisfaction with surgical interventions.[93] Therefore, patients with at least one functional testicle and reasonable penile tissue on palpation should be raised as males.[50,94] A stimulation test with hCG can estimate the ability of the testicle to produce testosterone by assessing the response of the external genitalia. When there is poor production of testosterone by the testis, exogenous administration is warranted. Patients with very poor response to testosterone remain a difficult group to assign, and a multidisciplinary decision is essential.

If male gender is assigned, surgical management will usually entail orchidopexy and hypospadias repair, topics that will be covered in other chapters.

Complete Androgen Insensitivity Syndrome

Patients with CAIS do not present with genital ambiguity. A mutation in the AR is identified in up to 80% of patients with CAIS.[84] Such mutations are transmitted following an X-linked pattern; i.e., females are carriers, whereas males develop clinical manifestations. Complete absence of androgen action precludes any virilization of the external genitalia. Patients with CAIS are usually diagnosed in infancy or childhood when a testicle is palpated or found in the groin during an assessment or exploration for an inguinal hernia in an otherwise phenotypically normal female (Figure 70.22). Another possible clinical presentation is primary amenorrhea at puberty. These patients usually have a male-typical androgen profile, commonly responding with significant elevation in testosterone levels after stimulation and no identifiable Mullerian structures. Most CAIS patients are being raised as females at the time of diagnosis, so gender assignment is not commonly an issue. About 60% of CAIS patients develop Wolffian structures (vas deferens and seminal vesicles) due to a paracrine effect of testosterone.

FIGURE 70.22 Testicle identified in the inguinal canal during a hernia repair in a phenotypically normal female with CAIS.

Historically, these patients underwent gonadectomy soon after diagnosis, due to an increased risk for germ cell malignancies, followed by lifelong hormonal replacement to induce pubertal changes and development of secondary sexual characteristics. The exact risk of malignancy in patients with CAIS is not well known, but is clearly above that in the general population.[95] Since the gonads are not dysgenetic and most patients with testicles in situ will experience spontaneous puberty secondary to conversion of testosterone into estrogen through aromatization, a case has been made for delaying gonadectomy at least until puberty is complete.[96] Furthermore, recent reports challenge the need to perform gonadectomy at all, since there have been anecdotal reports of loss of libido following gonadectomy. In addition, concerns have been raised around long-term hormonal replacement and even the potential of the gonads harboring viable germ cells that could be used for fertility purposes in the future with advanced technology.[95] Appropriate follow-up modalities and screening intervals for gonadal tumors have not yet been delineated, as most patients have undergone gonadectomy at the time of diagnosis or after the completion of puberty. In postpubertal patients who choose to retain the gonads, surveillance with yearly ultrasounds is strongly advised.[95]

CAIS patients usually have a short, blind-ending vagina; procedures that may be required to ensure proper intercourse range from simple dilatations to more complex reconstructive procedures, like sigmoid vaginoplasty.[97] Such interventions should only be offered to patients who are motivated to engage in sexual activities, and therefore comply with the need of postoperative dilatations. Despite being well adjusted as females based on long-term follow-up studies,[92] high rates of dissatisfaction with sexual activity have been reported in this patient population, underscoring the importance of long-term psychological support.[93]

Disorders of Androgen Synthesis

Included in this subcategory are 5-alpha-reductase and 17-beta-hydroxysteroid dehydrogenase deficiencies, some rare forms of CAH (3-beta-hydroxysteroid dehydrogenase

and 17-alpha-hydroxylase deficiency), Leydig cell agenesis or hypoplasia (associated with LH receptor mutations), and other exceptionally rare enzymatic defects.

5-Alpha-Reductase and 17-Beta-Hydroxysteroid Dehydrogenase Deficiencies

These enzymatic deficiencies represent disruptions of the final pathways of androgen synthesis in the testis. 5-Alpha-reductase is composed of two isoenzymes, and SRDA2 is responsible for conversion of testosterone into DHT. Deficiency of this enzyme will usually lead to variable clinical features of genital ambiguity, but complete female phenotypes or isolated micropenis is also possible.[98] Along with PAIS, SRDA2 deficiency is part of the differential diagnosis for undervirilization in patients with a normal pituitary–gonadal axis (i.e., normal gonadotropins and testosterone levels). The diagnosis is suspected due to an abnormally high T/DHT ratio, with several mutations being described. Interestingly, the analysis of a large cohort of patients with XY DSD and normal testosterone production yielded a mutation in the AR in 42.5%; however, new polymorphisms associated with mutations in the SRD5A2 gene were recognized with a frequency higher than once considered (6.2%), thus explaining variable phenotypes of 46 XY DSD.[99] This finding has been corroborated by other publications that, besides identifying new mutations in SRD5A2, found a higher than previously reported incidence of mutations in XY partially virilized adult females.[100]

17-Beta-hydroxysteroid dehydrogenase isoenzyme 3 converts androstenedione to testosterone. The most common phenotype associated with abnormalities on its gene (HSD17B3) is a complete female-appearing external genitalia, although ambiguity is also possible. Diagnosis is suspected on the basis of an elevated androstenedione/testosterone ratio.

The interesting common feature shared by 5-alpha-reductase and 17-beta-hydroxysteroid dehydrogenase deficiencies is that although most patients are initially raised as females,[98] severe virilization can take place at the time of puberty, leading to self-reassignment to the male gender.[30] Hence, when the diagnosis is made in infancy, the consensus position is that strong consideration for male assignment should be given, as even the potential for fertility can be expected.[1]

CAH in XY Patients

Males with CAH due to CYP21 deficiency do not present with genital ambiguity. Nonetheless, higher infertility rates have been reported in this group than in the general population. Testicular adrenal rest tumors (TARTs), which are located in the rete testis and can cause obstruction of the seminal ducts with subsequent testicular damage, are thought to be the main cause for infertility.[43,101]

Less common enzymatic defects, such as 3-beta-hydroxysteroid dehydrogenase and 17-alpha-hydroxylase deficiencies, are examples of forms of CAH that can produce variable degrees of undervirilization due to blockage of testosterone production. Adrenal crisis is anticipated due to a lack of production of mineralocorticoids and cortisol. Such patients follow replacement protocols similar to those for females with salt-wasting CAH and require reconstructive penile procedures following the techniques described for hypospadias repairs.

Nonclassic Lipoid Congenital Adrenal Hyperplasia

Lipoid CAH is a rare autosomal recessive disorder of both adrenal and gonadal steroidogenesis. It is caused by mutations in the steroidogenic acute regulatory protein (StAR) gene and is characterized by a defect in the conversion of cholesterol into pregnenolone, leading to complete deficiency of glucocorticoids, mineralocorticoids, and sex steroids. There is a spectrum of clinical presentation, which correlates with the molecular defect. In the most severe end, XY patients depict complete sex reversal and severe adrenal crisis early in life with significantly enlarged adrenal glands on imaging studies due to cholesterol accumulation. The occurrence of less severe manifestations, including variable degrees of undervirilization and adrenal crisis with late onset, explains why even patients with a PAIS-like profile may have this disease and underscores the importance of genetic studies to enhance the understanding of DSD mechanisms and thus aid in treatment and counseling.[102]

Disorders of Testicular Development

Genes involved in normal testicular development have been described in the "Genital Development" section. These disorders will impair the ability of the testicle to produce testosterone to a variable extent, ranging from no production whatsoever (featured clinically by sex reversal) to subnormal production presenting with a spectrum of undervirilization. An overview of the different clinical situations is outlined below.

Pure Gonadal Dysgenesis: XY Sex Reversal

In pure gonadal dysgenesis (PGD), also known as Swyer's syndrome, patients are phenotypically female with normal Mullerian structures and bilateral streak gonads. These patients usually present in adolescence for primary amenorrhea. In contrast with CAIS, their testosterone levels are usually low, even after stimulation. Early gonadectomy at the time of diagnosis is advised due to the high risk of malignancy (gonadoblastoma [GB] and dysgerminoma, which have been described as early as the second decade of life[103]), and female gender assignment is a consensus.

Ovotesticular DSD

Only 15% of patients with this condition have an XY karyotype; refer to the "XX DSD" section for details.

Other XY DSDs

Persistent Mullerian Duct Syndrome

Persistent Mullerian duct syndrome (PMDS) does not present with genital ambiguity. Patients are usually males with cryptorchidism found to harbor Mullerian structures in the abdomen (uterus, cervix, and proximal third of the

vagina). It is caused by a mutation on the gene that encodes either AMH or its receptor; such mutation is transmitted following an autosomal recessive trait. Surgical removal of the Mullerian structures seems logical since malignancies have been reported and at times their attachments can hinder the performance of a tension-free orchidopexy. Removal can be achieved laparoscopically with care being taken not to damage the vas deferens.[104] When Mullerian remnants are found during an inguinal orchidopexy, the proximal aspect of the fallopian tube can be transected and removed with the uterus, leaving its distal component attached to the vas deferens, allowing the testis to be brought to a scrotal position. Such a maneuver avoids separation of the tube from the cord structures, protecting the deferential and testicular blood supply.

Causes of Micropenis Associated with Hypogonadism

Two conditions that present with micropenis with or without cryptorchidism deserve to be mentioned: congenital hypogonadotropic hypogonadism (CHH) and testis regression syndrome.

CHH presents more commonly as an isolated condition transmitted following an autosomic recessive pattern, but it can be part of a pan-hypopituitarism disorder. Moreover, CHH coupled with anosmia characterizes Kallman's syndrome, with variable patterns of inheritability being described (X linked, autosomic dominant, or recessive). CHH usually presents with isolated micropenis (without hypospadias) accompanied by cryptorchidism in the most severe form of the disease. A biochemical profile shows low levels of FSH, LH, and testosterone, but a good response to an hCG stimulation test. The cornerstone of CHH treatment is exogenous replacement of gonadotropins, which allows for reasonable penile length to be achieved.[105] Cryptorchidism, whenever present, is approached surgically without any peculiarities.

Testis regression syndrome (also referred to as bilateral vanishing testis syndrome) has a very similar clinical and biochemical profile, with the exception that testosterone levels do not respond to exogenous stimulation with hCG.[106] Testes are usually very small and undescended, and the need for their removal is somewhat controversial but favored by most given the presence of viable germ cells in roughly 10% of cases.[107] Testosterone replacement should in theory be able to drive pubertal changes, but long-term follow-up is scant.[106]

SEX CHROMOSOME DSD (MOSAIC KARYOTYPE)

This subgroup includes any DSD patient with a mosaic karyotype (Figure 70.23). It encompasses patients with Turner (45 X) and Klinefelter syndromes; the latter can be associated with genital ambiguity (usually undervirilization), although rarely so. In most patients with Klinefelter syndrome, the testicles and the pituitary–gonadal axis are normal until the onset of puberty.[108] From the DSD perspective, the main diagnosis in this group is MGD associated with a 45 X/46 XY karyotype. Interestingly, more than 90% of patients with a 45 X/46 XY karyotype

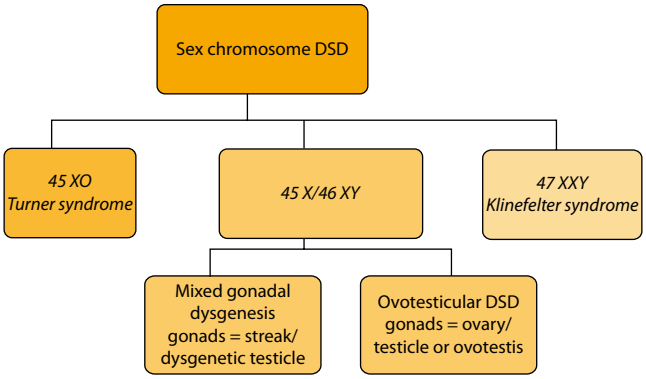

FIGURE 70.23 Diagram of the most common sex chromosome DSD situations.

detected prenatally have a normal male phenotype and present later in life with short stature and/or infertility.[28] Patients with ovotesticular DSD can also present with such karyotype (see above).

Mixed Gonadal Dysgenesis

Patients with MGD generally present with genital ambiguity, asymmetrical external genitalia, and not uncommonly, inguinal hernias. Their gonad configuration is streak or testicle. The testicular position is variable, ranging from orthotopic to intra-abdominal. The testicle can be histologically normal or dysgenetic. Intra-abdominal testes are more commonly dysgenetic.[109] It is not uncommon to see evidence of virilization only on the side where the testicle is present and Mullerian structures on the side of the streak gonad. The degree of virilization is variable and compatible with the ability of the dysgenetic testicle to produce testosterone. Similarly to ovotesticular DSD, clinical presentation (appearance of the external genitalia), as well as hormonal profile, is widely variable, which explains the reason for the absence of a formal recommendation for gender assignment, with reports approaching 50% for male and female.[21,109]

The streak gonad is at risk for GB and should be removed irrespective of the sex of rearing. In patients raised as females, the testicle should be removed as well. Conversely, it is acceptable to keep the testicle in patients raised male, as long as they can be brought to a scrotal position for surveillance, since it seems that tumor risk in this population is directly related to the degree of masculinization[110] (i.e., the more masculinized, the lower the risk of malignancy). The long-term potential for fertility is deemed as low, but exact figures remain unclear.[109]

DSD GONADS AND CANCER RISK

Virilized 46 XX DSD patients are *not* at increased risk for gonadal tumors. Nevertheless, patients with any form of gonadal dysgenesis or undervirilization can develop germ cell tumors (GCTs), which are dichotomized further into seminomatous (seminoma of the testis and dysgerminoma of the ovary or streak, which are morphologically and genetically identical[111]) and nonseminomatous, the

latter being associated with multiple variants, i.e., yolk sac tumor, teratoma, choriocarcinoma, and embryonal carcinoma.[112] The type of tumor developed will be contingent on the degree of masculinization or "testicularization" of the gonad.[111]

The precursor lesion of GCTs in testes is carcinoma in situ (CIS), also called intratubular germ cell neoplasia. Conversely, the CIS counterpart in the dysgenetic gonad with a low level of virilization (streak or ovary) is called GB. The coexistence of both precursor lesions in the same gonad is possible. Furthermore, the risk of GCT development in DSD patients seems to be directly related to the presence of a particular portion of the Y chromosome, known as the gonadoblastoma region (GBY). Currently, the candidate gene that stands out in this region is the testis-specific protein (TSPY). Characteristics that modify the risk for developing GCT apart from the presence of the GBY region are position (abdominal, inguinal, or scrotal) and state of maturation. Seminomas have been shown to be much more frequent in intra-abdominal testicles.[111]

Gonads that have accomplished more in terms of maturation (ovary, testicle, and even ovotestis) are at lower risk for tumor development than the ones retaining immature structures. The aforementioned characteristics constitute the rationale to use molecular markers for the prediction of risk of tumor development, depending on the diagnosis, clinical features, and histology of gonadal biopsies. Hence, coexpression of OCT3/4, markers of the presence of gonocytes or primordial germ cells, and TSPY flag germ cells at risk. It should be noted that germ cells may depict such markers just as a consequence of delayed maturation, which is particularly common within normal testicles in young infants, since spermatogonia only complete their development after puberty, in contrast to oogonia, which have been converted to oocytes at birth. Stem cell factor (SCF), the ligand of c-kit, seems crucial for migration and survival of primordial germ cells; however, it is not identifiable under physiologic conditions in human gonads. Remarkably, it is consistently present in testicles showing CIS and GB, but not maturation delay. Therefore, immunohistochemical staining for such markers combined with SOX9 (Sertoli cell marker) and FOXL2 (granulosa cell marker) in biopsy specimens may provide the grounds for proper risk stratification and follow-up decisions.[111]

Whenever operating on a supposedly dysgenetic gonad, careful attention should be directed to its shape, color, adnexa structures, and size. Streak gonads should be removed, and the ideal approach will be either laparoscopy or inguinotomy, depending on the location. In patients assigned male gender, Mullerian structures associated with the streak gonad can be removed simultaneously with it; however, the testicle should be preserved. If it is not in an orthotopic position, an orchidopexy should be performed. Once in a scrotal position, periodic surveillance with physical examination is advised; testicular biopsy at the time of orchidopexy and after puberty should be given consideration.[109] Whenever performing a biopsy on such testicles, a piece of tunica albuginea overlying the parenchyma should be included in the specimen, as well as blotted areas, which usually correspond to areas containing seminiferous tubules.

MULTIDISCIPLINARY APPROACH AND PSYCHOSOCIAL SUPPORT

DSDs represent a broad, complex field that requires interaction of multiple disciplines with a diverse knowledge base. One of the most significant contributions of the consensus was to bring such an assortment of professionals and patients' representatives to the same table in order to improve the care of patients with these difficult conditions, as well as provide standardization that facilitates communication between researchers.[113,114] Multidisciplinary care for DSD patients should be seen as standard and focused on the patient's best interest.[113]

Essentially, the roles in the multidisciplinary clinic should be well established: geneticists and genetic counselors have key participation in incorporating new methods for improved etiologic diagnosis, aiding insight into pathophysiological mechanisms and counseling; endocrinologists and surgeons and urologists are responsible for the central aspects of patient management; and gynecologists are key in the follow-up of teenage girls and issues related to sexuality and fertility. Participation of patient support groups in a constructive fashion[115] in forums of discussion and decisions about DSDs should be encouraged. Finally, lifelong psychosocial support cannot be underrated and is mandatory for every patient with a DSD. This support can be provided by a range of those with expertise in pediatric mental health, including social workers, psychologists, and/or psychiatrists (ideally all three). They provide support and guidance to families coping with the difficult period prior to the decision about sex of rearing, through the normal developmental transitions of childhood and adolescence, and support the move into adult care. They also provide links to peer support, whether it is through connecting families, facilitating contacts with patient support groups, or running groups for adolescents with DSDs. The benefits of such support cannot be underestimated. The clinic group may also include child life specialists, ethicists, and nurses. The multidisciplinary clinic ideally should also focus on transition from childhood into adulthood and research aspects at both the basic science (genetics and molecular biology) and clinical (long-term outcomes) levels.

CHAPTER 71

Anorectal Malformations and Cloaca

Andrea Bischoff, William R. DeFoor, Curtis A. Sheldon, and Alberto Peña

INTRODUCTION

The pediatric urologist must be familiar with the management of anorectal malformations (ARMs) and cloacal malformations (CMs). ARMs are commonly associated with surgically relevant urinary tract and vaginal pathology. The pediatric urologist is responsible for the management of these defects. Because these malformations are relatively uncommon, it is vitally important for the reconstructive surgeon to be familiar with the anatomy and pathophysiology of each of these. Considerable morbidity ensues if the surgeon fails to manage these defects in a thoughtful, deliberate manner. A multidisciplinary approach to children with complex CMs is appropriate and involves pediatric colorectal surgeons, pediatric urologists, pediatric anesthesiologists, and pediatric radiologists.

ARMs occur in approximately 1 in 4000 to 1 in 5000 live births.[1] Cloacal anomalies occur in 1 in 50,000 live births.[2] The incidence of mortality with ARMs has dropped dramatically over time. The morbidity associated with these anomalies is extensive and includes psychosocial developmental disorders, fecal incontinence, urinary incontinence, urinary tract infection (UTI), impaired intercourse, impaired fertility, and other abnormalities, such as limb anomalies, vertebral anomalies, neurologic deficits, and tracheoesophageal fistulas.

The history of imperforate anus management dates back to the seventh century, where the earliest reports of survival with surgery (rupture of an obstructing anal membrane) may be found. In 1835, Amussat performed a perineal proctoplasty. In the 1850s, various authors reported the use of colostomy, which opened the door for successful management of high ARM. An abdominal-perineal pull-through procedure was undertaken in the 1880s and advanced further by Rhoads.[3–5] In 1953, Stevens promoted a direct sacral approach to reconstruction, and in 1967, Kiesewetter combined these approaches into a two-stage sacroabdominoperineal pull-through procedure. Peña and Hendren ushered in the modern era of ARMs as well as cloacal management. Peña performed the posterior sagittal approach for the treatment of these malformations initially in 1980 and reported the results soon thereafter.[6]

Surgeons recognized the frequent association of urologic abnormalities associated with ARMs.[7–11] Similar recognition of the high incidence of spinal cord abnormalities, including occult spinal dysraphisms such as tethered cord, lipomas, neurenteric cysts, and diastematomyelia, advanced the management of these patients.[12–15] Patients with ARMs frequently require complex urinary reconstruction for which unique concerns must be addressed.[16]

DIAGNOSIS

Prenatal diagnosis of anorectal and urogenital malformations occurs with a frequency that ranges from 0% to 15.9% of screened cases.[17–19] It tends to be more commonly diagnosed in the more complex defects, such as cloaca and cloacal exstrophy. The advantages of having a prenatal diagnosis of these defects include planning for the delivery at a tertiary center that is familiar with the neonatal management of these types of anomalies, and preparing the parents for the birth of a child with serious congenital anomalies. Prenatal findings that should make the physician suspect an anorectal and urogenital malformation include distended distal bowel with or without intraluminal calcifications, in combination with urological abnormal findings (hydronephrosis or absent kidney) and/or vertebral anomalies.[20] Approximately 30% of the patients with cloacas have hydrocolpos, which can be seen in utero as a cystic pelvic mass of the fetus. Therefore, prenatal findings that suggest the presence of a cloacal anomaly include cystic pelvic masses and a combination of gastrointestinal and urological abnormalities. It is important to remember that 60% of patients with cloaca have duplications of the Mullerian structures; therefore, the finding of three cystic pelvic masses (bladder anterior and two hemivaginas with hydrocolpos posterior) represents a classic image of a CM.[20,21] Prenatal findings in cases of cloacal exstrophy include the nonvisualization of the bladder, a large midline anterior wall defect with an omphalocele, lumbosacral anomalies, and an elephant trunk–like image, representing the prolapsed ileum in between both hemibladders.[22,23]

CLASSIFICATION

The following proposed classification is anatomically descriptive and has therapeutic and prognostic implications. The defects are listed from the most benign to the most complex types. Interestingly, urologic anomalies, as well as digestive and skeletal ones, occur with

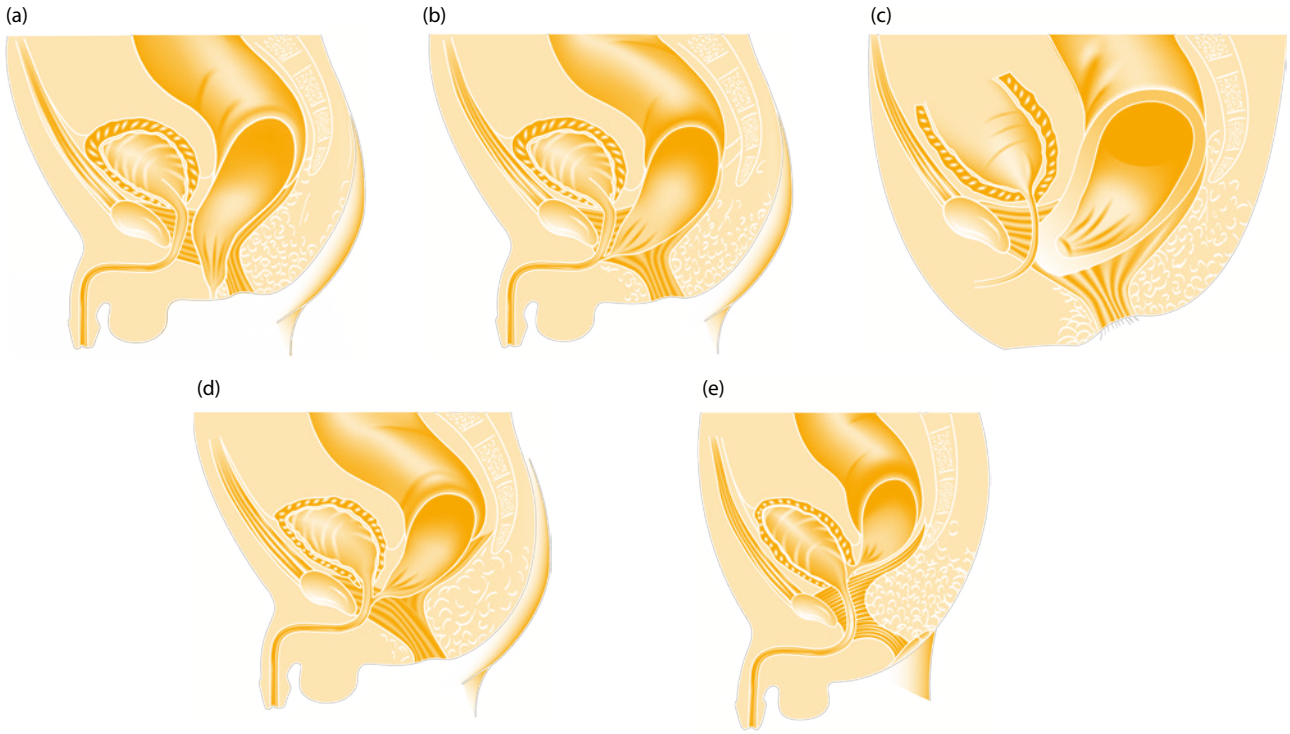

FIGURE 71.1 Diagrams of male ARM. (a) Rectoperineal fistula. (b) Rectourethral bulbar fistula. (c) Imperforate anus without fistula. (d) Rectourethral prostatic fistula. (e) Rectobladder neck fistula.

increasing frequency, almost in a linear fashion; the frequency increases the more complex the ARM.

ASSOCIATED SYNDROMES

We now know that urinary, genital, and anorectal development are intimately interconnected. As early as 1829, Mayer recognized an association between vaginal agenesis and other congenital anomalies.[24] Kuster and Rokitansky independently confirmed this observation.[25,26] Hauser and Schreiner, in 1961, emphasized the association of vaginal agenesis with skeletal and renal anomalies.[27] Thus, the final association became known as the Mayer–Rokitansky–Kuster–Hauser syndrome. Upper tract anomalies are encountered in approximately one-third of these patients, mostly consisting of renal agenesis, renal ectopia, and renal fusion anomalies.[28,29] Frequent skeletal anomalies were also noted, many of which involved abnormal cervical and thoracic somite development. Duncan, in 1975, referred to this as the MURCS association: Mullerian duct aplasia, renal aplasia, and cervicothoracic somite association.[30]

Similar to those observations associated with vaginal agenesis, repetitive patterns of anomalies were seen with anorectal anomalies. This constellation originally became known as the VATER association: vertebral, anorectal, tracheoesophageal, and radial. Later, it was expanded to the VACTERL association: vertebral, anorectal, cardiac, tracheoesophageal, radial or renal, and limb.[31–33]

ASSOCIATED SACRAL AND VERTEBRAL ANOMALIES

Two important anomalies that have a demonstrated influence on the functional prognosis of patients with anorectal and urogenital malformations are those of the sacrum and the presence or absence of tethered cord. These two defects can be evaluated during the first few days of life; this will allow the doctor to establish the future quality of life of the patient. A patient with a poor sacrum and tethered cord has little chance of having normal bowel and urinary control. In addition, those patients must be followed on a long-term basis since they have a tendency to suffer renal injury.

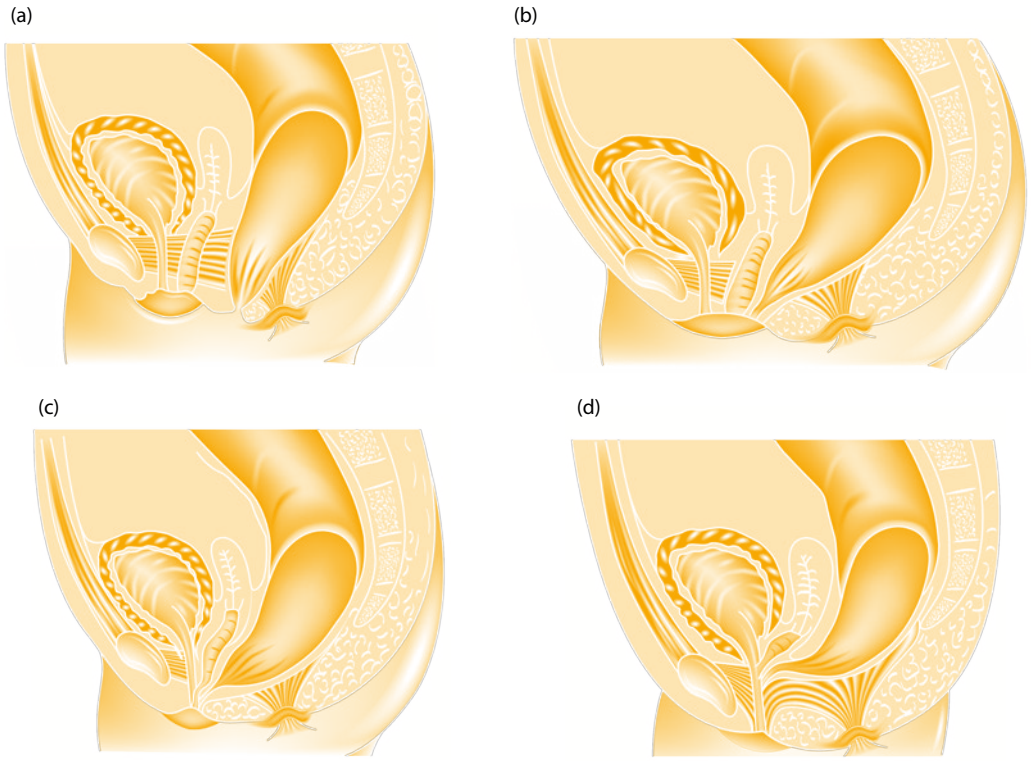

FIGURE 71.2 Diagrams of females with ARM. (a) Rectoperineal fistula. (b) Rectovestibular fistula. (c) Cloaca with a common channel length of <3 cm. (d) Cloaca with a common channel length of >3 cm.

The absence or presence of tethered cord seems to have more influence in the urinary tract. A deficient sacrum affects both urinary and bowel function, but it seems to have a major effect on bowel function. The sacral ratio is a valuable prognostic tool (Figure 71.3) because it quantifies the degree of sacral hypodevelopment. Patients with ratios of less than 0.4 are generally incontinent of stool. A sacral ratio of >0.7 predicts a good prognosis for bowel control. A sacral defect, particularly hemisacrum, in association with imperforate anus and a presacral mass is known as Currarino's triad; it has a strong familial tendency, and it is usually correlated with poor functional prognosis.[34,35] The types of ARMs more often associated with sacral defect and presacral mass are perineal fistula, vestibular fistula, and anorectal stenosis or atresia.

Lumbosacral anomalies, such as hemivertebrae, scoliosis, butterfly vertebrae, and hemisacrum, are common. The most frequent spinal cord problem is known as tethered cord,[14,36,37] but spinal lipomas, syringomyelia, and myelomeningocele are also commonly seen. The more complex the anorectal anomaly, the more likely the presence of associated spinal and vertebral anomalies. These problems are found by ultrasound or magnetic resonance imaging in a third to half of patients with ARMs.[13,38–40] It is still unclear how many of these lesions are clinically significant and which lesions require prophylactic surgery.[36,41]

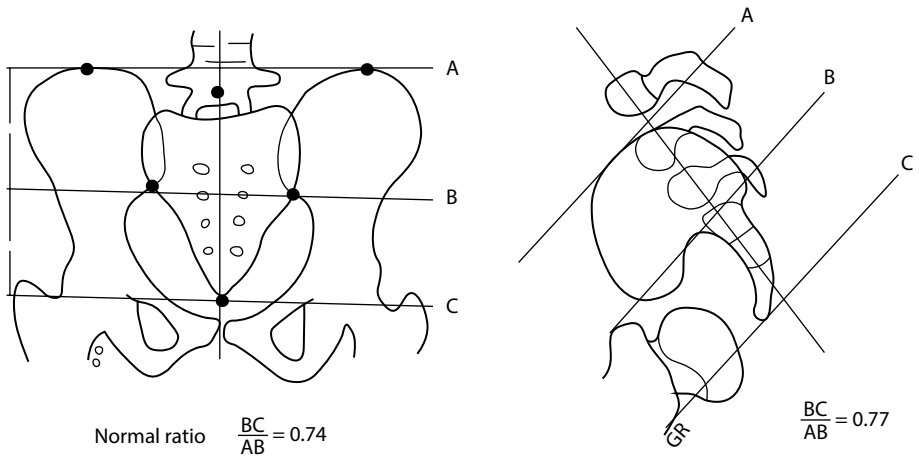

FIGURE 71.3 How to calculate the sacral ratio on AP and lateral sacral radiographs.

ASSOCIATED UROLOGICAL ANOMALIES

The prevalence of structural anomalies of the urinary tract in patients with anorectal anomalies is not insignificant. A review of a large ARM database from the senior author reveals the following urologic anomalies.[42] The most common urologic malformation associated with an ARM is an absent or multicystic kidney. The second most common defect is hydronephrosis. Another common urologic structural abnormality is vesicoureteral reflux (VUR), which was present in 290 out of 1370 female (21%) and 186 out of 1112 male (17%) patients in our ARM database. The presence of hydronephrosis and megaureter in a patient with ARM strongly suggests high-grade VUR, since the presence of a primary ureterovesical obstruction is uncommon in this population. There is one particular group of male patients born with the highest type of all defects (rectobladder neck fistula) who are born with a single kidney, hydronephrosis, and megaureter. We have seen this in 25 out of 111 (23%) patients born with that specific malformation. This particular group must be carefully followed since they tend to deteriorate and may progress to end-stage renal disease (ESRD), particularly if they have an abnormal sacrum and tethered cord. Some male babies are born with a narrowing or tortuosity in the proximal urethra. This is typically located at the fistula site where the rectum joins the urethra. We have seen this in 18 out of 1112 (2%) male patients. It can be helpful to repair this defect during the posterior sagittal anorectoplasty (PSARP), taking advantage of the excellent exposure provided by this approach. Approximately 10% of all male patients born with ARM have a bifid scrotum that can be mild or severe and associated with a penoscrotal transposition. The presence of a bifid scrotum can suggest a serious type of ARM (rectobladder neck or rectoprostatic fistula). Hypospadias can be present in approximately 8% of all male patients. Ectopic ureters occur in approximately 2% of patients with ARM, and the ureters tend to be connected close to or at the bladder neck level. They can occasionally be connected to the posterior urethra. In female patients, the ectopic ureter can be connected to the urethra or to the vagina. An ectopic vas deferens can be present in patients with ARM. An intraoperative vasogram has been used to document the connection to the bladder and/or ureter. These patients can develop recurrent orchioepididymitis. Epididymitis may reflect UTIs in the presence of dysfunctional voiding or urethral stricture pathology, or may be associated with intermittent catheterization. Congenital neurogenic bladder is present in babies born with a very deficient sacrum (sacral ratio <0.4), hemisacrum, and tethered cord. Neurogenic bladder in patients with normal lumbosacral spinal cord without cord tethering can be iatrogenic, secondary to a poor surgical technique observed during the repair of the ARM.[43] In addition to all the conditions mentioned above, the pediatric urologist will be consulted to take care of patients suffering from the sequelae of catastrophic operative complications. These include acquired urethral atresia, acquired urethral stricture, recurrent rectourethral fistula, and acquired rectourethral fistula. With the advent and popularization of the laparoscopic approach for the treatment of ARMs, a "posterior urethral diverticulum" has been described that actually represents a piece of rectum left attached to the urethra (usually in cases of rectourethral bulbar fistula).[44] That is one of the reasons we believe that the laparoscopic approach is appropriate in cases of rectobladder neck and some rectoprostatic fistulas. However, in cases of rectourethral bulbar fistula, it is difficult to reach the bulbar urethra and expose the distal extent of the fistula. This results in an amputation of the rectum, leaving a distal portion attached to the urethra. These patients characteristically pass large amounts of mucous through the urethra and dribble urine from the posterior urethral diverticulum in between voiding episodes.

Hyperchloremic metabolic acidosis is another potential problem for these children.[45,46] This condition results from urine passing from the bladder through a rectovesical or rectourethral fistula into the defunctionalized distal limb of colon following initial diverting colostomy. The resultant absorption of urinary constituents by the bowel results in the metabolic abnormality. The occurrence of this complication requires the presence of a urorectal fistula. A long segment of defunctionalized colon (large absorptive surface) that communicates with the fistula worsens the metabolic imbalance. Distal urinary obstruction, which may be structural (stricture) or functional (neurovesical dysfunction), also worsens this risk. UTI and renal insufficiency may also make this metabolic abnormality more likely. Creation of a low, fully diverting colostomy and ensuring effective bladder drainage help to avoid hyperchloremic metabolic acidosis. Once established, hyperchloremic metabolic acidosis is treated by the administration of oral alkalinizing agents, intermittent catheterization, vesicostomy, or early anorectal reconstruction with division of the fistula, depending on the clinical setting.

ASSOCIATED GYNECOLOGICAL ANOMALIES

The two most common gynecological anomalies are duplication of Mullerian structures, which happens in 34% of female patients with ARM, and absent vagina, which happens in 5.6% of patients with ARM.[47,48] Duplication of the Mullerian structures can be suspected when a vaginal septum is identified during the physical exam or during endoscopy in cases of cloaca. The vaginal septum is associated with two hemivaginas and two hemiuterii. In patients with cloaca, when a duplication of Mullerian structures is detected, we recommend testing the patency of both Mullerian structures by injecting saline solution through a 3 Fr feeding tube inserted into the fallopian tube on each side and confirming its patency by watching the fluid coming through the vagina. This maneuver can be done during the colostomy closure in patients with cloaca in which the abdomen was not entered during the main repair (cloacas with a common channel length shorter than 3 cm) or during the main repair when a laparotomy is needed (cloacas with a common channel length longer than 3 cm). With this maneuver, we hope to avoid patients with undetected

atretic Mullerian structures that can manifest during puberty as an acute abdomen from retained menstruation or blood in the abdominal cavity.[49] It is also important to make patients and parents aware when a duplication of Mullerian structures is detected due to its future obstetric implications (tendency for miscarriage and premature delivery). The incidence of duplicated Mullerian structures increases as the complexity of the malformation increases: perineal fistula 3%, vestibular fistula 6%, and cloaca 60%. A vestibular fistula with an absent vagina seems to be more frequent than previously thought, and was found in approximately 10% of the rectovestibular cases in our series.[48] The importance of early detection relies on the fact that the posterior sagittal approach offers an excellent opportunity for the vaginal reconstruction. An absent vagina occurs in perineal fistulas in 1% and in cloacas in 3.5%.

TREATMENT

Newborn Management

The decision-making algorithm during the initial management of male and female patients born with an ARM can be seen in Figures 71.4 and 71.5. A thorough perineal physical examination is the first step, which usually provides the most important clues about the type of malformation present. It is important not to make a decision about a colostomy or a primary surgery before 20–24 hours of age. The reason for waiting is that a significant intraluminal bowel pressure is required in order for the meconium to be forced through a fistula, overcoming the natural tone of the muscle complex that surrounds the rectum (Figure 71.6). The presence of meconium in the perineum represents evidence of a rectoperineal fistula or a rectovestibular fistula. A perineal fistula in females is easily seen (Figure 71.7); a vestibular fistula, on the other hand, must be searched for, immediately outside the hymen, and sometimes it is not easy to identify (Figure 71.8).

The presence of meconium in the urine in a male patient establishes the diagnosis of a rectourinary fistula. The presence of a single perineal orifice in a female newborn makes the diagnosis of a cloaca. Radiologic evaluations do not show the true anatomy before 24 hours because the rectum is collapsed and compressed by the muscle tone of the sphincters that surround its lower part (Figure 71.6). Therefore, radiologic evaluations done too early (before 24 hours) most likely will reveal a false image of a "very high rectum."

During the first 24 hours, the newborn should receive intravenous fluids, broad-spectrum antibiotics, and nasogastric decompression to prevent aspiration of gastric content. The clinician should use these hours to rule out the presence of associated defects, such as cardiac malformations, esophageal atresia, and urologic problems. An echocardiogram can be performed, and the baby should be checked for the presence of esophageal atresia. A plain anterior-posterior (AP) and lateral radiographs of the lumbar spine and sacrum should be taken to evaluate for hemivertebrae and sacral anomalies. A spinal ultrasound helps to screen for tethered cord. Ultrasonography of the abdomen will detect the presence of hydronephrosis, and a pelvic ultrasonography in females with cloaca evaluates for the presence of hydrocolpos.

A pediatric urologist should be involved in the initial management of a newborn with an ARM. The baby should not be taken to the operating room to create a colostomy or to receive an anoplasty without being evaluated for important urological problems, mainly hydronephrosis. At the minimum, a renal and bladder ultrasound should be performed. A spinal ultrasound should also be included in the initial evaluation. A voiding cystourethrogram will

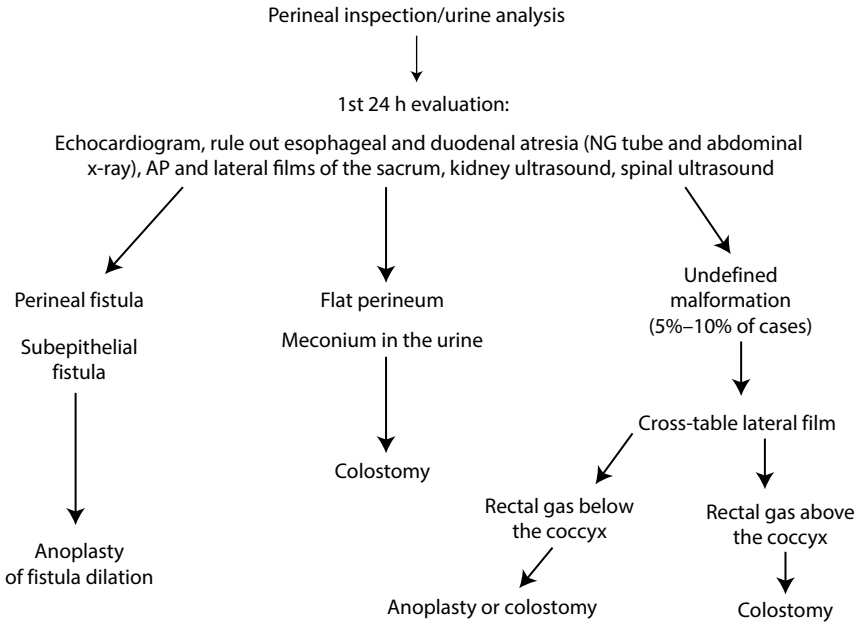

FIGURE 71.4 Decision-making algorithm for newborn males with ARM.

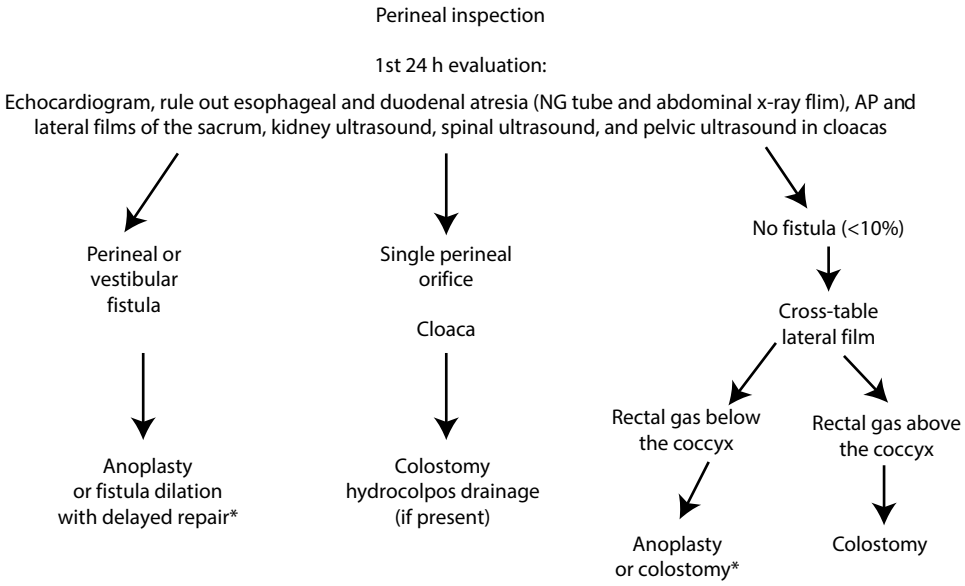

FIGURE 71.5 Decision-making algorithm for newborn females with ARM.

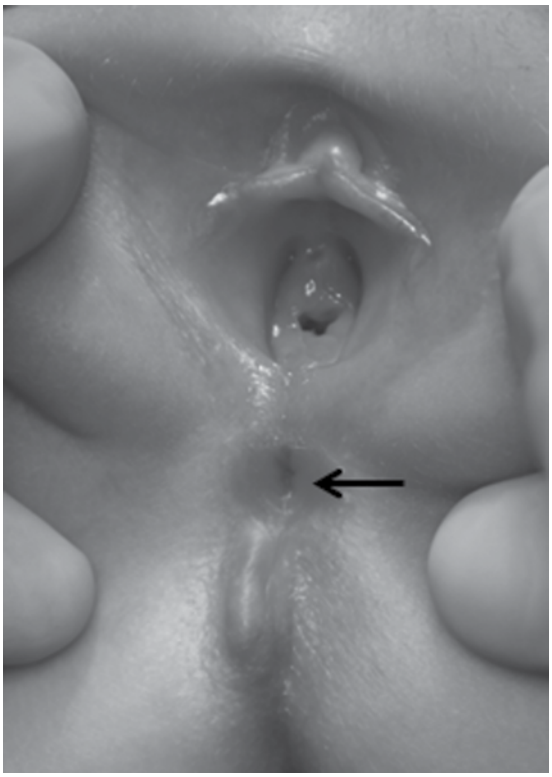

FIGURE 71.7 Female patient with a rectoperineal fistula (arrow).

ultimately be needed, but its interpretation with an intact fistula can be somewhat difficult, and so it may be deferred until after the primary operative intervention.

A significantly abnormal sacrum (sacral ratio of less than 0.4) and/or the presence of a tethered cord increases the risk of developing a neurogenic bladder, even if the initial ultrasound does not demonstrate hydronephrosis. A long common channel (>3 cm) in cloacal patients is also a risk factor for neuropathic voiding dysfunction.[42] Some patients with normal upper urinary tracts develop nephropathy as time goes by, especially when they have an abnormal sacrum and/or tethered cord. Careful urologic follow-up is mandatory in those patients deemed at high risk for neuropathic involvement to avoid irreversible renal injury.

At the time of colostomy creation in cloaca patients, it is mandatory to drain any hydrocolpos, if present. The hydrocolpos can compress the trigone of the bladder and may produce an extrinsic ureterovesical obstruction.

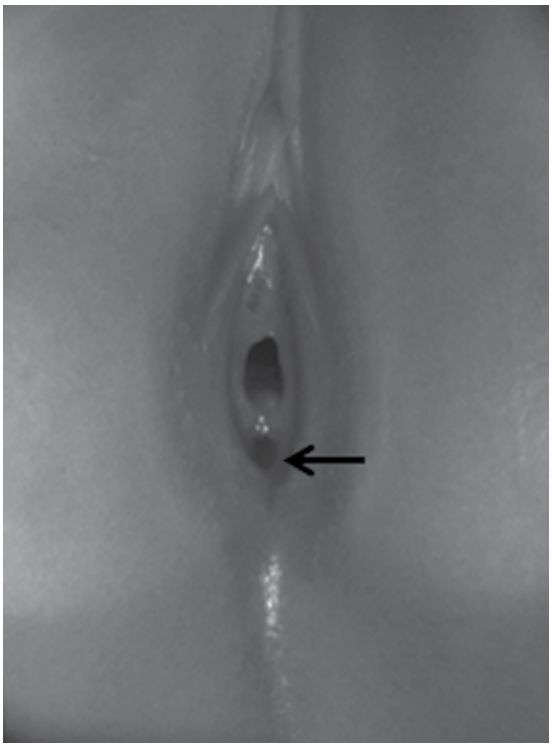

FIGURE 71.8 Female patient with a rectovestibular fistula (arrow).

This can result in secondary hydroureteronephrosis. If left undrained, there is also the risk of pyocolpos and even perforation. If the hydrocolpos is not large enough to reach the abdominal wall above the bladder, to be matured to the skin as a stoma, it can be drained with a transabdominal pigtail drain. Because a significant number of these patients have two hemivaginas, the surgeon must be certain that the tube inserted into the hydrocolpos is draining both hemivaginas. Occasionally, one has to open a window in the vaginal septum to drain both with a single tube. The hydrocolpos should be drained permanently until the main cloacal repair. Many patients are subjected to unnecessary vesicostomies, ureterostomies, and nephrostomies to alleviate the obstructive uropathy. In many cases, the simple drainage of the hydrocolpos allows for the decompression of the ureters and renal pelvis. We specifically suggest draining the hydrocolpos first, and then, after 48 hours, reevaluate the magnitude of the hydronephrosis and ureteral dilation. Interestingly, in many cases the drainage of the hydrocolpos will allow for better drainage of the ureters and will facilitate more efficient bladder emptying.

If the baby has signs of a perineal or vestibular fistula, an anoplasty can be performed without a protective colostomy in the newborn period. If the baby is clinically unstable from associated abnormalities or is extremely premature, or if the clinician chooses to wait until the baby is a little older, the fistula can be gently dilated. The repair in such cases should not be delayed more than several months.

After 24 hours, if no meconium is seen on the perineum or in the urine, a cross-table lateral x-ray film with the baby in prone position (Figure 71.9) should be obtained. If the gas in the rectum is located below the coccyx and the baby is in stable condition with no significant associated defects, depending on the surgeon's experience, a posterior sagittal operation without a protective colostomy can be considered. A more traditional, conservative alternative would be to perform a colostomy, with the definitive repair planned for a second stage. If rectal gas is seen above the coccyx or the patient has meconium in the urine, a single perineal orifice (cloaca), significant associated defects, and/or an abnormal sacrum or a "flat bottom," a colostomy is recommended with postponement of the main repair for a subsequent operation. This can be performed 2–3 months later after a distal colostogram delineating the anatomy is performed, provided that the baby is gaining weight normally. Antibiotic chemoprophylaxis is indicated to prevent urinary tract infectioun complications, particularly if VUR is present. Performing the definitive repair at 2–3 months of age has important advantages for the patient, including less time with an abdominal stoma, less size discrepancy between the proximal and distal bowel at the time of colostomy closure, easier anal dilation, and no recognizable psychological sequelae from painful perineal maneuvers. In addition, at least theoretically, placing the rectum in the right location early in life may provide an advantage in terms of the potential for acquired local sensation. The potential advantages of an early operation must be weighed against the possible disadvantages of an inexperienced surgeon unfamiliar with the minute anatomic structures of an infant's pelvis. A trend to repair these defects without a protective colostomy[50–52] must be balanced against the concern that such a repair without a colostomy is done without precise anatomic information about the patient's specific type of anorectal defect. The most catastrophic complications seen in patients operated on without a colostomy occurred in patients in whom the surgeon did not have a properly done preoperative distal colostogram. While looking for the rectum, the surgeon might inadvertently find and injure the urethra, an ectopic ureter, the bladder neck, the vas deferens, or the seminal vesicles.[43]

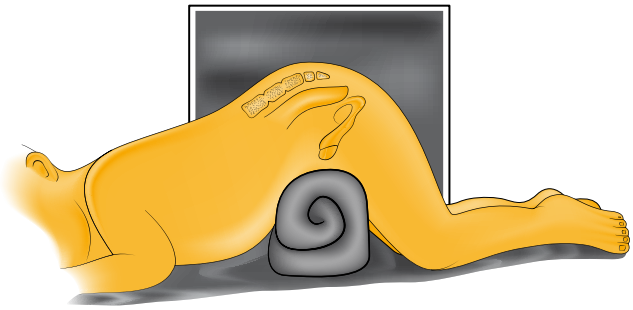

FIGURE 71.9 Cross-table lateral x-ray film with the baby in prone position.

Newborn Unified Management for Cloacal Exstrophy

When a patient is born with cloacal exstrophy, we strongly recommend a unified neonatal approach that should involve

a pediatric surgeon, a pediatric urologist, a pediatric gynecologist, an orthopedic surgeon, and a neurosurgeon in order to give the patient the best possible functional and anatomical outcome.[53] During the initial intervention, it is critical to ensure that the entire gastrointestinal tract is incorporated into the fecal stream, creating a real end colostomy. The most common error in the early management of these patients is the creation of an ileostomy, leaving the colon attached to the urinary tract. This allows the urine to be absorbed in the colon, provoking hyperchloremic acidosis, as described above. During the first operation, surgeons must refrain from using gastrointestinal tissue to reconstruct the urogenital tract since the future possibility of the patient having a bowel pull-through depends on the presence of enough colon to form solid stool.[54] The decision to use colon, small bowel, or stomach to reconstruct the urinary tract must be made much later in life, after the decision between a pull-through or permanent stoma has been made. The omphalocele should be closed, if possible, during the initial procedure. The Mullerian structures in females must be inspected, and the two hemibladders must be approximated and sutured together in the midline for a later urological reconstruction.

Colostomy

The recommended colostomy in patients with ARM is created in the descending colon with separated stomas (Figure 71.10), to ensure that a complete diversion is performed in order to avoid fecal contamination of the urinary tract. It is important to leave the entire loop of sigmoid colon distal to the colostomy to allow the rectal pull-through. The colostomy is fashioned by making an oblique left lower quadrant incision. The colon is divided, with the bowel openings placed at opposite ends of the wound. The proximal stoma is located just after the colon comes off its left retroperitoneal attachment. The distal stoma is created in the upper sigmoid, and is made intentionally small in an attempt to prevent prolapse. The distal segment should be copiously irrigated to remove all meconium. The mucous fistula should be placed far enough away from the functional stoma, leaving enough space for a stoma bag to cover only the proximal stoma. This way, no stool spillage downstream can occur, and the stoma bag stays on more easily. Significant morbidity is associated when a colostomy is not properly done.[55]

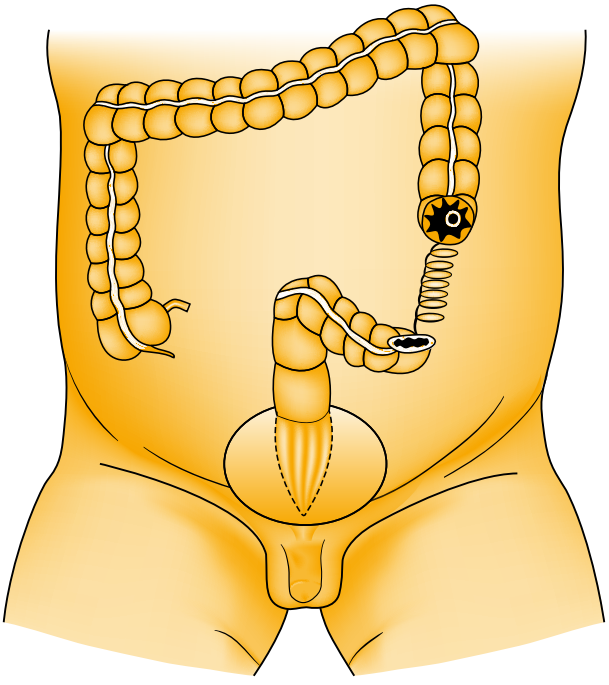

FIGURE 71.10 Descending colostomy with separated stomas.

It is a relatively frequent event for a pediatric urologist to be called in consultation to see a baby with an ARM with a colostomy, suffering from frequent episodes of urosepsis. The urologist must first look at the colostomy, to rule out fecal contamination of the urinary tract due to a defective colostomy. Transverse colostomies have serious disadvantages, which include prolapse, difficult cleaning of the distal segment, and difficult and risky delineation of the downstream rectourinary anatomy during the distal colostogram. Such colostomies also lead to megarectosigmoid and a left microcolon in the defunctionalized segment, particularly when the colostomy is left in place for many months. A colostomy that is placed too low in the sigmoid can interfere with the pull-through. A loop colostomy leads to distal contamination of the urinary stream if there is a fistula and to a dilated megarectosigmoid from stool spillage.

High-Pressure Distal Colostogram

Before the definitive repair, the most valuable radiologic study to be performed is the "high-pressure distal colostogram" to define the precise location of the fistula in male patients. In fact, the risk of urologic injuries seems to increase when patients undergo repair without this study.[43] Water-soluble contrast medium is instilled into the distal stoma, which fills the distal intestine and enables demonstration of the location of the blind rectum, the precise site of a rectourinary fistula, the relationship with the sacrum, and the amount of distal colon available for the pull-through. Since the rectum is surrounded by striated muscle, upon injection of the contrast, the distal rectum remains collapsed and prevents filling of the most distal part, giving the false impression that we are dealing with a "high defect," and it may also prevent demonstration of a rectourinary fistula, which is always located at the most distal part of the rectum. To avoid this problem, the contrast material must be injected with considerable hydrostatic pressure under fluoroscopic control, to overcome the muscle tone. The use of a Foley catheter is recommended; it is passed through the distal stoma, the balloon is inflated (2–5 mL), and it is pulled back as far as possible to occlude the stoma during the injection of the contrast medium. All this is done under fluoroscopic control. The first images are obtained in an anterior posterior position, and they allow the surgeon to determine the length of bowel distal to the colostomy that is available for the pull-through. The patient is then placed in perfect lateral position, and the high-pressure injection of contrast must continue until the contrast passes through the fistula into the urinary tract. In cases of rectourethral fistula

(prostatic and bulbar), with this study, the surgeon knows precisely where to find the rectum. In cases of rectobladder neck fistulas, the surgeon does not expect to find the rectum through the posterior sagittal approach and so avoids a blind perineal dissection. In this latter case, the surgeon can prepare the patient for an additional laparoscopy or laparotomy to mobilize a very high rectum.

PSARP for Rectoperineal Fistula in Males and Females and for Rectovestibular Fistula (Figure 71.11)

The repair of these defects consists of a small anoplasty with minimal mobilization of the rectum, sufficient for it to be transposed and placed within the limits of the sphincter. This is a meticulous operation and can be done during the neonatal period without a colostomy. The most common complication during the repair of this defect is a urethral injury in male patients, which can be avoided by placing a urethral catheter and taking particular care during the dissection of the anterior rectal wall. In female patients, a vaginal injury may occur, and it can be avoided by meticulous dissection and constant checking of the vagina and rectal wall's thickness with the usage of a lacrimal duct probe. Special emphasis should be placed on this dissection in cases of rectovestibular fistula in which there is a very thin common wall between the rectum and vagina. These patients, both boys and girls, have an excellent functional prognosis for bowel and urinary control, provided they have a normal sacrum and no tethered cord, and receive a good operation. These patients only have problems with bowel control if they are subjected to an inadequate surgical technique; if they are not treated adequately to prevent constipation, fecal impaction, and overflow pseudoincontinence; and if they have significant associated spinal or sacral problems.

PSARP for Rectourethral Bulbar and Prostatic Fistula and Imperforate Anus without Fistula (Figure 71.12)

A Foley catheter is inserted through the urethra. In about 5% of cases, this catheter goes into the rectum rather than into the bladder. To avoid this, the catheter must be intentionally directed anteriorly by the use of a curved lacrimal duct probe inserted in the distal tip of the catheter or using a coude catheter to find its correct path. When these maneuvers fail to pass the catheter into the bladder, the catheter can be placed through a wire introduced through the cystoscope. Occasionally, the catheter must be positioned intraoperatively under direct vision once the fistula is visualized. The patient is placed in prone position with the pelvis elevated. A posterior sagittal incision is used. The skin is opened using a very fine-needle cautery, and the parasagittal fibers and muscle complex are divided exactly in the midline. The fibers of the muscle complex run

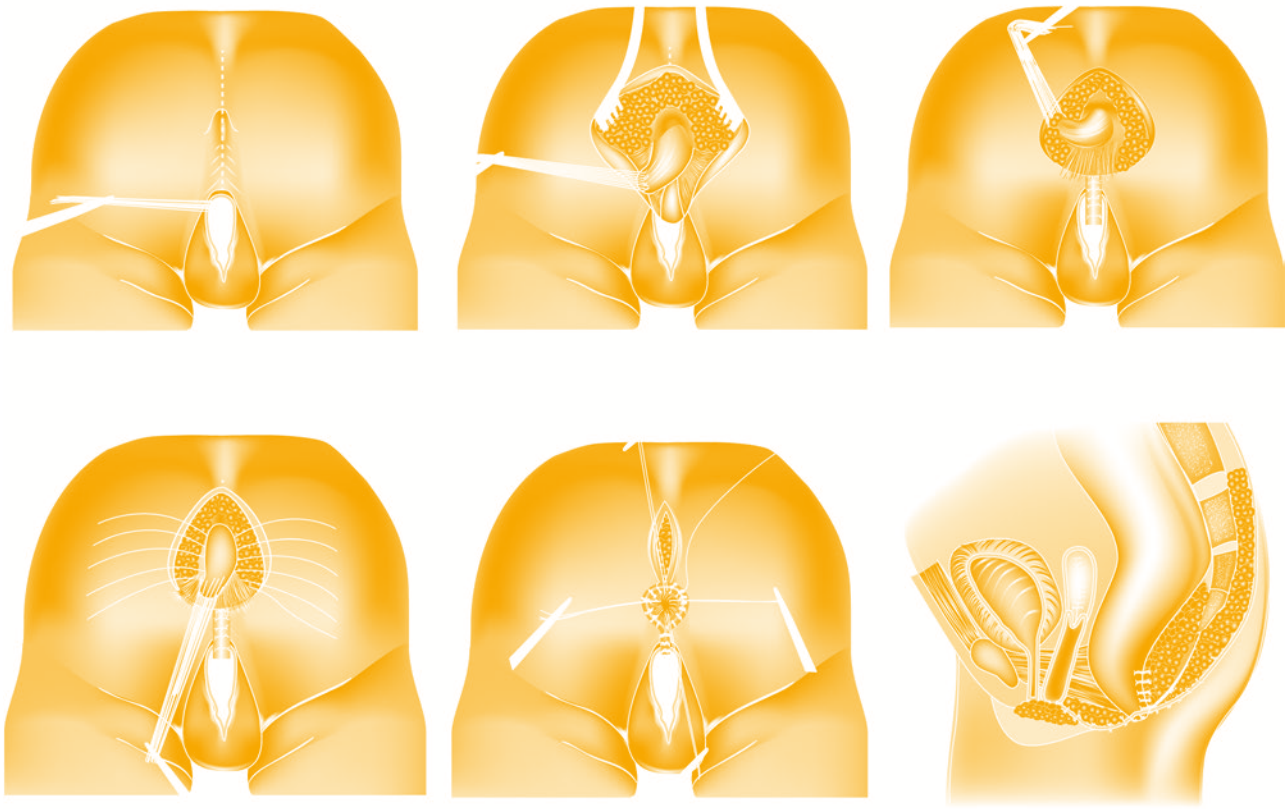

FIGURE 71.11 Diagram showing the surgical repair in the case of a rectovestibular fistula.

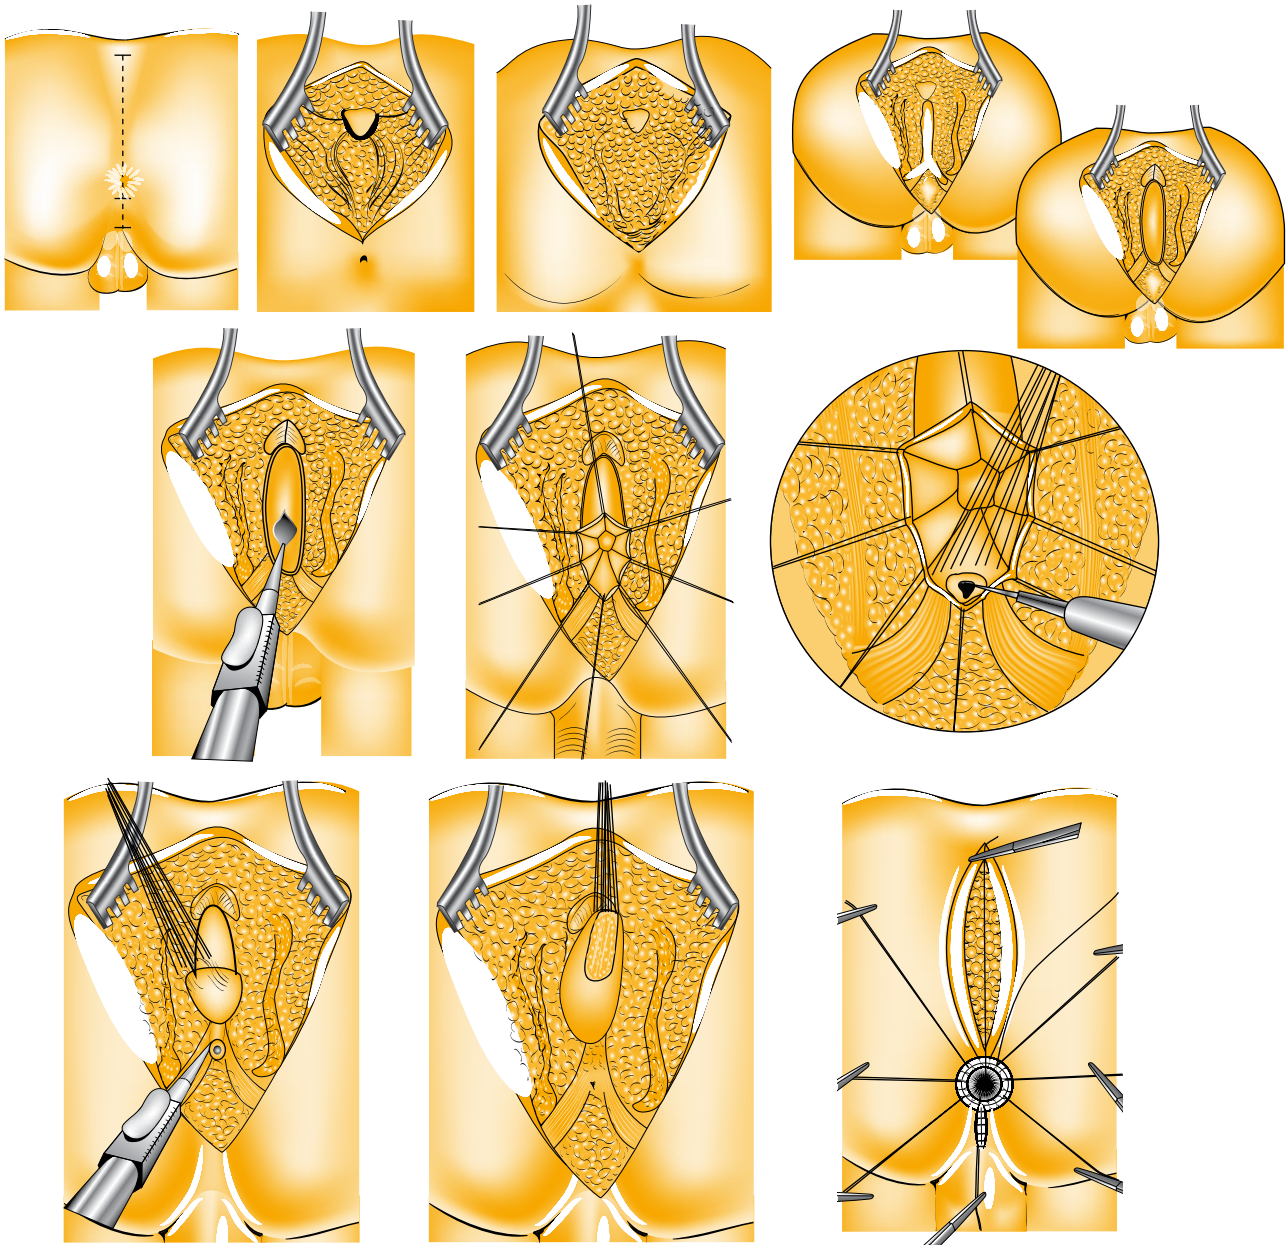

FIGURE 71.12 Diagram showing the surgical repair in the case of a rectourethral bulbar fistula.

perpendicular and medial to the parasagittal fibers. The crossing of the muscle complex fibers with the parasagittal fibers represents the anterior and posterior limits of the new anus. These limits can be seen most clearly with the use of an electrical stimulator. The levator muscle, which lies deep in the incision, is then divided in the midline. The higher the malformation, the deeper the levator muscle is found. The levator muscle fibers run parallel to the skin incision. Levator muscle and muscle complex are in continuum. When all muscle structures have been divided, the rectum can be seen. In cases of rectourethral bulbar fistulas, the distal rectum is prominent, and it almost bulges into the wound. In cases of rectoprostatic fistulas, the rectum is located much higher, just under the coccyx, and is not as prominent. In cases of rectobladder neck fistulas, the rectum is not visible through this approach, and searching for it risks injuring other structures.

Two silk sutures are placed in the posterior rectal wall on both sides of the midline. The rectum is opened between the sutures, and the incision is continued distally, exactly in the midline, down to the fistula site. Temporary silk sutures are placed on the edges of the open posterior rectal wall for traction. One silk stitch is placed inside of the fistula, and it will serve as a guide to locate the fistula site after the rectum is completely separated from the urinary tract. In patients with imperforate anus without fistula, the rectum is usually located at the level of the bulbar urethra, and even though there is no fistula connection, the common wall with the urethra is the same as in a case of a rectourethral bulbar fistula. The anterior rectal wall

immediately above the fistula is a thin structure. There is no plane of separation between the rectum and urethra in that area. A plane of separation must be created in the common wall. Multiple 6-0 silk sutures are placed through the rectal mucosa immediately above the fistula in a semicircle. The rectum is then separated from the urethra, creating a submucosal plane for approximately 5–10 mm above the fistula site. During this delicate dissection, it is very helpful to dissect the rectum laterally, very close to the rectal wall, until both dissections (lateral and medial) meet, separating the rectum completely from the urinary tract. The separation of the rectum from the urinary tract is the most delicate part of the operation, and it represents the main source of urologic catastrophic complications, including damage of the vas deferens, seminal vesicles, prostate, and bladder denervation, as well as damage to the nervi erigent. This is particularly common when these operations are performed without a distal colostogram and during the operation the surgeon is searching for the rectum. We have seen patients who suffered a complete section of the urethra, a pull-through of bladder, or an ectopic ureter.

Once the rectum is fully separated, a circumferential perirectal dissection is performed to gain enough rectal length to reach the perineum. The rectum is surrounded by a conspicuous whitish fascia. The dissection must be performed between this fascia and the rectal wall to avoid damage to the innervation of the bladder and genitalia. In cases of a fistula opening into the bulbar urethra, the dissection necessary to pull the rectum down to the perineum is minimal, whereas in cases of prostatic fistula, the perirectal dissection is considerable. In both cases, enough rectal length must be gained in order to perform a comfortable, tension-free anastomosis between the rectum and the skin. As traction is exerted on the mobilized rectum, some grooves can be seen in the rectal wall, which demonstrate the tension lines that hold the rectum. These indentations are nerves and vessels that must be divided.

Once the rectum has been fully mobilized, a decision must be made concerning the need for tailoring of the rectum. The size of the rectum can be evaluated and compared with the available space so that its size matches the limits of the sphincter. If necessary, the rectum can be tapered by removing part of the posterior wall, and reconstructed with two layers of interrupted, long-lasting, absorbable sutures. The tapering of the rectum must always be done on the posterior rectal wall. The rectum must be mobilized enough to guarantee that the part of the intestine that will be adjacent to the closed urethral fistula is normal rectal wall to avoid a recurrent rectourethral fistula. The anterior rectal wall is often damaged to some degree as a consequence of the separation between the rectum and urethra. To reinforce this wall, the smooth muscle layers can be sutured together with interrupted 5-0 absorbable suture. The urethral fistula is sutured with long-term, absorbable sutures. The rectum is placed in front of the levator muscle and within the limits of the muscle complex and external sphincter. The electrical stimulator is helpful in identifying the limits of these muscle structures. Anterior and posterior limits of the external sphincter are temporarily marked with silk sutures. In cases in which the incision is extended anteriorly beyond the limits of the sphincter, it is necessary to repair the anterior perineum with interrupted, long-term, absorbable sutures to bring together both anterior limits of the external sphincter. Long-term absorbable sutures are placed on the posterior edge of the levator muscle. The posterior limit of the muscle complex must also be reapproximated behind the rectum. These sutures should include part of the rectal wall in order to anchor it and help avoid rectal prolapse.

The anoplasty is performed with 16 interrupted, long-lasting, absorbable sutures. Anoplasty sutures are placed under slight tension, so that once cut, the anus retracts slightly. The wound is then closed, bringing together corresponding sphincteric structures in the midline. The Foley catheter is left in place for 7 days. The patient receives broad-spectrum antibiotics for 1 day and prophylactic antibiotics while the Foley is in place.

PSARP with Laparoscopy or Laparotomy for Rectobladder Neck Fistula

For the repair of rectobladder neck fistulas, the entire lower part of the patient's body, from the chest down, is included in the sterile field (total body preparation), so that the surgeon can work alternatively in the abdomen and the perineum (Figure 71.13). The abdomen is entered via either laparotomy or laparoscopically,[56] and the rectosigmoid colon is mobilized. The peritoneum should be divided

FIGURE 71.13 Total body preparation in order to have a sterile field from the nipple line down, including the back.

around the distal rectum to create a plane of dissection to be followed distally. The dissection must be conducted right on the rectal wall. At the point where the rectum becomes narrow, where it communicates with the bladder neck, it should be divided. The bladder side of the fistula should be sutured by laparotomy or ligated with an endoloop by laparoscopy. In this very high defect, the rectobladder neck fistula is located approximately 2 cm below the peritoneal reflection, and the rectum communicates with the urinary tract in a T fashion, which means that there is no common wall between the distal part of the rectum and the urinary tract. This anatomic fact makes the separation of the rectum from the bladder neck a much easier and safer maneuver. That is the reason why this separation can be done safely laparoscopically. The surgeon must be careful to avoid damage to the vas deferens, which runs very close to the bowel. With a laparoscopic technique, separation of the rectum from the bladder neck is straightforward. Gaining adequate length, particularly with a high rectum, is challenging, and must be meticulous so as to avoid devascularizing the distal rectum.

The next step consists of mobilizing enough rectum to reach the perineum without tension. As this is a very high defect, mobilization of the rectum requires special maneuvers. Ligation of the inferior mesenteric vessels as high as possible, very close to their origin near the aorta, would mobilize the rectum, but would probably compromise the blood supply of the rectum because the arcades that connect the middle colic vessels with the inferior mesenteric ones may have been interrupted at the time of the colostomy creation. Therefore, the surgeon must instead ligate the most distal branches of the inferior mesenteric vessels close to the rectum. If this is done, the more proximal branches of the inferior mesenteric vessels must be left intact to guarantee a good blood supply that runs intramurally to the rectum.

If it is necessary to gain extra length, a plastic operation of the distal dilated portion of the rectum can also be performed. A combination of these maneuvers usually allows the intestine to reach the perineum, provided the colostomy does not interfere with the pull-through of the rectum. This can be anticipated by the careful analysis of the distal colostogram images, which demonstrates the precise length of intestine available from the colostomy to the end of the rectum. If the colostomy was placed too distal in the sigmoid, the surgeon may have to take down the mucous fistula and leave it as a Hartman's pouch to allow for the pull-through. The rectum should be preserved and never discarded, as it performs a vital reservoir function. At this point with the legs lifted, a perineal midsagittal posterior incision is performed. The presacral space is dissected and visualized through the abdomen. The rectum is pulled through. Further laparoscopic or laparotomy dissection can be performed while pulling gently on the rectum. The rectum is tacked to the muscle complex, and an anoplasty is performed as described previously.

PSARVUP with or without Laparotomy for Cloacal Malformation

This female malformation is considered separately because of its complexity. The reconstruction requires a very delicate, meticulous technique (posterior sagittal anorecto-vagino-urethroplasty [PSARVUP]), as well as creativity, imagination, and a resourceful, experienced surgeon. Repair of this defect has three main goals: achievement of urinary control, bowel control, and sexual function. Because a spectrum of defects exist, these goals are achieved in some cases; in others, however, the defect is repaired anatomically but the patients are left with functional sequelae that require extensive medical assistance to provide a good quality of life. During the surgical exploration, the surgeon must be prepared to find bizarre anatomic arrangements of the rectum, vagina, and urinary tract.

Before undertaking the repair of a cloaca, the surgeon should perform an endoscopy with the specific purpose of determining the length of the common channel. A contrast study of each of the three systems is very valuable and can be ideally done with a three-dimensional rotational scan, injecting contrast material through the stoma and through the single perineal orifice.[57] The accompanying videos demonstrate the rotational scan in different malformations (Videos 71.1–71.5).

There are two well-characterized groups of patients with a cloaca. These two groups represent different technical challenges and must be recognized preoperatively. The first consists of patients with a common channel shorter than 3 cm. Fortunately, this group represents the majority. These patients can usually be repaired via a posterior sagittal approach alone, without laparotomy.

The second group consists of patients with longer common channels. These patients usually need laparotomy, followed by a decision-making process that usually requires intricate vaginal maneuvers or vaginal replacement, tricks to mobilize a high rectum, knowledge of bladder neck anatomy, and decision making related to ectopic ureters, if found. This group should be cared for at centers with special dedication to the repair of these defects.[58]

Cloacas with a Common Channel Shorter than 3 cm

The incision extends from the middle portion of the sacrum down to the single perineal orifice. The entire sphincter mechanism is divided in the midline. The first structure that the surgeon will find after division of the sphincter mechanism is usually the rectum. The rectum is opened in the midline, and silk stitches are placed along the edges of the posterior rectal wall. The incision is extended distally through the posterior wall of the common channel. The entire common channel is opened, and its lumen is exposed to allow confirmation of its length under direct vision. The rectum is then separated from the vagina. This is performed in the same way as for repair of a rectovestibular fistula because the rectum and vagina share the same common wall already described. In patients with a vaginal septum, the rectum must be searched for at the posterior aspect of this septum.

Once the rectum has been completely separated from the vagina, a maneuver called total urogenital mobilization is used.[59] Prior to this maneuver, the vagina was separated from the urinary tract, which was a technically challenging maneuver associated with significant morbidity.

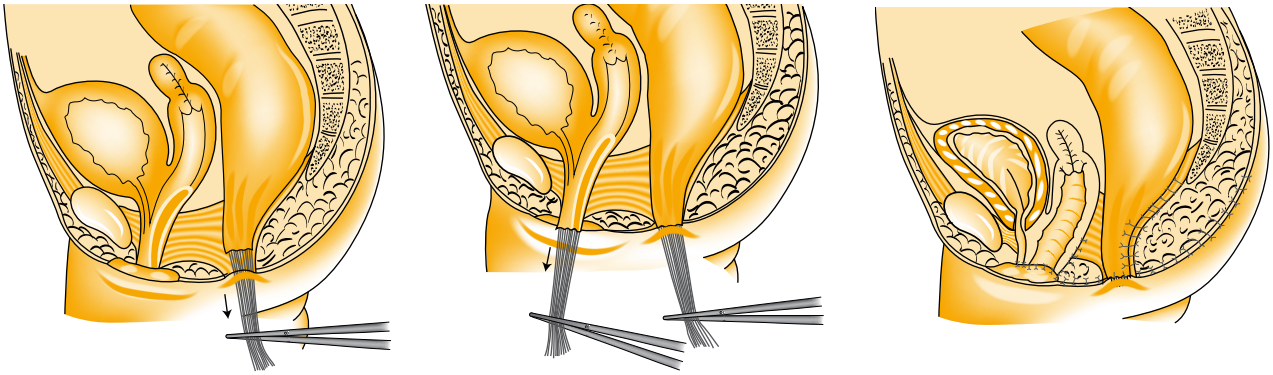

FIGURE 71.14 Total urogenital mobilization maneuver.

Total urogenital mobilization consists of mobilization of both the vagina and urethra as a unit without separating one from the other (Figure 71.14). After the rectum has been separated, multiple silk stitches are placed through the edges of the vagina and the common channel to apply uniform traction on the urogenital sinus. Another series of fine stitches are placed across the urogenital sinus approximately 5 mm proximal to the clitoris (Figure 71.15). The urogenital sinus is transected between the last row of silk stitches and the clitoris. Applying uniformed traction on the multiple sutures, the common channel (urogenital sinus) is separated from the pubis. The dissection takes advantage of the fact that there is a natural plane between it and the pubis. Very rapidly and in a bloodless field, one can reach the upper edge of the pubis. There, a fibrous, avascular structure that gives support to the vagina and bladder is identified.

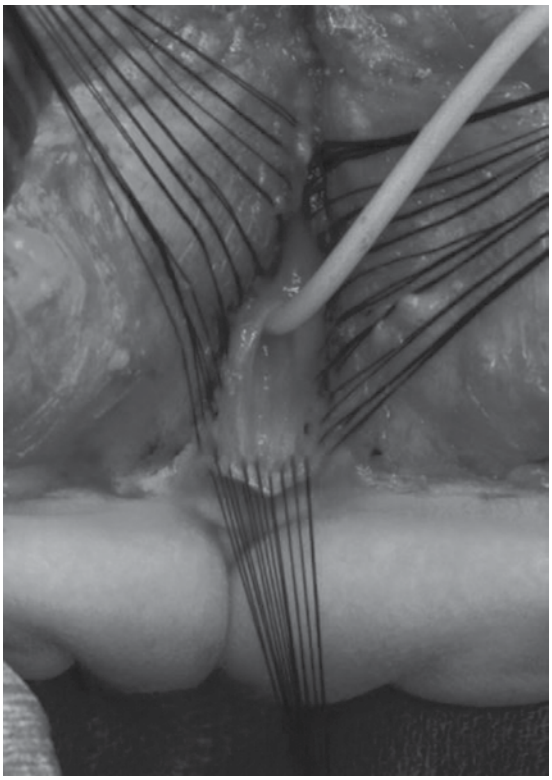

FIGURE 71.15 Silk stitches placed in the lateral walls of the common channel and behind the clitoris for the total urogenital mobilization.

This structure is called the suspensory ligament of the urethra and bladder. This ligament is divided, which immediately provides significant mobilization (between 2 and 3 cm) of the urogenital complex. One can then dissect the lateral and dorsal walls of the vagina to gain an extra 5–10 mm. This dissection is enough to repair about 60% of all cloacas and is a reproducible maneuver. It has the additional advantage of preserving an excellent blood supply to both the urethra and vagina. It places the urethral opening in a visible location and provides a smooth urethra that can easily be catheterized, if necessary. What used to be the common channel is divided in the midline to form two lateral flaps that are sutured to the skin to create the new labia. If a vaginal septum is present, it is resected. The vaginal edges are then mobilized to reach the skin to create the introitus. The limits of the sphincter are electrically determined. The perineal body is reconstructed by bringing together the anterior limit of the sphincter. The rectum is placed within the limits of the sphincter in the manner previously described. Patients can eat the same day, and the pain is usually easily controlled. Patients are discharged 48 hours after surgery. The Foley catheter is kept in place for at least 2 weeks.

Cloacas with a Common Channel Longer than 3 cm

When endoscopy and a cloacagram show that the patient has a long common channel, the surgeon must be prepared to face several significant technical challenges.

Patients with a long common channel should receive a total-body preparation because it is likely that laparotomy will be required. The rectum is separated from the vagina and urethra via a posterior sagittal incision, or via laparotomy when it is located very high. In cloacas with a common channel of 3–5 cm, the total urogenital mobilization is attempted. Occasionally, we have been able to repair one of these cases without opening the abdomen. However, in the majority of these cases it is necessary at this stage to open the abdomen to divide all the avascular attachments of the urethra and vagina. This extra dissection may be enough to complete the repair. If that is not the case, the vagina must be completely separated from the urinary tract. This represents the most technically

demanding maneuver in the repair of these defects. The bladder is opened in the midline, and feeding tubes are placed into the ureters to protect them. A long and wide common wall between the vagina and the trigone of the bladder exists, and both ureters run through this common wall. The ureters sometimes have to be skeletonized during this separation, and therefore require protection. The assistant places two fingers inside the bladder and holds traction to it so the separation between the urinary tract and vagina is initiated. This dissection is continued all the way down to meet the previous dissection initiated from below. The vagina is thus separated from the urinary tract, with care being taken to preserve its blood supply from the uterine vessels. Once the vagina has been separated from the bladder and urethra, the surgeon has to make a decision based on the specific anatomic findings. The vagina at this point may reach the perineum. If it does not reach the perineum by a few millimeters, at this stage the surgeon can carve the pubic bone cartilage and make the trajectory of the urethra and vagina shorter by making it straighter (normally, the urethra and vagina have to pass underneath the pubic bone in order to reach the perineum). If the vagina does not reach the perineum, a Heinecke–Mikulicz maneuver may be done, which seems to be useful to gain some minor vaginal length. After these maneuvers, if the vagina cannot be mobilized to the perineum, the next step includes considering a maneuver called vaginal switch, if the anatomy allows for it.

The patency of the Mullerian structures is investigated by passing a No. 3 feeding tube through the fimbriae of the fallopian tubes and injecting saline. If one of the systems is not patent, the atretic Mullerian structure should be excised, with great care taken to avoid damage to the blood supply of the ipsilateral ovary. When both Mullerian structures are atretic, they should be left in place. The patient must be monitored closely and further investigated with ultrasound when she enters puberty.

Vaginal Switch Maneuver

A specific group of patients are born with hydrocolpos and two hemivaginas. The hemivaginas are very large, and the two hemiuteri are very separated, the distance between them being longer than the vertical length of both hemivaginas. In these cases, it is possible to perform a maneuver called a vaginal switch.[60] One of the hemiuteri and the ipsilateral fallopian tube are resected, with particular care taken to preserve the blood supply of the ovary. The blood supply of the hemivagina of that particular side is sacrificed. The blood supply of the contralateral hemivagina is preserved and provides for both hemivaginas. The vaginal septum is resected, and both hemivaginas are tubularized into a single vagina by taking advantage of the long lateral dimension of both hemivaginas. Then, what used to be the dome of the hemivagina where the hemiuterus was resected is turned down to the perineum (Figure 71.16). This is a useful maneuver that can be performed only when these specific anatomic characteristics are encountered.

Total or Partial Vaginal Replacement

In a patient with a small vagina or in the rare case of an absent vagina, a vaginal replacement is required. In such cases, the choices are rectum, colon, or small bowel. When the patient has internal genitalia or an upper blind vagina, the upper part of the bowel used for replacement should be sutured to the vaginal cuff. When the patient has no internal genitalia (no vagina and no uterus), a vagina is created and left with its upper portion blind and used only for sexual purposes.

Rectum

This form of vaginal replacement is feasible in patients who have a rectum that is large enough to be able to divide it longitudinally into a portion with its own blood supply that will form a new vagina and another portion with enough circumference to reconstruct an adequately sized rectum. The blood supply of the rectum will be provided transmurally from branches of the inferior mesenteric vessels. The distal rectum can also be used as a neovagina, with pull-through of the proximal colon as a neorectum, in patients that have poor prognosis for bowel

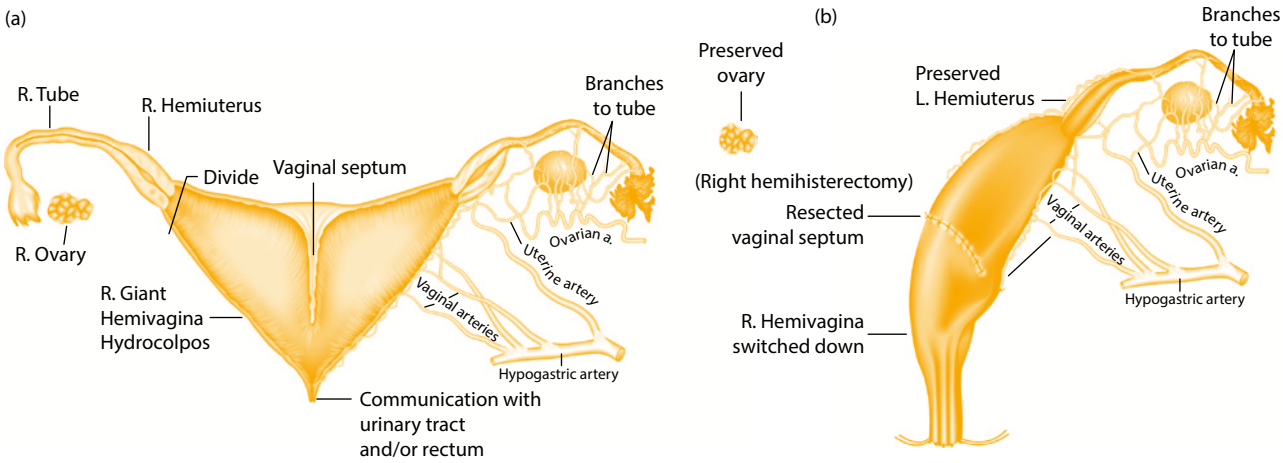

FIGURE 71.16 Vaginal switch procedure. (a) Anatomy required in order to use the vaginal switch maneuver. (b) Final anatomy after the vaginal switch maneuver.

control (sacral ratio <0.4). If the patient has good prognosis for bowel control, the rectum should be left as the rectum.

Colon

The colon is an ideal substitute to replace the vagina. However, sometimes the location of the colostomy interferes with this type of reconstruction. The left colon or sigmoid works well, as their arcades reach the perineum nicely. Sometimes taking the colostomy down and using the distal segment of it for the vaginal graft is a helpful maneuver.

Small Bowel

When the colon is not available, the most mobile portion of the small bowel is used for vaginal reconstruction. The mesentery of the small bowel is longer in an area located approximately 15 cm proximal to the ileocecal valve, which is the best portion of the small bowel for vaginal replacement. A portion of the ileum is isolated and pulled down while preserving its blood supply.

In the highest type of cloaca, one may find two little hemivaginas attached to the bladder neck or even to the trigone of the bladder. In these cases, the rectum also opens in the trigone (Figure 71.17). Separation of these structures is done abdominally. Unfortunately, when the separation is completed, the patient is frequently left with no bladder neck or a severely damaged one. At that point, the surgeon must have enough experience to make a decision of whether to reconstruct the bladder neck or close it permanently. In the first situation, most patients will require intermittent catheterization to empty the bladder. A vesicostomy is created in such cases, and the patient will require a continent diversion type of procedure and possibly a bladder neck procedure and/or bladder augmentation, done at the age of urinary continence (3–4 years old).

At the time of colostomy closure, endoscopy should be performed to be sure that the repair is intact and that there is no prolapse, stricture, or urethrovaginal fistula. If the cloaca repair did not require laparotomy, the time of colostomy closure is the opportunity to investigate the patency of the Mullerian structures when two hemivaginas and hemiuterii are present.

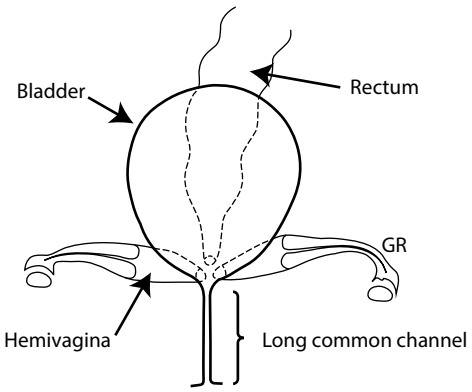

FIGURE 71.17 Highest type of cloaca showing the insertion of both hemivaginas and the rectum at the level of the trigone of the bladder.

NEUROPATHIC BLADDER

The mean incidence of neurovesical dysfunction in patients with ARMs is 35%. Table 71.1 demonstrates that the prevalence may vary quite widely among reported series.[12,15,61–64] As expected, high ARMs have the greatest incidence. However, neurovesical dysfunction can be present in children with low lesions. Therefore, we screen all patients with ARMs at birth with spinal sonography and a careful perineal exam. As previously noted, the recognition of the high incidence of occult spinal dysraphism has had a major impact on the management of these patients.[13–15,65] Such lesions may progress following surgical correction.[65–68] Although the timing of surgical intervention remains controversial, some authors suggest that early surgical intervention results in the best functional neurologic outcome.[69]

Screening ultrasonography has proven useful in the diagnosis of occult spinal dysraphism in infants.[70] Older children generally require MRI for diagnosis. The significance of these dysraphic states became apparent in the early 1990s. Early experience showed that dysfunctional voiding occurred in 31% and 5% of high and low ARMs, respectively. Structural spinal cord pathology was present in 12% and 4%, respectively.[15] One report from Appignani and colleagues suggested that screening by MRI for occult dysraphic myelodysplasia yields an even higher incidence of spinal cord pathology. They encountered dysraphic states in 17% of low ARMs, 34% of high ARMs, 46% of cloacal anomalies, and 100% of patients with cloacal exstrophy.[38] A study from Golonka in 2002 reported that 27% of those with high lesions and 50% with low lesions had a tethered cord by MRI.[71]

Some surgeons have wondered whether surgical correction of ARMs results in the development of the neuropathic bladder. Ralph, in 1992, evaluated 58 patients with imperforate anus who had reached an age of 18 years or greater. Of these, 43 patients had received rectal pull-through procedures, while the remainder received cutback procedures. They found evidence for a neuropathic bladder in 32 patients (55%). Ninety-one percent of these neuropathic bladders were hyperreflexic in nature.

TABLE 71.1 Incidence of neuropathic bladder in ARM

Series	No. patients	NVD (%)

Emir (1998)	33	45
Borg et al (2009)	37	24
Total	285	35

Abbreviation: NVD, neurovesical dysfunction.

Thirty patients (52%) had spinal deformities, 21 (70%) of which had evidence for neurovesical dysfunction. Only three patients (5%) had hypotonic bladders, normal spinal anatomy, and high ARMs, and were felt likely to have iatrogenic neurovesical dysfunction.[72] Boemers et al., in 1995, evaluated 32 patients with ARMs who underwent PSARP employing urodynamic investigation. In 27 patients, urodynamic investigation was performed both before and after PSARP. No evidence of somatic nerve injury happened in this series. Detrusor failure suggestive of autonomic denervation occurred in three males, two of whom had combined PSARP with transabdominal dissection. The authors concluded that in the absence of transabdominal dissection and significant retrovesical dissection, PSARP did not affect lower urinary tract function.[73] De Filippo et al., in 1999, also reported that bladder dysfunction does not appear to follow a properly performed PSARP.[74]

Long-Term Urologic Follow-Up

The importance of long-term urologic follow-up to assess for neuropathic voiding dysfunction cannot be overemphasized, particularly in cases with risk factors that include hydronephrosis, VUR, tethered cord, abnormal sacrum, and urinary tract damage or denervation provoked during the repair of the ARM. In these types of cases, we consider that the follow-up must continue during the entire life.

Ideally, all patients, even those with normal kidneys, good sacrum, and normal spinal cord, should have a renal ultrasound at quarterly intervals in the first year postrepair and at yearly intervals after that. If the patient has UTIs and/or an abnormal kidney ultrasound, it will be necessary to do a full urologic evaluation, including a formal urodynamic study. Some investigators advocate a spinal MRI on all patients with ARMs given that spinal anomalies can occur even with low lesions.[75]

Depending on the results of such evaluations, patients may require a program of clean intermittent catheterization in order to protect the upper urinary tracts, as well as to be continent of urine. Patients with uninhibited detrusor contractions, poor compliance, and/or high bladder filling pressures may benefit from the addition of anticholinergic medication to their catheterization regimen. Ongoing collaboration with the colorectal team is important to adjust the bowel regimen if needed, as these medications are quite constipating.

Collaborative Approach to Surgical Reconstruction

A collaborative urologic and colorectal approach to reconstruction around the time of toilet training is in the best interest of the patient, as lower urinary tract reconstructive procedures can be combined with creation of a Malone appendicovesicostomy and sigmoid colon reduction, if indicated. Incidental appendectomy at the time of the initial surgical procedure must be avoided, because the appendix may be needed for either Malone antegrade continence enema (MACE) or Mitrofanoff neourethral bladder access.

Reconstructive Principles

1. Most neurovesical dysfunction and urethral strictures encountered in patients with ARMs are not iatrogenic but congenital in origin.
2. VUR is usually bilateral or, if unilateral, occurs in conjunction with a condition that threatens the contralateral kidney. In addition, neurovesical dysfunction often accompanies the VUR.
3. Initial management should be focused on identifying and correcting the bladder dysfunction rather than antireflux surgery. Ureteral reimplantation into a dysfunctional bladder usually fails unless the underlying bladder dysfunction is controlled.
4. Prompt and efficient decompression of obstructive hydronephrosis is essential in order to optimize long-term renal function.
5. Patients with ARM have a risk for latex allergy that is similar to that of the myelomeningocele population.
6. The combination of neurovesical dysfunction or urethral stricture with rectourinary fistulas predisposes the patient to critical neonatal illness, such as sepsis and hyperchloremic metabolic acidosis.
7. A low, fully diverting colostomy is most protective of the urinary tract.
8. Patients with a cloaca should never have their anorectal and urogenital sinus malformations corrected separately. The best results are attained by a single-stage PSARVUP. Those patients who present for correction of a urogenital sinus mesenchyme (UGSM) who have previously undergone an anorectal pull-through procedure are best corrected by reoperative PSARVUP complete with repeat mobilization of the rectum.

Renal Transplantation in Patients with Anorectal Malformations

Renal transplantation in the setting of ARMs and CM deserves additional comment. ESRD in this setting may dramatically complicate patient management.[16,76] Peritoneal dialysis is more difficult, or may be impossible, in the presence of multiple adhesions from prior transabdominal surgical procedures. Surgeons should make every effort to preserve the peritoneal cavity in the very young, because hemodialysis access is difficult and associated with long-term complications, such as superior vena cava thrombosis.

Renal transplantation in patients with ARMs and UGSMs is extremely challenging, as the majority of these patients with ESRD have major bladder pathology that must be controlled or corrected before transplantation, in order to optimize the allograft outcome. In addition, abdominal and pelvic vascular anomalies are relatively common in these children.[77] Successful renal transplantation, however, in the setting of imperforate anus and cloacal anomalies can be achieved, even after lower urinary tract continent reconstruction.[16,76,78]

LONG-TERM BOWEL FOLLOW-UP

Despite a successful initial surgical repair, approximately 25% of patients born with an ARM suffer from fecal incontinence. For those patients, we offer a bowel management program consisting of the administration of a specially designed enema that cleans the colon and allows the patient to remain clean of stool in the underwear for 24 hours.[79–81] The first step consists of ordering a contrast enema to evaluate and classify the colon in two groups:

1. Dilated colon with hypomotility (tendency to constipation)
2. Nondilated colon with hypermotility (tendency to diarrhea)

The first group will need a large and concentrated enema to clean the colon. The second group will need a small volume and nonconcentrated enema, but usually requires additional treatment, such as medication, to slow down their colon and a constipating diet. It generally takes 1 week, with trial and error, of modifying the enema recipe to find the specific enema that works for each child. During this 1-week bowel management program, abdominal x-ray films are taken on a daily basis in order to have an objective way to evaluate the effect of the enema.

Another important group of patients have bowel control but suffer from severe constipation. They should also be managed aggressively with oral laxatives. If the constipation is left untreated, the patients can have leakage from overflow fecal pseudoincontinence. The severe constipation can also have a negative impact in the urinary tract. After the bowel management has been successfully implemented, we discuss with the family the possibility of performing an operation to administer the enemas in an antegrade fashion. The continent appendicocecostomy was initially described by Malone and has revolutionized the care of patients with even the most debilitating malformations.[82,83] The procedure consists of connecting the cecal appendix, when available, or a cecal flap, known as neoappendicostomy, to the umbilicus and creating a one-way valve mechanism by placating the cecum around the appendix to allow the passing of a catheter and to prevent leakage of stool.[84–86] The technique can be modified to allow the appendix to be split and used for both an antegrade continence enema and a Mitrofanoff appendicovesicostomy.[87,88] A bowel anastomosis to harvest enteric tissue for a second catheterizable channel is thus avoided when enterocystoplasty is not indicated. We only offer this operation to patients in whom the bowel management has been successful. In a great deal of patients with nonneurogenic voiding dysfunction (urgency, frequency, and urge incontinence), we find that the urinary symptoms improve dramatically with better bowel management.[89]

CONCLUSION

Anorectal and CMs are highly complex diagnoses that can have lifelong implications to gastrointestinal, urinary, and reproductive health. A systematic and collaborative, multidisciplinary approach to management and treatment is highly recommended to achieve the best outcomes. Colorectal, urologic, and gynecologic surgeons should routinely meet and communicate to perform care coordination. The principles outlined in this chapter regarding the management of these conditions, along with the advancements in the science of perioperative surgical management and transplantation, have enabled even those children born with the most devastating congenital anomalies to be restored to health and a functional social status.

CHAPTER 72

Surgery for Intersex Disorders and Urogenital Sinus

Mark C. Adams, Romano T. DeMarco, and John C. Thomas

INTRODUCTION

Advances in surgical management have improved both the cosmetic and functional outcomes of patients with urogenital sinus abnormalities and those with varying degrees of intersexuality, at least when judged by treating surgeons. Early descriptions of methods such as clitoridectomy or convenient "forgetting" of the hypoplastic vagina are now considered archaic because of improved understanding of genital anatomy and function. Better exposure and innovative surgical techniques have produced surgical improvements, but while our understanding of these complex problems is indeed better, it is certainly not complete. Much remains to be learned about female genital function, the effects of surgery on genital innervation, and the significant psychological effects of these problems and their reconstruction on the patient.

GENITAL DEVELOPMENT AND IMPLICATIONS FOR SURGERY

Normal development in any organ system proceeds through a highly selective and complex cascade of interactions. Errors in development virtually always occur in a spectrum of severity and can lead to minor, inconsequential aberrancies or profound problems affecting patient survival. Embryologic errors in the urogenital tract similarly have a wide range of magnitude. Genitourinary embryology is discussed in detail in Chapter 14 of this text.

Under the influence of SRY (the sex-determining region of the Y chromosome), the bipotential gonad should differentiate into a testis near the seventh week of gestation. Normal phenotypic expression of male differentiation is then actively controlled by secretion of the Müllerian inhibiting substance (MIS) by Sertoli cells, and testosterone by Leydig cells. MIS causes rapid regression of the paramesonephric (Müllerian) ducts between the 8th and 10th weeks. In normal females, the absence of the Y chromosome and SRY protein secretion leads to the formation of ovaries without Sertoli or Leydig cells, and therefore the absence of MIS and androgens.

The paramesonephric ducts give rise to the fallopian tubes, uterus, and the upper two-thirds of the vagina. The distal third of the vagina is formed from endodermal tissue, the sinovaginal bulb. In these simple terms, the female phenotype was previously thought of as the passive or default sex, forming in the absence of the Y chromosome.[1] In fact, recent evidence suggests that specific genes, such as Wnt-4, are necessary for formation of the Müllerian duct, suppression of Leydig cell development during the indifferent stage, and maintenance of oocytes in the developing ovary.[2]

In a sense, normal males have a persistent urogenital sinus with ultimate entry of the Wolffian ducts, as well as a remnant of the Müllerian system at the veru montanum. It would therefore seem that the most proximal confluence of a persistent urogenital sinus in a female would be the area of the proximal urethra. While the vast majority of girls with a urogenital sinus anomaly have a confluence at that level or more distally, exceptions do rarely occur. The vagina may be found entering the bladder itself even cephalad to the level of the ureteral orifices. It is not known whether the Müllerian duct opening may migrate into the bladder in tandem with the ureteral bud or whether communication simply develops between the intimate structures.

Clearly, the normal vagina has two embryologic components. That complex development may contribute to the typical appearance of the vagina in the setting of a urogenital sinus. The distal portion of the vagina is virtually always narrow for a variable length (Figure 72.1). Recognition of that finding is critical in surgical reconstruction. Failure of flaps to reach all the way through the narrow segment and well into the more normal proximal portion may lead to stenosis. The paramesonephric ducts and entire Müllerian system are initially paired structures that should fuse distally in the midline. Errors in fusion do occur,[3] and patients with a persistent urogenital sinus or cloaca are at increased risk for such problems (Figure 72.2). In the setting of a urogenital sinus, the finding of a vagina to either side of the midline should arouse suspicion that a second vagina, even if obscure or obstructed, may well exist on the other side. Failure to recognize the second vagina at the time of reconstruction may eventually lead to hydrometrocolpos.

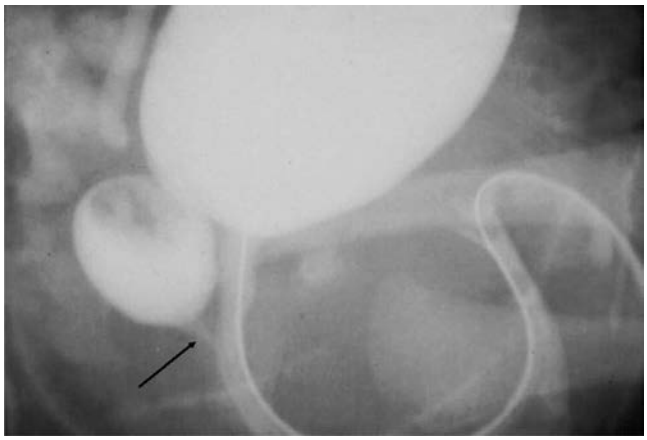

FIGURE 72.1 Genitogram on a female with a urogenital sinus. No matter the level of confluence, the distal vagina (arrow) is usually narrow.

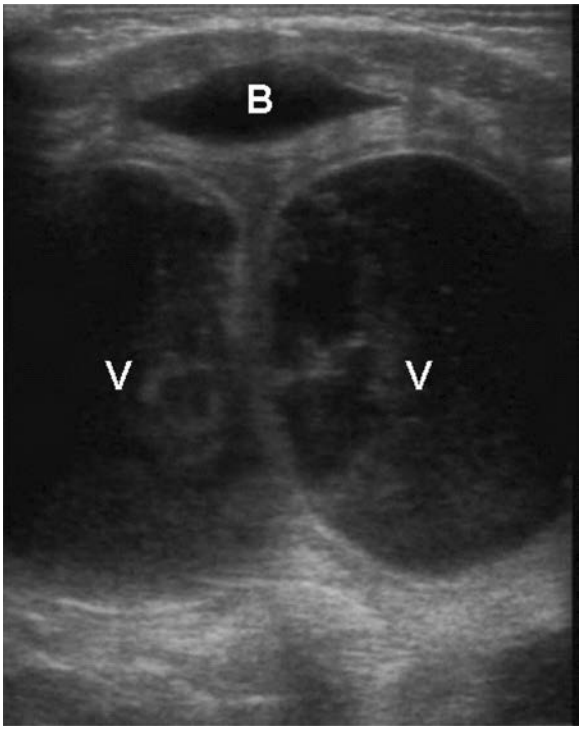

FIGURE 72.2 Postnatal ultrasound on newborn with urogenital sinus and duplicate vagina. Such vaginal distention with urine may be noted on antenatal studies. (B, bladder; V, vagina.)

CLASSIFICATION SCHEME

A urogenital sinus abnormality is present when a persistent communication occurs between the genital and urinary tract in the female. Typically, the urethra and vagina are joined and exit to the perineum as a common channel. If there is associated rectal involvement and imperforate anus, a persistent cloaca or cloacal anomaly exists with a single perineal opening for all three structures. A urogenital sinus with an anteriorly displaced rectum may represent the form früste of a persistent cloaca. Such a finding may have implications for rectal function and exposure during surgical reconstruction of the urogenital sinus. Patients with urogenital sinus anomalies commonly have associated abnormalities of the clitoris, labia, and external genitalia. In fact, the most common etiology of a persistent urogenital sinus is congenital adrenal hyperplasia (CAH).

The most useful classification schemes for urogenital sinus anomalies relate to the level of the confluence of the urethra and vagina. Hendren made a landmark contribution to genital reconstructive surgery when he divided urogenital anomalies into those with a confluence above or below the female external sphincter and suggested that a different surgical approach was indicated for the two types.[4] In females with extreme virilization related to CAH, the external sphincter may be well developed and quite obvious. In most females, the sphincter mechanism may be indistinct and the level of the pelvic floor a more reliable landmark. The absence of a well-defined external sphincter in such patients has led to subjective classification based on the level of confluence as low, moderate, or high. It is important to recognize that the level of confluence should be considered relative to the bladder neck and not the external meatus. Virilization of the distal urethra or urogenital sinus may create a confluence that is distant from the meatus yet still relatively low. The critical determinant is therefore the distance from the bladder neck to the confluence as it affects reconstructive surgery (Figure 72.3). Rink et al.[5] have proposed a more rigid classification scheme based on careful measurements from both directions.

The nature of the urogenital sinus distal to the confluence should also be considered. Hendren described the urogenital sinus distal to the confluence as urethra-like or vagina-like based on circumference.[6] This difference has typically been applied in descriptions of a persistent cloaca but may be useful for isolated urogenital sinus anomalies as well. The difference between the two has

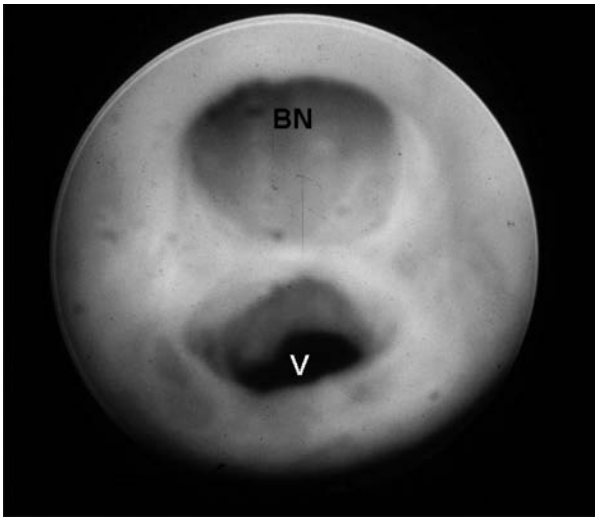

FIGURE 72.3 Endoscopy. A vaginal (V) opening this close to the bladder neck (BN) represents a high confluence no matter the distance from the external meatus.

potential influence on surgical reconstruction in terms of the amount of local tissue available for reconstruction of the urethra or vagina.

EVALUATION

A thorough evaluation of the newborn with a urogenital sinus should be completed expeditiously. Immediate attention to and stabilization of any fluid or electrolyte imbalance is paramount. Delays in appropriate medical evaluation of those patients with CAH and unrecognized salt wasting carry significant risks. Initial screening studies in such patients include assessment of serum electrolytes, biochemical assay screening for CAH, and evaluation of karyotype using cultured peripheral leukocytes. A multidisciplined assessment is initiated, including medical professionals from neonatology, endocrinology, child psychiatry, medical genetics, urology, gynecology, and at times, medical ethics. Gender assignment based on karyotype and potential for genitourinary function should be made after discussion within the entire treatment team and the parents. A child should not be named until the appropriate gender assignment is made.

History and Physical Examination

A careful maternal and family history is mandatory. Maternal use of alcohol or drugs and exposure to androgenic substances, as well as a family history of previous neonatal death, infertility, genital ambiguity, abnormal pubertal development, or inguinal hernias associated with retained Müllerian structures, may contribute to proper diagnosis.

Physical examination of the child is important and may provide further clues. The general well-being of the child should be assessed. Signs of dehydration and lethargy suggest a diagnosis of CAH. Blood pressure should be evaluated since hypertension can be found in patients with 11-β-hydroxylase deficiency. The abdominal exam should note any lower, midline abdominal masses, which might represent a distended bladder or vagina. The back should be assessed for any findings associated with an underlying neurologic anomaly. Gonads are palpated to determine their location, number, and size and associated structures, such as an epididymis and vas deferens. Rectal examination should carefully evaluate the location of the anus, and palpation with the little finger may identify the midline cervical cap or uterine tissue. Careful inspection of the female introitus is required to identify an isolated urogenital sinus if no clitoral or labial abnormalities are present.

Radiographic Evaluation

Ultrasound is a valuable adjunct to physical examination in these patients. The newborn period is the optimal time for evaluation because maternal hormones make the ovaries and uterus more prominent.[7] The spinal cord may also be evaluated to rule out cord tethering. While sometimes helpful, the sensitivity for locating a nonpalpable or intra-abdominal gonad with sonography is at best 60%.[8] Hydrocolpos, in this setting usually related to retained urine, and bladder distension are easily seen with sonography. Likewise, the kidneys should be evaluated for hydronephrosis, dysplasia, and agenesis. Additionally, patients with CAH usually have a cerebriform appearance of their adrenal glands, which may be helpful in diagnosis.[9]

All patients with a urogenital sinus anomaly should undergo contrast genitography. These studies require interest, skill, and determination on the part of the radiologist. The study may be performed by insertion of the tip of a Foley catheter into the opening of the urogenital sinus. The balloon may then be inflated outside the meatus to prevent spillage of contrast, and retrograde instillation of radiopaque dye used to define the anatomy. In many cases, it is then possible to advance a feeding tube into the bladder for formal voiding cystourethrography. Proper studies can define the length of the common sinus and the level of confluence.

Magnetic Resonance Imaging

Although the above-mentioned studies are used to evaluate urogenital sinus abnormalities after the child is born, fetal MRI can give distinct anatomic details that may allow for more accurate postnatal counseling when a cloacal anomaly is suspected on ultrasound. Cloacal malformations can be suspected on MRI with a high degree of certainty in the presence of a multicystic pelvic mass, abdominal ascites from retrograde flow of urine via the fallopian tubes, a dilated bladder, hydrocolpos, or hydrometrocolpos. Small rectovesical fistulas can be difficult to see on fetal MRI; however, meconium extending below the level of a pelvic cystic mass supports the diagnosis of a urogenital sinus. In addition, associated renal and limb anomalies can also be identified.[10]

MRI is especially helpful in the evaluation of Müllerian anomalies, which are common with urologic anomalies and disorders of sex differentiation. The sensitivity of pelvic MRI for detection of a Müllerian duct abnormality ranges from 77% to 100%.[11] For patients with Mayer–Rokitansky–Kuster–Hauser, pelvic MRI can confirm the absence of the midline uterus and assess the presence of uterine remnants, which may be obstructed. The most sensitive time for detection of Müllerian duct remnants is during puberty, as the uterine structures grow with estrogenization. Attempt to delineate uterine structures prior to puberty by MRI has been associated with misleading diagnoses, as the uterus is small and may be difficult to visualize.[12] In any patient with a cloaca, dysmenorrhea is an indication for evaluation of an obstructed uterine horn, which may not have been identified during prior prepubertal operations.

Endoscopic Evaluation

Endoscopic evaluation of the anatomy is critical and should be performed on all children with a urogenital sinus. Generally, this is done under the same anesthetic as open reconstruction, particularly for lower or intermediate lesions. If the anatomy is not well understood after

radiographic evaluation, particularly in the presence of a high confluence or after failure to identify any vaginal structure on genitography, cystoscopy may be performed alone in order to better understand or delineate the anatomy and better prepare the patient and family for reconstructive surgery. Careful endoscopy is generally more accurate than genitography in defining the true level of confluence.[13]

Further Studies

In rare circumstances, usually related to the diagnosis of intersex, the definite diagnosis may remain elusive after conventional studies. At times, hormonal stimulation to evaluate the presence and function of testicular tissue may be indicated. Gonadal biopsy may be necessary for diagnosis. An adequate biopsy requires a full-length, deep longitudinal incision into the gonad to ensure adequate tissue sampling. This may be done in an open fashion or laparoscopically. Such a procedure allows for thorough examination of the pelvis and abdomen for Müllerian and Wolffian structures.

Timing

Significant improvements in surgical techniques and outcomes have occurred over the past several decades. Despite these apparent improvements, controversies remain. Intersex advocacy groups, patients, and some medical professionals still question the timing of surgery and whether reconstruction should be performed at all until the patient can contribute to informed consent. Discussions with a multidisciplinary team and parents must address these controversies prior to female genital surgery. Today, most genital reconstructive surgery is performed in congruence with genetic sex. Only in very rare situations is gender conversion considered.

Most girls with a urogenital sinus diagnosed as infants have CAH. Waiting several months allows good stabilization of the patient from an endocrine and metabolic standpoint. Appropriate medical treatment will, at times, produce improvement in the external virilization but seldom result in complete normalization. Relatively early intervention may carry the benefit of thicker, more vascular skin and easier dissection or manipulation of the clitoris and paravaginal tissue related to maternal estrogen stimulation. There may also be some psychological benefit for the parents from early correction of the virilized external genitalia.

The optimal age for vaginal reconstruction is also controversial. Total genital reconstruction with vaginoplasty has most often been performed as a single stage with clitoroplasty within the first several months to first year of life. This has been particularly true for patients with CAH, most of whom have clitoromegaly and a low to moderate confluence of the urogenital sinus. Potential benefits include improved tissue transfer and reduced scarring secondary to estrogen stimulation, minimization of parental anxiety over the child's condition, and earlier self-acceptance of the child's gender identity and genital anatomy. It must be noted that delayed vaginal construction has been recommended by some surgeons.[14] Early vaginal reconstruction may carry some increased risk of vaginal stenosis when evaluated in the adolescent or young adult.[15] Advocates for delayed reconstruction note the psychological concerns in older patients with subsequent vaginal stenosis, particularly when vaginal dilation is required. It is not clear that later, major reconstruction for vaginoplasty will carry a lesser psychological impact on the patient. We strongly favor complete, early repair, as we have found the exposure and surgical reconstruction then to be considerably easier than in an older patient, and value the availability of genital skin from the clitoris for vaginal reconstruction.

Patient Preparation

Most children undergoing vaginoplasty for a urogenital sinus anomaly, unless the confluence is extremely low, undergo a full bowel preparation using polyethylene glycol-electrolyte solution (Go-LYTELY, etc.). For young children, this preparation is done as an inpatient, with bowel catharsis administered by a nasogastric tube. Adolescent patients may self-administer the bowel preparation orally at home with parental guidance. A series of oral antibiotic doses are often administered, as well as perioperative broad-spectrum intravenous antibiotics.

After general anesthesia is administered, the child is usually placed first in the dorsal lithotomy position for endoscopy. Even if endoscopy has previously been performed in the newborn period, we generally repeat endoscopy at the time of surgical reconstruction, as the internal genital findings may be much more obvious in an older patient. The rectum and distal colon may also be irrigated clear of any residual fecal matter at this time. For higher lesions, a Foley catheter is placed into the bladder, and a second catheter, either a Fogarty or Foley, is placed into the vagina. Cystoscopy aids in confirmation of catheter placement in the appropriate position.

Surgical preparation is dependent on the extent of the planned reconstruction and surgical preference, as well as the age of the patient. In all but the lowest of urogenital lesions, we perform a full, lower body prep from the nipple to toes, front and back (Figure 72.4). The catheters are kept sterile and prepped into the surgical field. The feet and lower legs are wrapped, and the patient passed through an aperture in the surgical drape. This preparation allows exposure to the entire lower body in both the prone and supine positions. It is simple and safe to move smaller patients between the two positions. It is often helpful to perform the external feminizing genitoplasty with the patient supine while exposing and repairing the proximal sinus in the prone position. Trying to prep and move a larger teenage patient in a similar fashion may be cumbersome and impractical. If prone positioning is desired for exposure and vaginoplasty in such patients, a modified skydiver position may be used. Positioning and padding must be utilized carefully to avoid injury.

Feminizing Genitoplasty

The surgical management of the child with clitoromegaly has undergone marked evolution from early methods

advocating clitoral amputation.[16,17] While satisfactory cosmetic results were reported after such procedures,[18] impairment in orgasm and psychosexual development were later noted.[19] The first attempts at sparing the clitoris with modification of the appearance involved clitoral recession or concealment.[20–22] All current techniques have as their cornerstone preservation of clitoral sensation and function and are influenced by Schmid's landmark description of corporal body excision and neurovascular bundle conservation.[23] Early reports described complete excision of the corpora cavernosa of the phallus, including the tunica, while the neurovascular bundle was preserved only with Buck's fascia.[24] It then became clear that subtunical resection of the corporal erectile tissue with preservation of the dorsal tunica might protect the glanular nerve and blood supply.[25] Recently, Baskin and colleagues have suggested that a more ventral tunical incision may be prudent after carefully demonstrating lateral fanning of the clitoral nerve supply.[26] Other interesting work has helped define the spatial relationship of the normal clitoris, urethral meatus, vaginal introitus, and other anatomic landmarks,[27] as well as begun to examine which areas of external genital skin may be most involved in genital sensation and orgasm.[28]

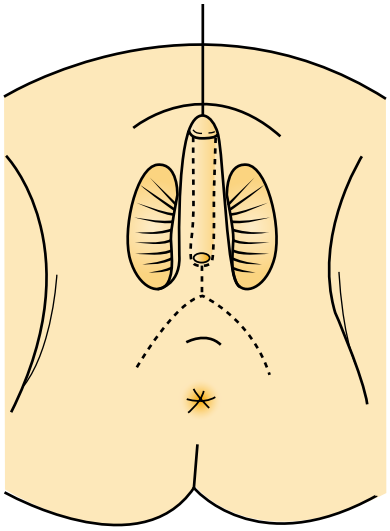

FIGURE 72.5 Feminizing genitoplasty. (a) The dashed lines mark the initial incisions. (b) After mobilization of the skin and posteriorly based flap, the clitoris and sinus are exposed.

Clitoral resection is performed with the child supine with legs spread or in a low lithotomy position. A traction suture is placed in the glans clitoris, and the initial incision is marked and made in a circumcising fashion just off the glans over the dorsum and lateral aspect of the clitoris. Ventrally, the incisions are carried in a parallel fashion from distal to proximal on either side of what would be the urethral plate (Figure 72.5). These incisions are carried proximally to and around the meatus of the sinus. The lines of incision and base of the clitoris may be infiltrated with 1:200,000 epinephrine with or without lidocaine for aid in hemostasis. Incisions are carried down to Buck's fascia and the clitoris degloved of phallic skin. The urethra is generally left attached to the glans with consideration of glanular blood supply, while the urethral plate with spongiosum is dissected off of the corpora cavernosa to expose the ventral tunica of the cavernosa.

The tunica of the corpora are incised proximally at their bifurcation on the ventromedial side (Figure 72.6). Longitudinal incisions are carried out toward the glans all the way through the tunica to exposure of the erectile tissue. Erectile tissue is then sharply excised from the proximal bifurcation out to the level of the corona, along with the ventral tunics. The proximal ends of erectile tissue may be oversewn or suture ligated for hemostasis. Even after treatment with steroids, the glans clitoris may be remarkably enlarged. If so, the glans may be reduced by excising a wedge of glanular tissue on the ventral surface. Baskin et al. have shown that ventral excision of the glans is the most appropriate when considering the nerve supply.[26] The reduced glans should be approximated to the base of the corporal bodies by anchoring sutures. The location of the glans should give consideration to the position of the clitoral hood and symphysis pubis.

Feminizing genitoplasty also involves construction of labia minora from clitoral skin, as well as modification of the labia majora (Figure 72.7). The phallic skin

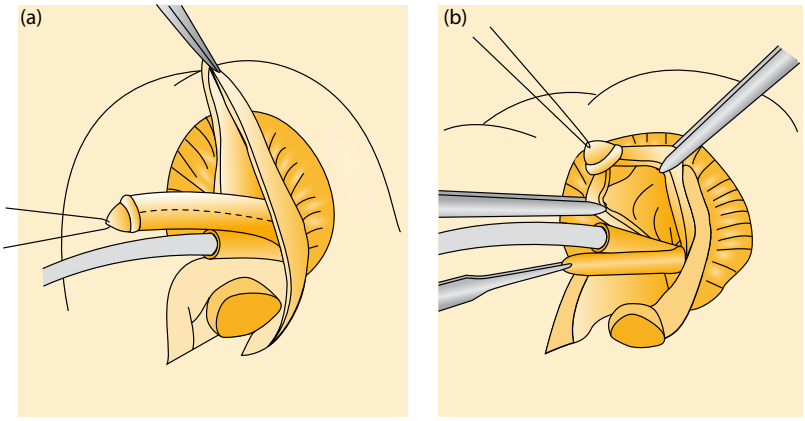

FIGURE 72.6 Corporal reduction. (a) The urethral plate and spongiosum are mobilized off the ventral corpora. The dashed line shows the ventromedial incision into the tunica on either side. (b) The erectile tissue is excised with ventral tunica.

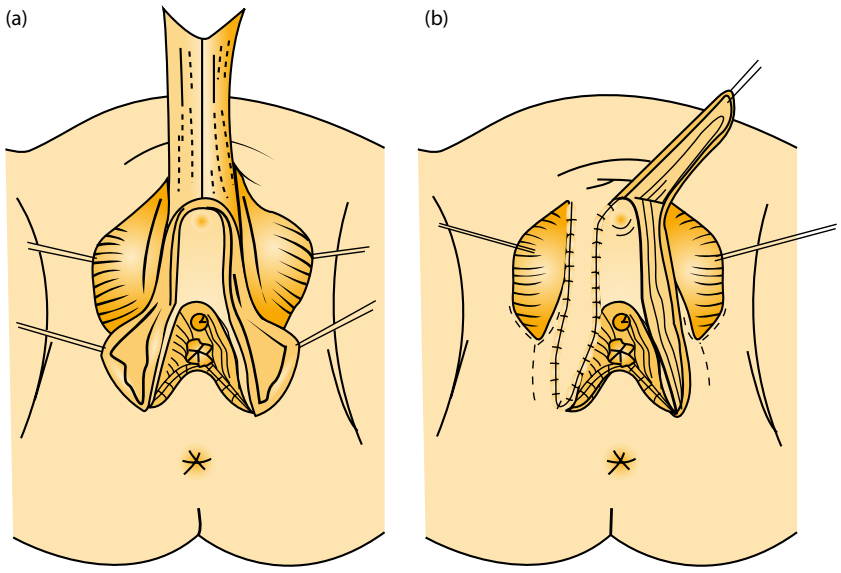

FIGURE 72.7 Labioplasty. (a) Redundant dorsal phallic skin is mobilized and incised in midline. (b) The phallic skin is used as labia minora on either side. Y-V plasty is performed on the labia majora. The posterior flap is advanced into the vagina.

is released dorsally and unfurled by mobilizing the inner from the outer prepuce. The skin is then usually incised in the dorsal midline. The midline incision is stopped short of the base of the phallus in order to preserve an appropriate hood over the dorsal clitoris. The excess skin is rotated ventrally, trimmed, and approximated to either side of the urethral plate medially, as well as the modified labia majora laterally. The flaps, as such, can serve as labia minora. Alternatively, the phallic skin may be used for an anterior vaginal flap in more proximal repairs. The labia majora, as the result of virilization, are often initially short and rounded. An aggressive incision around the medial, posterior, and lateral aspects of the labia majora on either side allows the labia to be lengthened and narrowed using a Y-V plasty. This plastic reconstruction of the labia is often performed in conjunction with flap vaginoplasty, and modifications in the posteriorly based vaginal flap may allow the labia from either side to swing inward posteriorly and avoid an overly wide posterior introitus.[29]

Surgical Correction of the Low Confluence

Cutback Vaginoplasty

A cutback vaginoplasty is a simple procedure performed in the patient with labial fusion. This technique involves incision of the fused skin posteriorly to the perineum to expose the vaginal orifice. The incised lateral edges are oversewn. While such a procedure is simple and may produce a good result in the appropriate patient, it is only a consideration in patients with a common urogenital sinus on the phallus with confluence of a normal vaginal opening at the level of the perineum. That combination is extraordinarily rare; thus, the procedure is very rarely, if ever, indicated.

Flap Vaginoplasty

Flap vaginoplasty is best suited for those patients with a low confluence of the urogenital sinus. The perineal skin incision is marked and made as a broad-based, inverted

U flap.[30] The closed end of the flap is created at the posterior lip of the meatus of the urogenital sinus, and the lateral margins should be well inside the ischial rami. The flap may be variable in length, depending on the length of the urogenital sinus; however, the posterior extent should leave a normal-sized perineal body. Design of the flap should respect considerations of length versus width so as to ensure a good blood supply. Maintaining a U rather than narrow V shape at the tip anteriorly helps to make sure that the end of the flap is not ischemic. The skin flap should be mobilized away from the posterior aspect of the urogenital sinus while maintaining a thick layer of subcutaneous tissue and fat with the flap. This mobilization exposes the urogenital sinus, which is eventually incised in the midline posteriorly. The incision is carried into the vagina and must extend through the distal vagina, which is typically narrow. Failure to place the flap well into the proximal vagina, which is normal in circumference, may result in stenosis, as can ischemia at the distal end of the flap. The flap of perineal skin is advanced into the vagina and secured with interrupted absorbable suture and should reach without tension (Figure 72.7).

The broad-based flap may create an abnormal appearance to the introitus posteriorly when the labia are spread. Careful trimming of the dermis and epidermis at the base of the flap may allow creation of a rhomboid or omega shape without sacrificing viability of the flap (Figure 72.8).[29] Such excision at the base should only remove skin elements but not the underlying subcutaneous tissue. Modification of the flap allows subsequent use of the labia to provide some posterior closure of the introitus and a more normal appearance. Posterior excision of the skin should not be so extreme as to compromise the vascularity of the flap, and the subcutaneous tissue must be carefully preserved at that level.

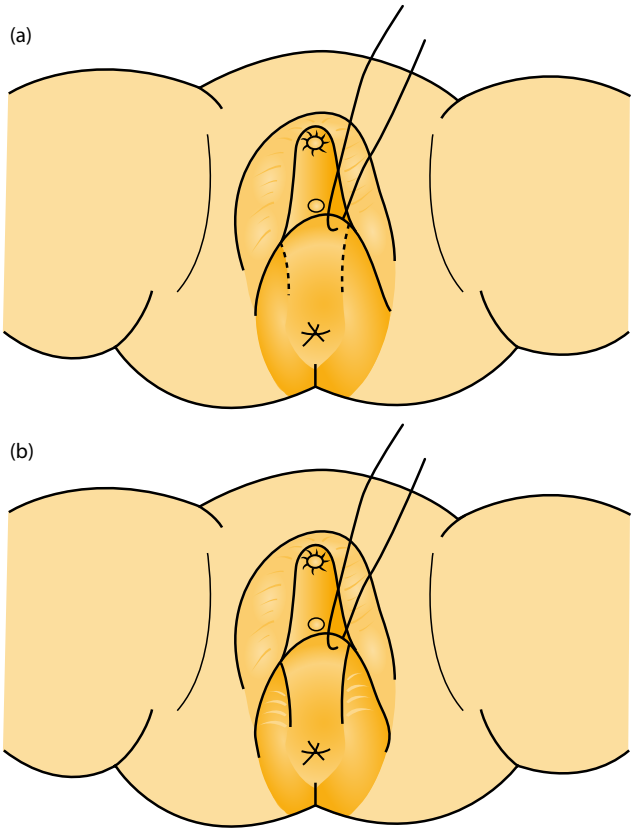

FIGURE 72.8 Omega flap. Skin elements may be excised carefully at the base of the flap to create a more normal-appearing posterior introitus. Subcutaneous tissue and blood supply should be preserved at the base.

It should be noted that flap vaginoplasty does not totally correct the urogenital sinus. Without any separation of the vagina from the urethra and lengthening or advancement of the urethra itself, the patient is still left with a urogenital sinus. The sinus, however, is much broader distally, and may therefore not be of any functional or cosmetic significance. Consequently, flap vaginoplasty should not be a viable surgical option for correction of a high-confluence urogenital sinus. One appropriate role for total urogenital mobilization may be to advance the level of confluence toward the perineum in a patient with a moderate-level lesion in order to make conventional flap vaginoplasty an appropriate technique for repair.

Surgical Correction of the Higher Confluence

Pull-Through Vaginoplasty

This repair, as described by Hendren and Crawford,[4] was a landmark advance in female genital reconstructive surgery; its basic principles still apply for children with higher lesions. Hendren's initial description includes the use of shallow, opposing U-shaped incisions on the perineum at the spot for placement of the eventual vaginal introitus (Figure 72.9).[4,30] Dissection is then made parallel and slightly posterior to the distal urogenital sinus until the vaginal catheter is encountered. A finger placed in the rectum may help maintain the proper plane of dissection posteriorly. The vagina is divided at its entrance to the sinus and then mobilized extensively. The proximal urogenital sinus at the site of prior confluence is closed, and the urogenital sinus used as a functional urethra. As originally described, the vagina is mobilized extensively in a circumferential fashion. The proper plane of dissection between the proximal urethra and anterior vagina is always quite difficult. For the first several millimeters, there is often virtually no connective tissue between the mucosa of the two structures. Dissection must continue through this difficult area in order to achieve adequate mobilization, and Hendren[4] and others[31] initially promoted mobilization of the vagina to the extent that it could be advanced as is to the perineum. Avoidance of the bladder and urethral sphincter mechanisms is mandatary as one proceeds proximally. In general, it is better to err by dissecting too close to the vagina than on the side of the bladder or urethra. This method is technically challenging, largely due to limited exposure to the critical area of the confluence. Early results produced an isolated and separate vaginal opening that is cosmetically unappealing. Additional problems related to vaginal stenosis have been reported and may be due to tension created by attempts to mobilize relatively thin vagina all the way to the perineum.[32]

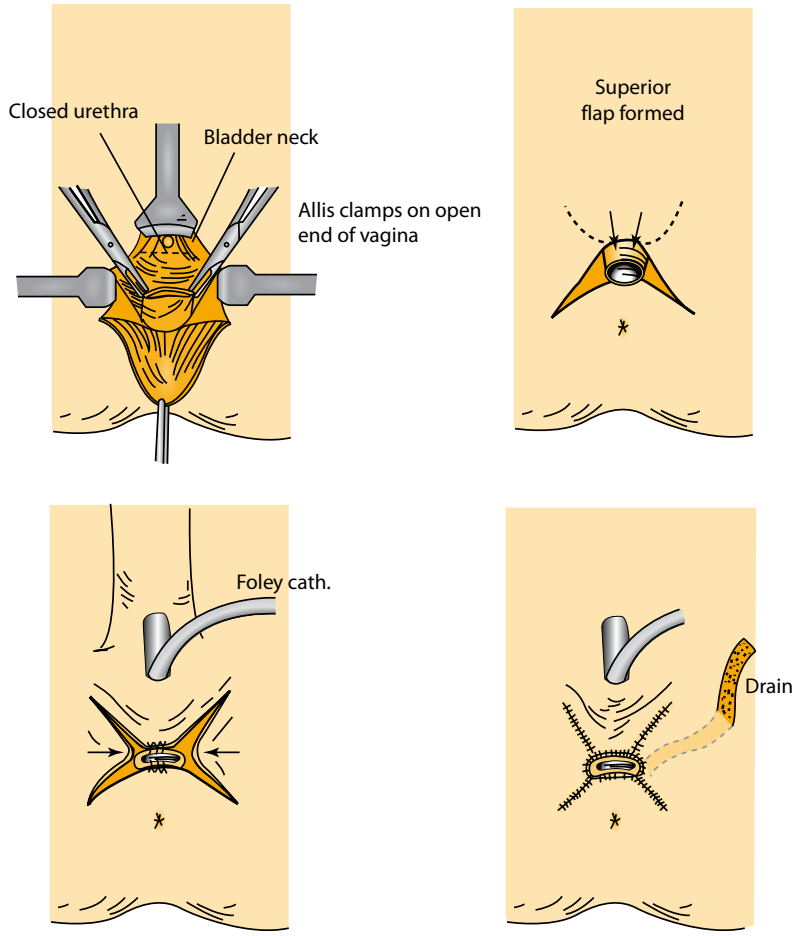

FIGURE 72.9 Pull-through vaginoplasty. The vagina is mobilized off of the urogenital sinus and advanced to the perineum. The sinus is closed as urethra.

Exposure

Much of the difficulty with pull-through vaginoplasties was related to exposure of the high confluence, and modifications have been described to improve the approach to the critical proximal area. Passerini–Glazel, in 1989,[32] popularized Monfort's transtrigonal approach in which the vagina is approached from a midline incision in the posterior wall of the bladder. It does provide superb exposure to a very high lesion but is usually not necessary. During dissection from below, simple incision of the posterior wall of the entire urogenital sinus from the meatus to the level of the confluence may improve exposure over that achieved when leaving the distal portion intact. Opening of the entire sinus then necessitates subsequent tubularization of the same structure for use as a urethra and theoretically increases the length over which a urethrovaginal fistula may occur. Most such fistulas, however, when they occur, do so at the level of the initial confluence where the exposure and repair are most tenuous. Anything done to improve exposure and the quality of the repair at that level may ultimately be advantageous. This extended incision into the sinus is particularly beneficial when the distal anomaly is vagina-like. Such a lesion requires tapering distally to achieve a more normal urethra.

The persistent cloaca is a more complex lesion than a urogenital sinus because the rectum is also involved. Cloacal anomalies are generally approached and repaired through a posterior sagittal incision extending from the coccyx. Once the rectal fistula has been removed and the more proximal rectum mobilized, the patient is left with a urogenital sinus that is nicely exposed through an incision that is much longer in the sagittal axis. Reports do exist of a posterior sagittal approach to a high urogenital sinus with splitting of the rectum either completely or anteriorly.[33] Such exposure is superb but potentially adds morbidity and is generally not necessary. Rink et al.[34] encouraged use of an anterior sagittal prone approach without division of the rectum. This approach provides excellent exposure during the difficult mobilization of the vagina off of the posterior urethra and bladder neck and does not preclude use of an inverted U-shaped incision as described for flap vaginoplasty. The procedure begins with the child supine, and the initial steps of clitoroplasty, if necessary, are performed. Initial dissection onto the posterior aspect of the more distal sinus is begun in the supine position. The patient, prepped from nipple to toes, front and back, is then turned prone. The dissection, with remarkably better visualization after the change in position alone, is continued between the posterior wall of the urogenital sinus and the rectum in the midline. The intact rectum is displaced superiorly with a malleable retractor, and the urogenital sinus is opened well into the vagina

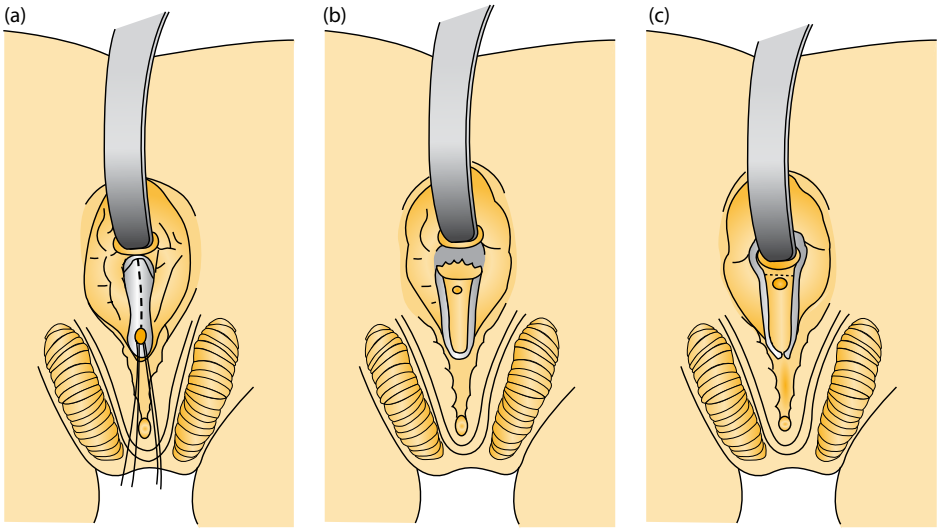

FIGURE 72.10 Prone exposure to high confluence. (a) After creation of a posteriorly based flap, the rectum is retracted to expose the sinus. (b) The sinus is opened into the vagina. (c) The malleable retractor is placed into the vagina to expose the critical area of dissection (dashed line).

(Figure 72.10). The same malleable retractor can then be placed into the vagina to provide excellent visualization anteriorly. Following aggressive anterior vaginal mobilization, the urogenital sinus is closed in several layers over a urethral catheter, creating a neourethra. Generally, several layers of tissue can then be approximated in the midline to separate the vagina and urethra.

Complex Flaps

It is often clear that the short vagina mobilized off of the urethra in a patient with a high-level urogenital sinus may not reach the perineum without tension. The use of flaps to reach the proximal vagina may provide the potential to improve the functional and cosmetic result of pull-through vaginoplasty. Complex flaps of labia majora or buttocks skin from either side may be used to reach the proximal vagina without tension.[35] Such flaps may provide a good result from the standpoint of a functional vagina but can distort the appearance of the introitus. Secondary perineal surgery 6–12 months after initial creation of the flaps may be appropriate to divide the base of such flaps and re-create a more normal appearance of the labia and perineum. Gonzalez and Fernandes[36] used flaps of phallic skin to construct the distal vagina. Passerini–Glazel[32] used the distal urogenital sinus opened anteriorly rather than posteriorly in a similar fashion. The sinus was folded back at the proximal end of the anterior incision and combined with phallic skin to tubularize as a distal vagina. Such flaps of clitoral skin or distal urogenital sinus may be useful in constructing the anterior vagina in combination with a posteriorly based, U-shaped flap. Rink and Cain[37] have recently described lateral incision into the distal urogenital sinus with spiral construction of a distal vagina that is mucosally lined at the level of the introitus (Figure 72.11).

Total Urogenital Mobilization

In 1997, Pena described the technique of total urogenital mobilization for repair of urogenital sinus in patients with a cloacal anomaly.[38] Applications for this repair were soon expanded to include patients with urogenital sinus abnormalities alone. Such mobilization is generally not necessary for patients with a low confluence, and the best indication for its use may be patients with a midlevel lesion in whom the level of confluence may be converted to a low one suitable for flap vaginoplasty. The role of total urogenital mobilization for patients with a very high lesion remains to be determined. Total urogenital mobilization may just be used in such patients to improve exposure at the critical level of confluence. The urethra and vagina can be mobilized toward the perineum and separated, and the structures released back to a proximal position for reconstruction. Total urogenital mobilization for high lesions with advancement of the confluence to the perineum has also been described; however, long-term validation of the results in such patients needs to be determined. Potential advantages of this technique include improved cosmesis, easier dissection leading to decreased operative time, and less risk of vaginal stenosis or urethrovaginal fistula.[38] There is no question that this operative technique with advancement is potentially easier, as it avoids the difficult dissection between the anterior vagina and proximal urethra or bladder neck; an easier operative approach, however, does not necessarily mean a better long-term result for the patient. Rare patients with a urogenital sinus, particularly those related to the persistent cloaca, may suffer from urinary incontinence or poor voiding. Such dysfunction may be related to the anatomic problem, abnormal innervation, or a combination of the two issues. Circumferential dissection of the urogenital sinus to the bladder neck potentially could exacerbate neurologic problems. Even if it does not do so in the short term, long-term follow-up of girls with high lesions undergoing total urogenital mobilization with advancement distally will be required to examine the risk of stress urinary incontinence.[39,40] Stress incontinence in patients after such a procedure would likely be very difficult to treat.

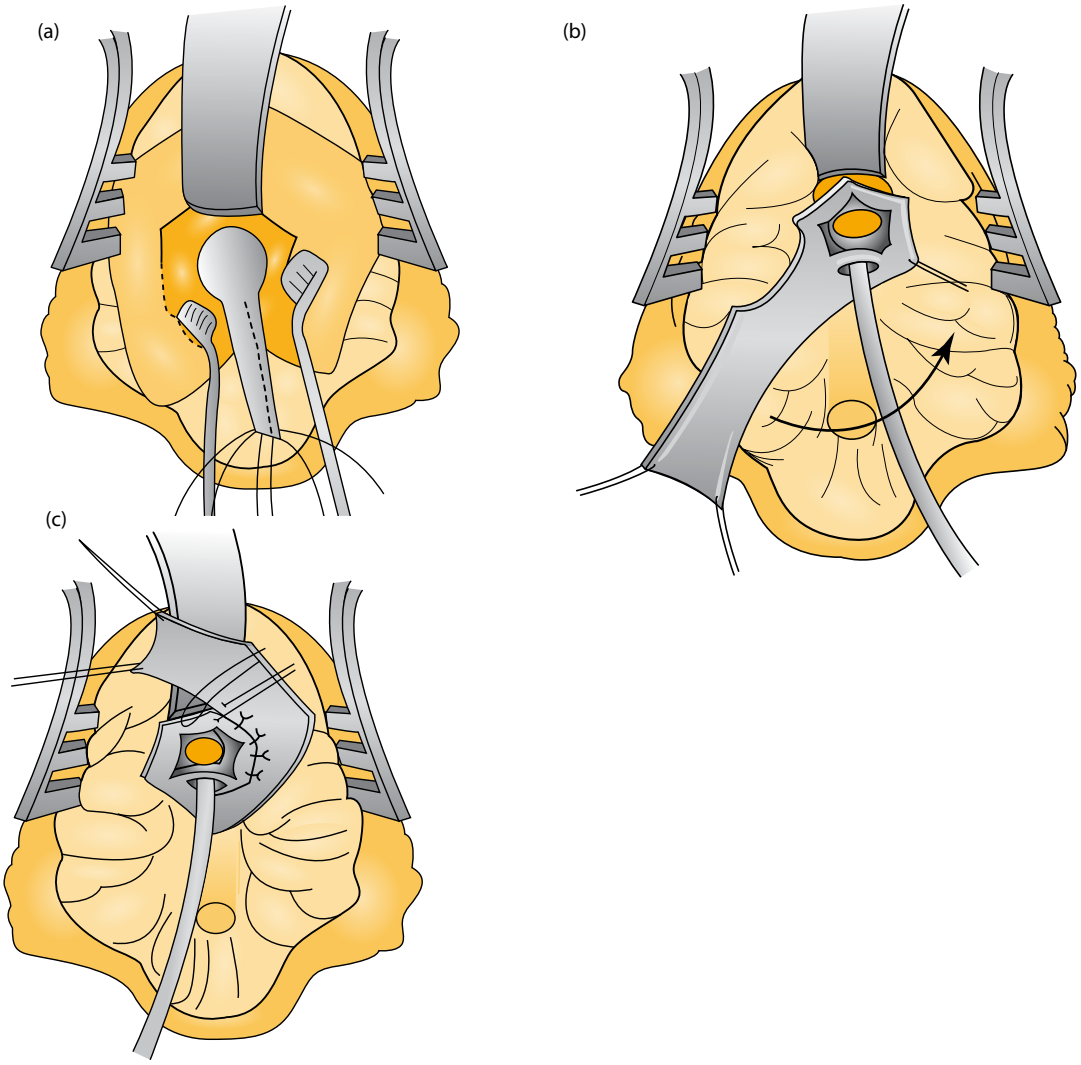

FIGURE 72.11 Use of distal sinus for vaginoplasty. (a) After total urogenital mobilization and exposure of the confluence, a lateral incision in the sinus (dashed line) is planned. (b) A healthy flap is created opposite the side of the incision. (c) The flap can be utilized in a spiral fashion to create a distal vagina.

In total urogenital mobilization, the sinus is initially approached from the midline posteriorly, and attachments between the rectum and sinus divided. This exposure may be done from a midline incision or after creation of a posteriorly based flap. The sinus is then circumscribed at the meatus on the clitoris and dissection carried circumferentially from distal to proximal. The distal sinus is carefully mobilized with all spongiosum off of the corpora cavernosa (Figure 72.12). Anteriorly, the ligamentous attachments of the sinus to the pubis are incised, allowing for adequate mobilization to the perineum. It is possible in some cases that anterior dissection may be stopped just short of these attachments.[41] The catheter in the vagina is palpated, identifying the posterior vaginal wall. The vagina is opened posteriorly between stay sutures well through the distal narrow segment. If the vagina reaches the perineum without tension, the sinus can be opened ventrally to create the vestibule. A posteriorly based flap may be useful in some such cases. If the vagina is very high and the urethra very short above the confluence, a decision must be made on whether advancement of the intact sinus toward the perineum is appropriate (Figure 72.13). If not, the patient may be turned to the prone position and the vagina separated from the sinus. The distal mobilized sinus may then be incised dorsally or laterally, as previously described,[32,37] and used for vaginoplasty after the more proximal sinus is tubularized as the urethra. The child is usually turned back to the supine position to complete the plastic repair of the labia and perineum. Bladder catheter drainage and vaginal packing are usually employed after such complex repairs.

Partial Urogenital Mobilization

Proximal circumferential dissection of the urogenital sinus can increase the risk of sphincteric musculature or nerve injury. Partial urogenital mobilization (PUM) was introduced by Rink and Kaefer as an alternative to manage most confluences, with the exception of the very high anomalies. The circumferential dissection may be stopped anterolaterally at the level of the pubourethral ligament and potentially avoid injury to the sphincteric complex or its nerve supply.[42]

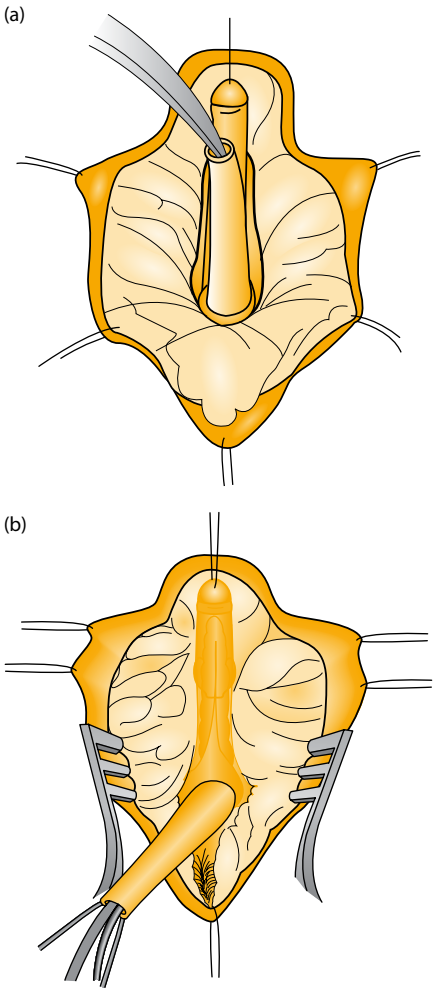

FIGURE 72.12 Total urogenital mobilization. (a) The skin is mobilized and the sinus exposed with a circumferential incision at the meatus. (b) The sinus is mobilized from the rectum posteriorly and the corpora anteriorly up to the pubis.

Vaginal Replacement

Dilation and Traction

In 1938, Frank described progressive dilation of the vaginal dimple with a dilator and manual pressure.[43] Ingram modified this technique in an attempt to minimize patient fatigue and time by instructing patients to sit on a bicycle seat with specially designed dilators to allow for progressive dilation by the weight of the patient's trunk. Ingram applied his technique both as a primary approach in some patients and as a secondary approach following neovaginal contracture after surgery. He reported neovaginal depths of 10 cm within 4–6 months, but it was unclear exactly what percentage of patients actually achieved this result.[44] In a larger series of patients with Müllerian agenesis treated with the Ingram method, functional success, as defined by satisfactory intercourse and acceptance of the largest dilator without discomfort, was reported in 34/37 patients (91.9%), although the series did not include younger patients (<18 years) and the mean time to achieve a functional neovagina was almost 12 months.[45]

There are advantages of this approach, including its noninvasive nature, low complication rate, preservation of native vaginal tissue, and lack of hospitalization. A longer starting vaginal length is advantageous. Another area in which the dilation method has been employed is contracture following a surgically created neovagina.[44] However, this seems to be much more successful when employed early (<6 months) following the operation. The main disadvantage to dilation techniques has been patient noncompliance, secondary to the time and persistent discomfort required to create a functional neovagina. Vaginal dilation can play an important role in the highly motivated patient who wishes to avoid surgery.

For patients with a simple vaginal dimple, a laparoscopic variation of the Vecchietti procedure may produce a neovagina. An acrylic mold with attached tension threads is placed at the dimple, with the threads passed under

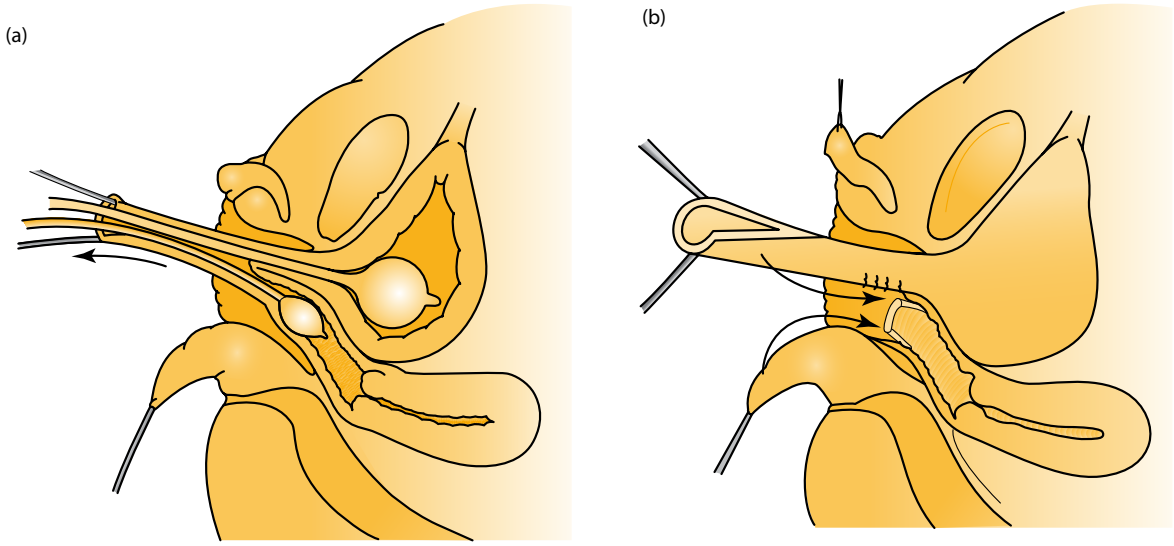

FIGURE 72.13 Options with total urogenital mobilization. (a) After adequate mobilization, the confluence may be advanced to the perineum. (b) Alternatively, mobilization allows good exposure for separation of the vagina and urethra. Anterior and posterior flaps may be used for vaginoplasty after releasing the urethra and vagina in the cephalad direction.

laparoscopic visualization through the abdominal cavity to a traction device on the abdominal wall. Increasing tension from the device is exerted daily over 1 week's time. The increase in tension is often painful, and vaginal dilation is necessary after removal of the mold to maintain vaginal length.[46]

Grafts

The use of split- or full-thickness skin grafts remains an option for vaginal replacement. McIndoe and Banister described the use of split-thickness skin grafts taken from the thigh and conformed to a cylindrical stent (Figure 72.14).[47] Space is created between the urethra and rectum in which the dermal surface of the skin graft is secured. The vaginal stent is left in place to be removed after a period of 7–10 days. A period of weeks to months of daily vaginal dilation is usually required to maintain patency and prevent vaginal stenosis. Full-thickness skin grafts have less reliable ingrowth of blood supply but contract less once in place and vascularized. Both skin grafts leave an obvious cosmetic mark at the donor site.

Buccal mucosa has been used for decades as a reliable substitution for urethra. Buccal mucosa is readily available and accessible, has mucosa-like characteristics, and acquires neovascularity quite easily and reliably if placed in an appropriate environment.[48] These grafts often show eventual squamous transformation when biopsied. The first reported series using buccal mucosa as a primary neovagina was in 2001.[49] There were no reported complications, and all patients reportedly had satisfactory experience with sexual intercourse. Since that time, other studies have reported successful outcomes using these grafts as a primary neovagina, while Oakes and colleagues reported the first use of buccal mucosa to augment a colonic neovagina following stricture formation.[48]

The obvious drawback to using buccal mucosa as a primary neovagina is the inability to achieve adequate-sized grafts.[48] The size of the graft itself can be augmented with small relaxing incisions prior to stretching over a mold, as in the Abbe–McIndoe technique. The ideal mold is 12 cm in length and 2 cm in width. Although a vaginal depth of 8 cm was reported in two series, long-term follow-up and validated sexual satisfaction questionnaires are lacking to conclude that this technique is superior to any of those previously mentioned.[49,50] These patients may also require prolonged postoperative dilation to maintain adequate neovaginal patency.[49,50] Zhao et al. were able to expand the size of buccal grafts by four- to sevenfold by mincing the tissue prior to implantation over a suitable mold.[51] Complications from these series were rare, but included inadvertent bladder and rectal injury, stricture, and bleeding.

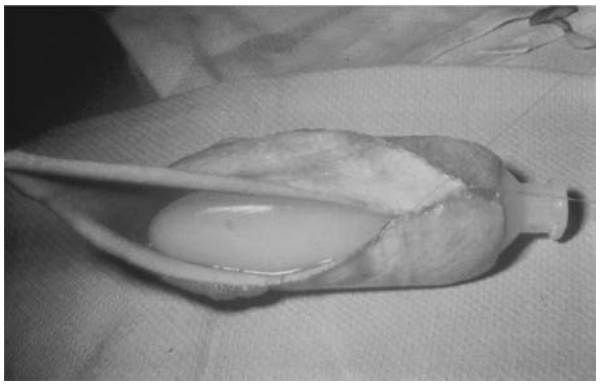

FIGURE 72.14 McIndoe skin vagina. A split-thickness skin graft is modeled over a stent.

The future of vaginal replacement may include grafting of engineered tissue. In 2007, Panici and colleagues cultured autologous vaginal epithelium that was incubated and grown to confluence in special medium. These cells were then mounted and embedded onto gauze that was placed within the host site over a mold. At 6 weeks, the patient was allowed to have intercourse. There were no reported complications.[52]

Flaps

Rotational flaps have been used to create a neovagina. Gracilis myocutaneous flaps,[53] pudendal thigh flaps,[54] labia minora flaps,[55] and flaps raised after tissue expansion have been described.[56] Unfortunately, patients with skin grafts or flaps for vaginal replacement may have problems with lubrication, graft contracture, or dyspareunia, and a need for chronic vaginal dilation.[57] Peritoneum from the pelvic sidewalls and pouch of Douglas can be mobilized laparoscopically and rotated to line a neovaginal space in a modification of the Davydov procedure.[58,59] Vaginal dilation is used after early removal of a mold. Sexual intercourse was successful for 25 of 28 women in a recent series, with vaginal dryness and discomfort a source of difficulty in some.[59]

Bowel Substitution

Advantages of the bowel vaginoplasty include natural lubrication from the intestinal segment, less problems with dyspareunia, and infrequent contracture or stenosis, usually without any need for routine vaginal dilation.[60–62] The sigmoid colon is generally preferred for vaginoplasty because of its proximity and ease of mobilization. In addition, the bowel segment does not need to be reconfigured. A segment of ileum, if more mobile, may also be useful but may require folding in an older patient. Patients may experience malodorous discharge after vaginoplasty, and stenosis may occur at the anastomosis site.

The patient is placed in a modified, low lithotomy position with careful support of the lower extremities to avoid neuropraxia. This position allows for a simultaneous abdominal and perineal approach by two surgeons. Through a low Pfannenstiel incision, the sigmoid is identified and evaluated for mobility. An 8–12 cm segment of sigmoid colon is identified and isolated with a window in the mesocolon at either end (Figure 72.15). A short segment is utilized because redundancy in length often results in eventual prolapse at the perineum. Bowel continuity may be reestablished with a stapled or hand-sewn anastomosis. Simultaneously, a second surgeon may perform perineal dissection by developing space between the bladder and rectum to the level of the peritoneal reflection in the cul-de-sac. Palpation of a catheter in the urethra aids

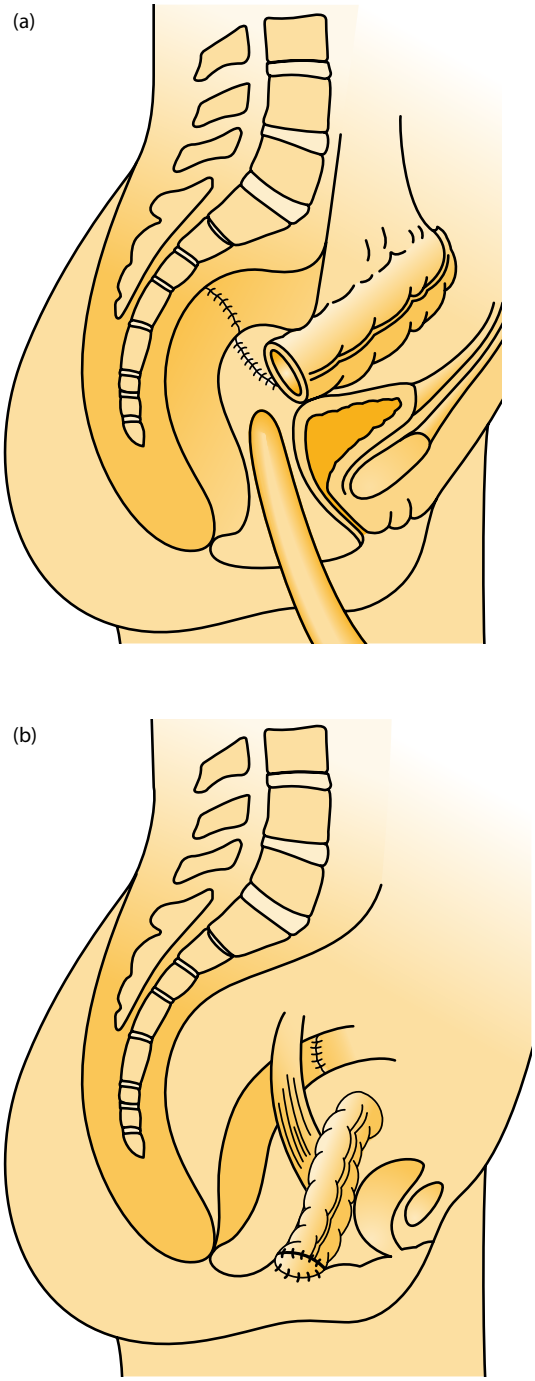

FIGURE 72.15 Sigmoid vaginal replacement. (a) A short segment of colon is isolated and space is created from below. (b) The bowel vagina is secured in place.

in identification of the proper plane. The peritoneum is incised from above and an adequate space created bluntly using a finger initially and then larger dilators. Care must be taken that the space is adequate along the entire length, particularly at the level of the pelvic floor. If an ileal segment is to be used, it is generally opened on its antimesenteric border and folded into a U configuration. Either segment of bowel is checked for viability. Very minimal tension at the distal end of the segment reaching to the perineum may not be problematic and may, in fact, help avoid future prolapse. Extreme tension on the mesentery of the bowel segment should be avoided whether using ileum or sigmoid colon. If such tension exists, creation of larger windows in the mesentery may be helpful, although careful identification of mesenteric vessels is critical. Serial transverse myotomies in the isolated sigmoid colon segment may also aid in lengthening of the segment. An inverted U-shaped perineal flap is often used to avoid the appearance of circumferential bowel mucosa at the introitus. The mobilized bowel segment is approximated to the perineal skin, the skin flaps, or a remnant of the native vagina with absorbable suture. The neovagina is packed with antibiotic-soaked gauze, which is removed after several days of healing. Irrigation of the bowel segment to avoid accumulation of excess mucus is then begun.

Other Procedures

Gonadectomy

A thorough chromosome evaluation is mandatory at the time of initial diagnosis in children with ambiguous genitalia. The presence of all or part of the Y chromosome in patients with disorders of gonadal differentiation may place them at increased risk for development of gonadoblastomas and other germ cell tumors.[63,64] Bilateral gonadectomies in such patients have been typically performed in the first several years of life; however, no consensus exists in regard to the optimal timing.

Gonadectomies are also performed in children with severe feminizing male pseudohermaphroditism who have undergone gender conversion. Laparoscopic excision may minimize morbidity and improve the cosmetic result; it also allows for therapeutic visualization of the abdomen, pelvis, and accessory sex organs. Longitudinal biopsy of the gonads may be appropriate in some patients for diagnosis or prior to excision.

Reconstruction for Male Pseudohermaphroditism

Male pseudohermaphroditism occurs when there is impaired genital differentiation of an XY male with developed testes and may result in a wide range of male and female phenotypes. Treatment of these children must be individualized, and appropriate surgical intervention may include relatively minor hypospadias repair, orchidopexy, or major genital reconstruction, including gender conversion. A detailed discussion of the treatment of these patients is found in Chapter 57.

RESULTS OF RECONSTRUCTION

Quality reviews documenting long-term results following feminizing genitoplasty or vaginoplasty in the setting of a urogenital sinus are lacking, particularly any with careful consideration to the initial anatomy or the surgical technique employed. Clitoral nerve conduction studies have identified preservation following clitoral reduction techniques and are encouraging in regards to ultimate clitoral

function.[65] Work evaluating orgasm and sexual satisfaction following such reconstruction is rudimentary at best.

More studies have evaluated the vagina after reconstruction in terms of more obvious complications, such as vaginal stenosis or urethrovaginal fistula. Studies evaluating the ability of the vagina to accommodate sexual intercourse after such reconstruction have provided sobering results. Jones and colleagues have noted that 30% of patients required surgical revision after initial vaginoplasty in order to achieve satisfactory intercourse,[66] and Azziz et al. reported satisfactory coitus in only 62% of patients 20 years following vaginal reconstruction in patients with CAH.[67] Many of those patients, however, had required secondary or tertiary procedures to correct stenosis at the introitus.

Early vaginoplasty may be a factor in the development of vaginal stenosis. Sotiropoulos et al. noted that all their patients operated on in the prepubertal period required revision of their introitus at a later date.[68] Bailez and colleagues, as well as Azziz, noted more revisions among children in whom vaginoplasty was performed prior to 1 year of age.[14,67] These older series included a wide range of patients with variability in the severity of the initial anomaly or even in the surgical techniques that were employed in their repair. It is possible that newer techniques for exposure, tissue handling, and use of flaps for vaginal reconstruction may change the surgical outcomes for the better; however, only long-term follow-up will determine if that is indeed the case. Careful attention must also be applied to define the severity of vaginal stenosis after reconstruction. Many stenoses may be minor and only result in the necessity for a minor revision, usually involving modified Z-plasty at the level of the narrowing. Such secondary procedures are certainly less troublesome than major rotational flaps that might be required for severe, extensive stenosis. The difference between the two has not always been well indicated in historic series.

The role of routine vaginal dilation in an attempt to avoid vaginal stenosis remains unclear. Routine dilation or calibration may help some patients avoid stenosis if done regularly, particularly patients destined to develop minor stenosis. It is less likely that routine dilation will avoid problems in patients headed for extensive fibrosis and stenosis. It is quite possible that long-term vaginal dilation or calibration may cause some psychological trauma for the patient or parent. Proponents of delayed vaginal reconstruction would suggest that the need for dilation or secondary surgical revision demonstrates the advantage of later reconstruction. It is clear that vaginoplasty, particularly for a patient with a moderate- or high-confluence urogenital sinus, is a major surgical procedure in an older patient. Such a procedure may likewise have a profound psychological impact on the patient and still carry risk for stenosis or other complications.

Urethrovaginal fistula can occur following reconstruction of the urogenital sinus, but fortunately is much less common than vaginal stenosis. Careful, yet aggressive, separation of the vagina and urethra allows adequate reconstruction of both structures and interposition of layers of tissue in between in order to minimize the risk of fistula. The most likely place to develop such fistula is the area of the initial confluence. Modern techniques that improve exposure and use more effective flaps for vaginoplasty should lower the risk of fistula formation. Total urogenital mobilization without separation of the proximal urethra from the vagina should carry virtually no risk for the problem.[38]

Despite the fact that modern techniques of clitoral reduction preserve nerve conduction following surgery, this finding may not equate to normal sensation or the ability to achieve orgasm, and further studies with self-reported validated questionnaires are warranted.[69–71] Pregnancy is possible in patients who have undergone vaginoplasty, and vaginal delivery can be safely recommended for those patients who undergo flap vaginoplasty and even total urogenital mobilization. However, pregnant women who undergo complex vaginoplasty with distal flaps are likely best served with an elective cesarean section.[72]

CONTROVERSY

Historically, the decision of gender assignment has been made shortly after birth by the parents in consultation with a multispecialty team. This choice involves many factors and includes genotypic sex and the functional potential of gonadal tissue, reproductive tracts, and the external genitalia. Such a scheme is still utilized in most centers. Sex assignment in infancy has been advocated by many, as it allows for early and consistent gender-specific social interactions throughout childhood. Support for this school of thought came from the observations and work of Money and investigators.[17,73–75] Partially driven by older patients unhappy with their sexual development, some of the lay and medical community have more recently questioned the timing and need for reconstructive surgery. Proponents of waiting and allowing for full participation in such decisions by the patient at a later age have appeared and gained support.[76,77] A few authors have called for a moratorium on genital reconstructive surgery until these concerns can be appropriately addressed.

It is beyond the scope of this chapter to address the moral, ethical, and gender identity issues involved with female genital surgery. It is important to note that while no universal practice policy has gained acceptance, it is incumbent upon the surgeon interested in such problems to be well aware of these issues and discuss them openly with patients and parents. Well-planned, long-term outcome studies are needed to address these problems and should lead to further refinement in the timing and techniques of genital reconstruction.

CONCLUSIONS

Significant strides have been achieved in surgical outcomes of patients with urogenital sinus abnormalities and intersex states. Evaluation of previous techniques, along with an improved understanding of genital anatomy and greater sensitivity to the complex nature of genital innervation, has led to improvements in terms of both cosmesis and, perhaps, function. Although complications, the most common being vaginal stenosis, may still occur following

female genital reconstruction, the ultimate expectation for the patient and family should be normal or nearly normal-appearing and functioning genitalia. Even when such a result is achieved, the underlying problem and process of reconstruction often have a profound psychological impact on the patient, particularly in terms of sexual identity. It remains to be determined how the best functional end point can be achieved for the patient with the least morbidity in that regard.

CHAPTER 73

Hypospadias

Warren T. Snodgrass and Nicol Corbin Bush

INTRODUCTION

With a prevalence of 1:200 males, hypospadias is one of the most common congenital anomalies. Each year, 10,000 boys are born with the condition in the United States, or an average of 27 every day. In contrast, there are 16 new infants with Down's syndrome, 12 with cleft lip, and only 4 with spina bifida born daily.[1]

Nevertheless, hypospadias is uncommon, and proximal hypospadias is a rare condition, with only 1000 new cases each year. After reviewing case logs submitted by pediatric urologists applying for specialty certification, the American Board of Urology reported that the median number of distal repairs done annually is only 12, and only 2 for proximal hypospadias.[2]

Given that hypospadias surgery, even for distal defects, is complex, and that a growing body of literature shows that outcomes from complex operations are best from surgeons who perform them frequently, it is not surprising that many patients develop complications after their repairs. Although surgeons may claim 95% success for distal repairs, the Dutch Hypospadias Study prospectively recorded results from surgeons throughout the country and found that complications ranged from 4% to as high as 63%, and averaged 16%.[3] Outcomes from proximal hypospadias surgery are even worse, with several U.S. centers recently reporting complications in 55% to nearly 80% of cases.[4–6]

No other surgery done by pediatric urologists harms more patients than hypospadias repair.

Furthermore, numerous studies regarding hypospadias reoperations agree that complications are higher than in primary repairs. We found that even the first reoperation had twice the risk for additional urethroplasty complications, and after three failed repairs the risk was 40%.[7] Even surgery for distal hypospadias sometimes results in a hypospadias cripple.[8]

These observations emphasize that there is no "minor" hypospadias, and that it is important that repairs be performed optimally the first time. To that end, this chapter presents a limited surgical algorithm and highlights the key steps of each procedure. By using fewer techniques and gaining expertise in their key steps, surgeons can improve their results and increase the likelihood for boys to achieve a normal penis.

PREOPERATIVE ASSESSMENT

Isolated versus Syndromic Hypospadias

Approximately 90% of hypospadias cases are isolated penile defects. Syndromic hypospadias is suspected when there are additional nongenital anomalies, especially dysmorphic facies and anorectal malformation.

Imaging

Renal abnormalities have been reported in approximately 20% of hypospadias patients, mostly ureteral duplications, malrotations, or minor hydronephrosis not requiring intervention. Vesicoureteral reflux has been found in approximately 10% of patients studied with voiding cystourethrography (VCUG). There is no correlation in reported series between the severity of hypospadias and these findings.[9,10] We do not image boys with isolated, that is, nonsyndromic, hypospadias regardless of its severity.

Imaging may also demonstrate an enlarged utricle in boys with proximal hypospadias. However, this information is of limited value, as nearly all utricles are asymptomatic. Those encountered intraoperatively because of difficulty passing a catheter into the bladder can be bypassed using a Coude-tipped catheter or a guidewire with or without urethroscopy.

Disorders of Sexual Differentiation

By definition, hypospadias and intersex are separate conditions. While some patients with a diagnosis of disorder of sexual differentiation (DSD) have hypospadias, few patients with hypospadias also have DSD, and even fewer question their male gender identity. No published series reports the results of evaluation in consecutive patients with hypospadias to determine the prevalence of DSD. Rather, testing has been selective, most often for the combination of hypospadias with an undescended testicle. Karyotyping in this situation has found chromosomal anomalies in <33% of those studied.[11–13] However, a normal karyotype does not exclude DSD, as occasionally an ovatestis is encountered during harvesting of the tunica vaginalis for a coverage flap in proximal repairs, despite both testes being descended.

It is important that physicians avoid casual use of such terms as *ambiguous genitalia* and *intersex* when discussing findings in a newborn with apparent hypospadias. First, palpable gonads essentially exclude ambiguous genitalia despite even perineal hypospadias. Second, caregivers are frequently already anxious about a diagnosis of hypospadias, which most have never heard of, and the Internet search that inevitably follows these words creates even greater anxiety, including worry about whether their son is actually a boy. The diagnosis of DSD associated with hypospadias almost never implies future gender identity confusion.

Hormonal Therapy

Preoperative hormonal therapy has been advocated to increase penile size and vascularity to improve outcomes of repairs, especially for proximal hypospadias. Numerous studies show that stimulation can increase penile length and glans circumference, and one study reported an increase in prepucial vascular density.[14] However, indications for treatment are ill-defined, dosing regimens are empiric, end points for therapy are rarely stated, and no study demonstrates reduced complications for proximal repairs after stimulation.

We realized that glans dehiscence occurred more often following proximal tubularized incised plate (TIP) repairs than distal TIP repairs done by the same surgeon using the same sutures and glansplasty technique.[15] Suspecting that a smaller glans size in proximal hypospadias potentially explained these findings, we next measured the glans diameter in consecutive boys undergoing distal and proximal repairs, and in newborns undergoing office circumcision.[16] The average width in those with proximal hypospadias was significantly smaller than that measured in other boys (12.9 mm vs. 14.3 and 14.8 mm in distal hypospadias and normal boys, respectively).

Next, we began testosterone injections in boys with a glans width of $\leq$13 mm, with the goal to increase it to $\geq$14 mm. We found that our use of testosterone doubled using the objective criteria of a measured glans width compared with earlier subjective use for a small-appearing glans. In addition, we found that the standard recommended regiment of two or three injections of 2 mg/kg testosterone cypionate failed to achieve the desired increased width in 57% of patients, indicating androgen resistance.[17] Finally, successful enlargement of the glans did not reduce urethroplasty complications after surgery done approximately 6 weeks later, which remained three times more likely than in boys with a similar glans width without stimulation. In fact, the statistical model found testosterone to be a risk factor for complications.[18] Therefore, we stopped using testosterone stimulation.

Potential side effects of hormonal stimulation include accelerated bone aging and pubic hair. Two studies regarding bone age reached different conclusions.[19,20] Pubic hair growth was reported in 0 of 25, 2 of 25, and 5 of 21 boys receiving various regimens of topical or injected testosterone.[19,21] We have evaluated several boys who grew pubic hair after stimulation (Figure 73.1).

FIGURE 73.1 Pubic hair growth following testosterone treatment. Six-year-old treated with testosterone after failed distal hypospadias repair. The hair has persisted during 4 years' follow-up.

It is also important to emphasize that few boys with proximal hypospadias have micropenis. That diagnosis requires a stretched penile length of $<$2 standard deviations (SD) below the mean in a patient with normal internal and external male genitalia.[22] For infants 6–12 months, a micropenis is $\leq$2.3 cm. Obviously, it is difficult to accurately determine penile length in boys with ventral curvature (VC). While boys with proximal hypospadias may have penile measurements below the mean, few are less than 2 SD, which means that their smaller penis sizes are nevertheless within the normal range.

Imprecise use of the term *micropenis* by physicians to caregivers of boys with hypospadias can cause unnecessary anxiety regarding future sexual potential.

Determining the Need for Repair

The goal of hypospadias repair is to create a normal penis, meaning a straight penis with the opening in the correct location at the tip. The normal glans encloses the urethra, and the distance from the lower lip of the meatus to the corona in normal boys is a mean of 4.7 mm and a minimum of 2.4 mm[23] (Figure 73.2).

The normal urine stream is straight and compact, that is, does not spray. When the meatus is not enclosed by the glans for at least 2.5 mm, the likelihood the boy or man will experience deflection and/or spraying increases. Parents usually do not notice these abnormalities in their infant sons, which become more apparent when the patient achieves a sufficient height after toilet training that the penis is not inside the toilet while urinating.

Even teens and adults with uncorrected hypospadias who stand to void without difficulties may experience body image concerns regarding their penis.[24] Those who

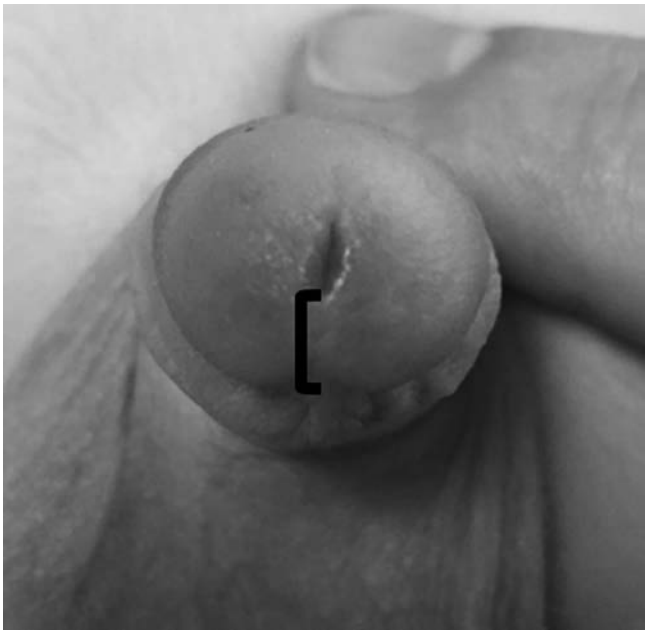

FIGURE 73.2 Normal penis. The bar shows the normal distance that the distal urethra is enclosed by the glans wings, which is >2.5 mm, averaging 4.7 mm. Deviation from normal in distal hypospadias increases the potential for urine spraying.

elect surgery commonly say they wish to "be whole," and report they had anxiety around peers and new sexual partners.

Hypospadias repair is not cosmetic surgery. The American Society of Plastic Surgeons defines *cosmetic surgery* as the enhancement of normal body parts, whereas *reconstructive surgery* includes repair of congenital defects.[25] This distinction is important, given that many parents express concern about performing cosmetic surgery on their son's genitalia, but are reassured when informed that the operation is reconstructive to achieve normal appearance and function.

No study describes functional and psychologic outcomes in an unselected cohort of teens and young adults with uncorrected hypospadias. Therefore, the number of those who will experience voiding disturbance and/or emotional distress is not known. However, a survey of patients with uncorrected hypospadias who presented to pediatric urologists found that 33% were dissatisfied with their penile appearance, 41% were concerned about what others would think about their appearance, and 54% were dissatisfied with their voiding, with 37% describing spraying or deviation of the stream. Fifty percent of these patients held strong negative feelings about their penis body image.[24]

Informed consent regarding surgery for distal hypospadias best states that there is a risk for functional and aesthetic concerns in patients with abnormal anatomy, and accurately describes repair as reconstructive surgery.

Caregiver Guilt

The diagnosis of any birth defect can be devastating to parents, who then often experience stages of grief for the "loss" of the normal child they expected.[26] Mothers often feel guilty, believing something they did, or failed to do, during pregnancy caused the problem. Adding to these concerns are the isolation and shame of a defect involving the penis that neither they nor their family and friends have heard of. Parents have told us that they went through staged reconstruction of their son's proximal hypospadias without the support of extended family or friends because others did not know about hypospadias and they were too embarrassed to discuss a defect of the penis.

Parents also may describe frustration trying to learn more about hypospadias once they have been told the diagnosis. In their view, office consultations with surgeons may be too focused on arranging surgery, and not on discussing the reasons hypospadias occurs and its potential impact on future sexual activity and fertility. Most have researched the Internet and grown even more confused about these subjects. They have also been exposed to both professionals and activists claiming that surgery is cosmetic, repairs are not durable, and surgery on the penis reduces future pleasure by creating scars and decreasing sensation. If they have gotten second opinions, parents can be frustrated by the lack of consensus regarding treatment.

Simply acknowledging these possibilities during the consultation can indicate both awareness of their concerns and an interest by the urologist in more than the surgical aspects of the condition. More research into parenteral reactions to the diagnosis of hypospadias is needed. Recommendations to appropriate mental health providers, such as licensed therapists to help patients and families deal with anxiety and stress related to hypospadias, should be provided.

Timing of Surgery

We published that surgery for distal hypospadias repair can be safely accomplished as early as 3 months of age for full-term and healthy infants, in facilities with pediatric anesthesia and nursing.[27] Infants with proximal hypospadias are more likely to be born prematurely, or with intrauterine growth retardation, which delays repair until the child is gaining weight and can undergo outpatient surgery. We wait until at least 6 months of age before operating for proximal hypospadias to also allow for maximum penile growth from postnatal mini-puberty.

There is belief that surgical outcomes are better in younger patients, but several retrospective case series reported conflicting results, with increasing complications after 6 months, 1.5 years, or 4 years of age.[28–30] Our data, collected prospectively in consecutive patients undergoing TIP repair, found age was not an independent risk factor for urethroplasty complications.[27]

Another question arises when there is both hypospadias and an undescended testicle, regarding surgical management. In distal cases, orchiopexy and hypospadias repair can be done simultaneously, or in a staged fashion according to surgeon preference. However, in proximal cases we first correct the hypospadias to preserve tunica vaginalis to cover the neourethra, and to correct penoscrotal transposition before anchoring the testes.

INTRAOPERATIVE MANAGEMENT

Nerve Blocks

Regional nerve blocks reduce the intraoperative level of general anesthesia, and initial postsurgical pain. Caudal blocks, penile nerve blocks, and pudendal nerve blocks are options, with the decision often made according to the preference of the anesthesiologist. A potential disadvantage of dorsal penile nerve blocks is migration of medication into the penile shaft, distorting the surgical field. Dissection along the ventral midline near the glans can also provoke discomfort if a supplemental injection is not done in the perineum or scrotum.[31] A potential disadvantage of caudal blocks is increased likelihood for intraoperative penile engorgement. No appropriately designed randomized controlled trial has been published to date that specifically investigates if complication rates vary by type of regional block.

Preoperative Antibiotics

There are no data supporting preoperative antibiotic administration for hypospadias repair. Similarly, there are no reports regarding wound infection following hypospadias surgery to determine the incidence, means for diagnosis, or organisms encountered.

We do not use antibiotic prophylaxis, except for a single dose of cefazolin before oral graft harvest.

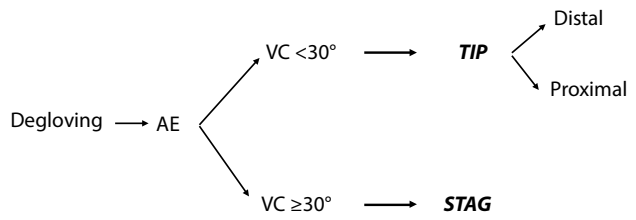
Decision Making for Primary Repairs

We correct all hypospadias using two surgical techniques: TIP repair and staged tubularized autograft (STAG) repair (Figure 73.3). These methods are similar in that TIP involves tubularization of the urethral plate, while STAG is tubularization of a neourethral plate of oral or prepucial autograft.

Traditionally, decision making among a variety of available techniques was made by the surgeon's assessment of the specific anatomy encountered, meatal location (distal or proximal), and the surgeon's preference. However, characterization of the anatomy includes subjective impressions with significant interobserver variation.[32] This introduces selection bias, which results in different recommendations for a given patient, and difficulties in comparing outcomes of various series.

Decision making for TIP versus STAG depends on the extent of VC determined after degloving and release of ventral penile dartos and any scrotal dartos extending up the penile shaft. Patients with a VC of <30° undergo TIP, while those with a VC of >30° have STAG repair, regardless of meatal location.

While we do not perform flap repairs, some, especially the onlay prepucial flap, remain in use as an alternative to proximal TIP.



AE: artificial erection

FIGURE 73.3 Algorithm for primary hypospadias repair. The surgical algorithm is based on the extent of associated VC, rather than primarily on meatal location. While there are other options, this algorithm covers all primary hypospadias.

SURGICAL REPAIR

Straightening Ventral Curvature

Ventral bending of the penis relates to three factors: short ventral shaft skin, a short urethral plate, and short ventral corpora ("corporal disproportion").

Preoperative assessment frequently suggests VC, even in patients with distal hypospadias, and caregivers are often informed that their son has "hypospadias with chordee." Much of this apparent bending resolves spontaneously while degloving the penis, commonly leaving a gap between the skin and the glans. In most distal hypospadias, degloving corrects any VC, indicating the etiology was short ventral skin.

Artificial erection after degloving, including release of ventral penile and scrotal dartos attachments to the shaft, may demonstrate that the penis is straight, or that there is a curvature of <30° or ≥30°. Measurement of bending should be done objectively, using a goniometer (Figure 73.4).

A VC of <30° is straightened by dorsal plication (Figure 73.5). Buck's fascia is opened longitudinally in the dorsal midline at the point opposite the greatest curvature. A single 5-0 polypropylene suture is placed into the tunica albuginea, burying the knot. The maximum distance traveled by the needle is approximately 4 mm. Adjacent dartos is then sutured over the plication to further conceal the knot. Repeat erection is done to confirm straightening.

Nesbit plication involves incision into the tunica albuginea, or removal of an oval of the tunica, before suturing. Traditionally, this was done bilaterally, lateral to the midline after elevating penile nerves. There are no data showing that this method is superior to the less invasive midline (Baskin) plication.

A VC of ≥30° should not be straightened by dorsal plications, because the straightening initially achieved may not be durable.[33–35] Rather, the next step is to transect the urethral plate at the corona and dissect it (including the wings of the corpus spongiosum) back to the meatus (Figure 73.6). We then continue this dissection proximally, releasing the formed urethra from the corpora to near the external sphincter (Figure 73.6). Any remaining dartos or corpus spongiosum ventrally is excised from the corporal surface. Then artificial erection is repeated. Correction of a VC, or its reduction to <30°, by this maneuver indicates that bending was largely due to a short urethral plate. A residual curvature of <30° is straightened by midline dorsal plication. A persistent curvature of ≥30° should not be

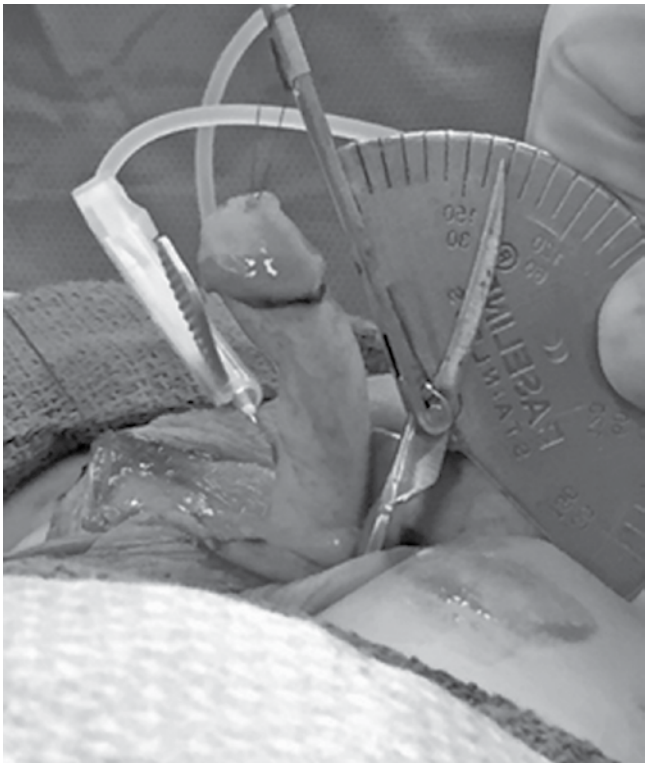


FIGURE 73.4 Measuring VC using a goniometer. This devise, used in hand surgery, makes determination of the degree of VC objective, and therefore more accurate. This patient has a 30° curvature, which is not visually impressive.

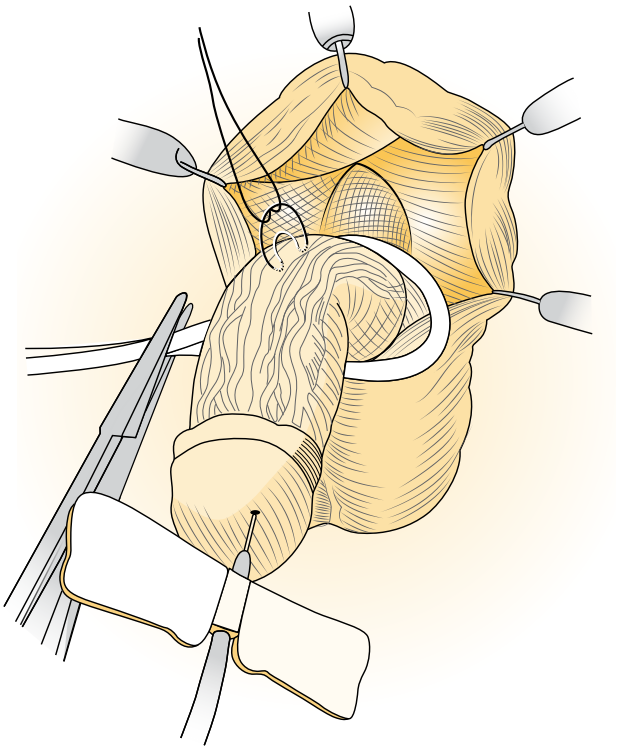

FIGURE 73.5 Midline dorsal plication.

straightened with plication alone due to the high recurrence rates of VC.

A persistent VC of ≥30° after dissection of the urethral plate and urethra off the corpora indicates short ventral corpora, which is corrected with ventral lengthening. We incise the ventral tunica albuginea in three locations, first through the area of maximum bending, and then 4 mm above and 4 mm below the first (Figure 73.6). These incisions are transverse, from approximately four to eight o'clock, extending just through the tunica. Artificial erection is repeated, now using a 21-gauge butterfly to achieve sufficient inflow, which should confirm straightening (Figure 73.6). Generally, there is a gain in length of 8–10 mm along the ventral surface of the penis after the three corporotomies. We do not place a corporal graft over the corporotomies, but we do additionally place a single midline dorsal plication to supplement the corporotomies.

Ventral lengthening has also been done by a single transverse corporotomy from three to nine o'clock, followed by a graft of dermis, or other materials, to cover

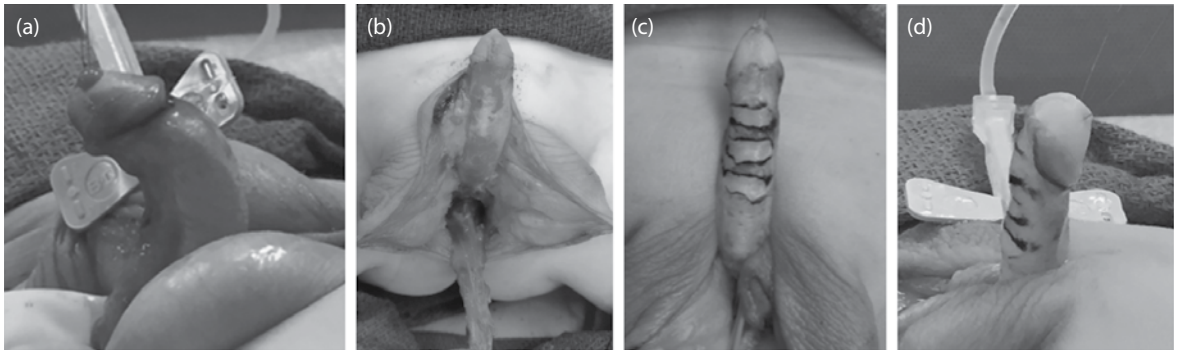

FIGURE 73.6 Straightening VC of >30°. (a) Artificial erection after degloving and dissection of ventral dartos and scrotal encroachments onto the penile shaft shows a persistent curvature of >30°. (b) The urethral plate was transected at the corona, and then dissected off the corpora to the intact urethra. Dissection continued proximally, mobilizing the urethral plate–urethra complex to near the external sphincter. Any remaining dartos and Buck's fascia was excised from the tunica albuginea of the ventral corpora. (c) Three transverse corporotomies have been made, extending just through the tunica albuginea from approximately four to eight o'clock. The first was made across the point of maximum bending, with the other two made 4 mm proximally and 4 mm distally. (d) Repeat artificial erection with a 21-gauge butterfly shows the penis to be straight.

the tunica defect. There are two disadvantages to this method. The most important is that it limits urethroplasty options to prepucial flaps, such as one-stage tubularized prepucial flaps or two-stage Byars prepucial flaps, both of which have been recently reported to have high complication rates.[4–6] In addition, there may be a greater risk for recurrent curvature when lengthening relies on a single, rather than multiple, relaxing incisions.

Most boys with distal hypospadias have no VC after degloving, and the remaining 10% have a VC of less than 30°.[36] The rare patient found to have a VC of ≥30° should be considered to have a proximal hypospadias variant. Certainly, the meatus will move proximally after the urethral plate is transected in this situation.

At least 50% of boys with proximal hypospadias have a VC of ≥30°.[35] Optimal management of this bending has been controversial. When Duckett observed the curvature persisted when the urethral plate was transected, he decided there was little benefit to that maneuver and instead advocated using multiple dorsal plications to make the penis straight. This decision reflected his increasing preference for onlay flap repair onto the urethral plate, versus the tubularized flap repair he used when the urethral plate was removed.[37]

In contrast, Bracka routinely excised the urethral plate, initially in all hypospadias repairs, because he performed two-stage graft procedures. He recommended that any persisting curvature be straightened by plications at the second stage.[38]

However, plications have been found less durable for straightening than ventral lengthening.[33,34] We have encountered a VC of ≥30° in 80% of patients evaluated for complications after primary proximal hypospadias repairs done elsewhere by pediatric urologists.[35] Not only do these boys have recurrent fistulas and wound dehiscences, presumably from tension on the urethroplasty from the curvature, but straightening requires excision of the neourethra and STAG repair using oral mucosa since the foreskin is no longer available. Often this is complicated by insufficient ventral penile skin related to the recurrent VC, which also complicates reoperation.

Inadequate straightening reflects not only earlier recommendations for plications, but also confusion regarding the etiologies of curvature. Because the term *chordee* mixes the three different causes of bending into a single description, it limits understanding of the condition and its best management. There is no chordee tissue, and bending is due to short ventral skin, a short urethral plate, or short ventral corpora.

Distal Hypospadias Repair

We repair all distal hypospadias by TIP. In the following description of the technique, key steps that impact outcomes are highlighted in bold type.

The glans width is determined using calipers (Figure 73.7), and a 5-0 polypropylene stay stitch is placed. An 8Fr sound is passed into the distal urethra, and if it appears "thin," indicating deficient spongiosum and dartos covering, the ventral incision is extended in a U shape proximally below the thin area. The two corners of the dorsal hood are lifted and lines for incision marked as shown (Figure 73.7).

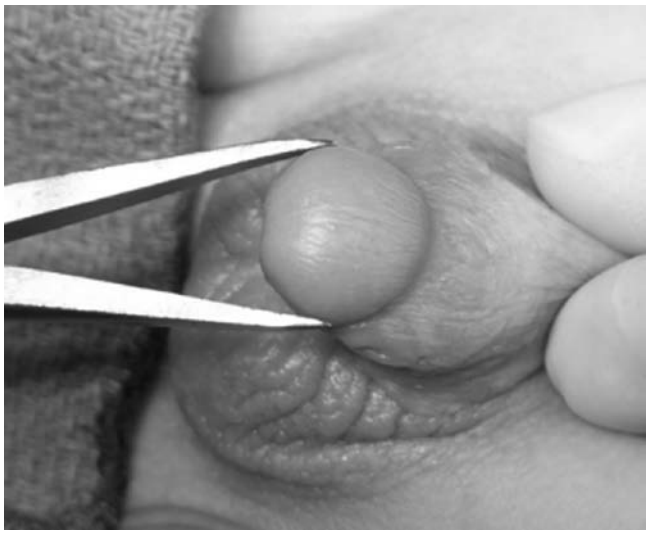

FIGURE 73.7 Measuring glans width. The width of the glans should be measured at the outset of every repair using calipers.

The oblique dorsal extensions allow inner prepucial skin to rotate ventrally and provide a uniform "collar" of inner prepuce, mimicking circumcision in normal boys.

The penis is degloved. The correct plane for ventral dissection is immediately under the skin, preserving the ventral dartos to subsequently create a flap to cover the neourethra. The ventral skin is released to the penoscrotal junction. Dorsal dissection is done along Buck's fascia to near the penopubic junction. Artificial erection is done, with a VC of <30° straightened by midline dorsal plication as described above.

A tourniquet is wrapped around the penile base, either before or after artificial erection. Next, the urethral plate–glans junction is marked, creating mirror image lines that run along the contour of the glans wings and end lateral to the meatus on each side (Figure 73.8a). We make these incisions extending distally 1 mm beyond the urethral plate, to approximate the glans wings at the correct location for the neomeatus. Epinephrine (1:100,000) is injected under the incision line. We use both a tourniquet and injected diluted epinephrine to reduce bleeding during glans wings dissection.

A 69 Beaver knife is used to superficially incise the marked lines, and then tenotomy scissors continue dissection deeper to the surface of the corporal bodies. The correct plane leaves the glans wings sufficiently thick for their later suture approximation, without creating holes in the urethral plate medially. Once the corporal surface is identified, the glans wings are mobilized laterally to three and nine o'clock (Figure 73.8b).

Based on our observation that urethroplasty complications increase with a decreasing glans width of <14 mm, further mobilization of the glans wings is done in those cases. After standard dissection to three and nine o'clock, "extended" dissection is done distally along the surface of the corpora for approximately 4 mm to reduce tension on subsequent glans wings approximation (Figure 73.9).

Occasionally, a hole is made in the side of the urethral plate as the glans wings are created. We loosely

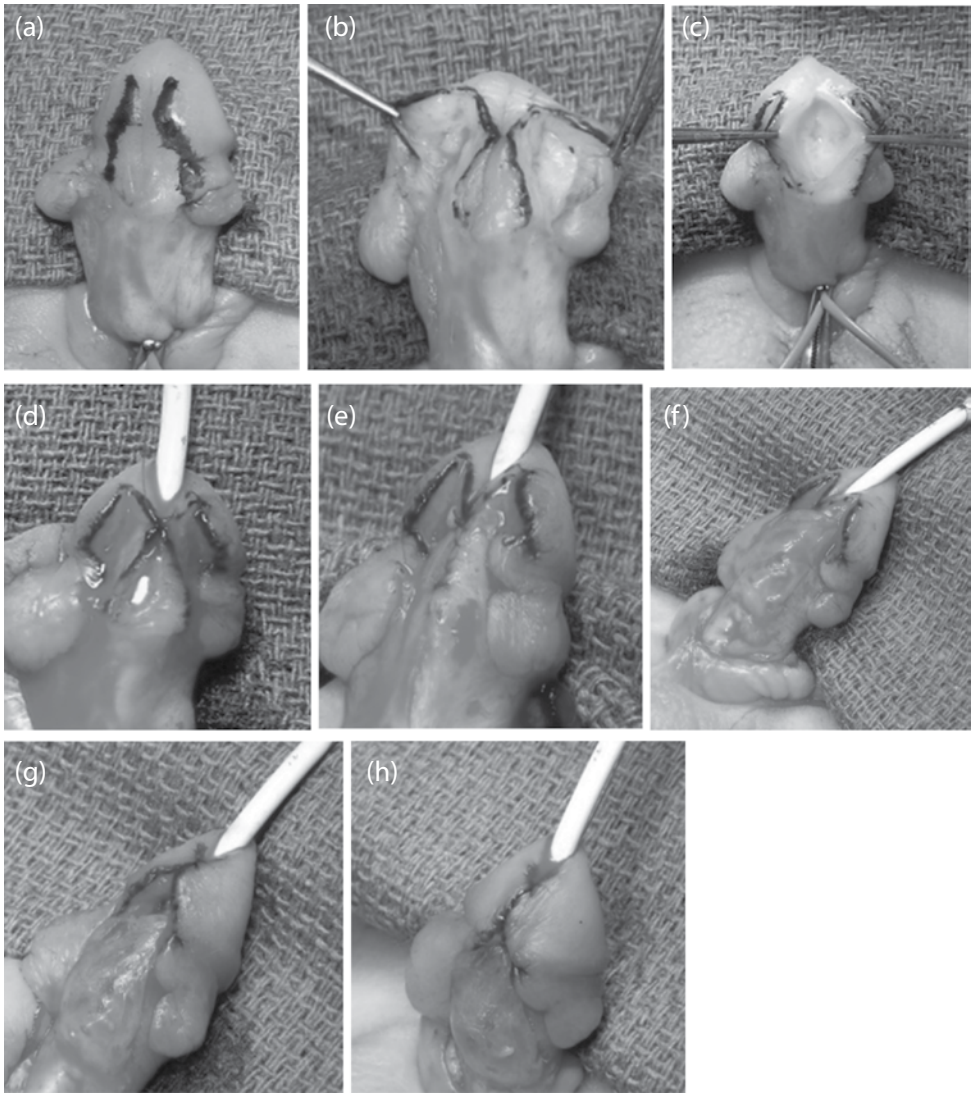

FIGURE 73.8 Key steps in distal TIP repair. (a) After degloving, lines mark the visible junction of the glans wings to the urethral plate. (b) Glans wings have been dissected from the corpora cavernosa laterally to three and nine o'clock. (c) The urethral plate has been deeply incised to the tunica albuginea of the corpora cavernosa. The incision extends from within the meatus to the end of the plate distally. *Urethral plate incision should always be done to this extent*. (d and e) The first stitch for tubularizing the urethral plate is placed at the midpoint of the glans wings. Note the wide oval opening. Placing the most distal stitch at this point avoids iatrogenic meatal stenosis. (f) A dartos flap covers the entire neourethra. (g) The first glansplasty stitch is also placed at the midglans, and the glans wings are approximated together but *not* sewn to the opening in the urethral plate. This stitch establishes the neomeatus. (h) Glansplasty is completed with a total of three interrupted subepithelial stitches. Note the distance from the lip of the neomeatus to the corona, which averages 4 mm in TIP and STAG repairs—well within the normal range.

close the defect using interrupted 9-0 polyglactin, realizing it will later be covered by the ipsilateral wing during glansplasty.

Next, the urethral plate is incised. The edges are held on either side with 0.5 mm Castro–Viejo forceps, gently stretching laterally to delineate the midline. The plate is incised from within the meatus to its tip, and from the epithelial surface deeply to the tunic of the corporal bodies underneath (Figure 73.8c). This key step is done in every case, and failure to incise the plate down to the corpora is a major technical error, increasing risk for complications.

A 6 Fr stent is passed into the bladder and tied to the glans traction suture. Its purpose is only to divert urine, and it is specifically not used to size or mold the neourethra.

Urethral plate tubularization begins distally at the midpoint of the glans wings (Figure 73.8d and e). Tubularization too far distally is also a major technical error.

The first stitch is through epithelium, and then the remainder of the closure is subepithelial, continuing proximally where a second knot is tied. Then the same suture returns a second subepithelial layer distally. We use 7-0 polyglactin on a TG 130 needle, because this ophthalmic needle is smaller than needles available on monofilament sutures. Failure to perform two-layer closure during urethroplasty increases the risk for complications and is another potential technical error.

FIGURE 73.9 Extended glans wings dissection for a glans width of <14 mm.

Next, a dartos flap is created and used to cover the entire neourethra (Figure 73.8f). The lack of a coverage layer increases the risk for fistulas.

If ventral degloving was done close to the shaft skin, sufficient dartos for this flap remains without having to reset traction to harvest it dorsally. However, a dorsal dartos flap can also be used, with care taken to avoid torsing the penis when it is transferred ventrally.

Glansplasty sutures the previously dissected glans wings together over the neourethra (Figure 73.8g and h). The glans is not directly sutured to the opening in the tubularized urethral plate. Most often, three interrupted subepithelial sutures complete the approximation, providing glans fusion that typically measures 4 mm.

We first place a 9-0 polyglactin stitch through the epithelium at approximately the midpoint of the glans wings to create the neomeatus. Then a subepithelial 6-0 polyglactin stitch on an S29 needle is placed immediately under the 9-0 suture, which is removed. The 9-0 stitch helps visualize the distal-most glans wings approximation before completing the glansplasty.

Then two more 6-0 polyglactin subepithelial stitches are placed, the second including a small bite of dartos to hold it in place, and the third approximating the coronal margin.

Mattress sutures should not be used for glansplasty, as they can result in suture marks or even deep cuts into the glans tissues (Figure 73.10).

Shaft skin from the area of the original meatus is next excised. Then the inner prepuce is joined in the midline using subepithelial 7-0 polyglactin. A 9-0 polyglactin can be placed through the glans epithelium just at or below the corona to close these skin edges, with little concern for later visible suture tracts due to the small size.

Next, the dorsal prepuce is cut down the middle to the lower edge of the inner prepucial collar and sutured there with 7-0 polyglactin. Ventral skin is closed into a median raphe, and finally, excess skin is excised to complete the circumcision. All skin edges are closed subepithelially to avoid suture tracts that can develop with epithelial sutures.

The catheter is removed in 5–7 days.

Prepucioplasty

Some parents prefer that the foreskin be reconstructed instead of hypospadias repair with circumcision. Given that nearly all published series report that urethroplasty and skin outcomes are the same for distal hypospadias repairs done with either circumcision or prepucioplasty, surgeons should follow caregiver wishes.[39] If a surgeon chooses not to do prepucioplasties, then it is most appropriate to refer interested families to others who will, rather than attempting to persuade them to accept circumcision. This is especially true in cultures where most boys and men are not circumcised, where those who are circumcised are considered by their peers to be different.

The two corners of the dorsal hood are identified and then held with 5-0 polypropylene stay stitches throughout

FIGURE 73.10 Glans injury from mattress sutures. Mattress sutures for glansplasty can cut through the glans wings, as seen in this case, and should not be used.

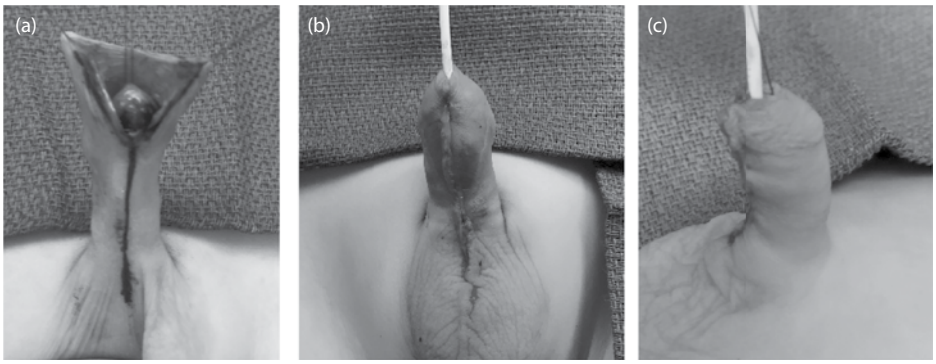

FIGURE 73.11 Prepucioplasty. (a) V or Y ventral skin incision. (b and c) Completed repair.

the operation (Figure 73.11a). A ventral V incision extends from the stay sutures to 2 mm below the meatus. This incision can be continued down the median raphe into a Y configuration, especially when minor scrotoplasty is needed to lower the scrotum. Degloving is confined to the ventral penile surface, but can extend as far proximally as desired, preserving the underlying dartos to create a coverage layer for the neourethra.

Should a VC of <30° be found, the dorsal midline can be approached for plication without degloving by dissecting the shaft skin around the dorsal surface of the penis while leaving the distal prepuce still attached.

Glans wings dissection, urethral plate incision, and tubularization, glansplasty, and dartos coverage of the urethra are done as described above, with the dorsal foreskin wings retracted down.

Then the inner prepuce is approximated using interrupted subepithelial 7-0 polyglactin. The foreskin stays are then pulled distally, and a second layer of sutures closes the dartos. Finally, the outer foreskin is sewn together, also using 7-0 polyglactin interrupted subepithelial stitches (Figure 73.11b and c).

Originally, we tested foreskin closure to enssure that it easily retracted and reduced over the glans, and repositioned the most distal stitches lower when it did not. However, we now place the distal stitches where needed to give the most normal cosmetic appearance and are not concerned if the skin retracts—since it does not usually retract in normal boys the age of those undergoing hypospadias repair. Although steroid cream can be applied to a reconstructed foreskin that does not retract, our experience is that no treatment is needed for the majority, as the skin will do so eventually. Parents are told that the glans may not be visualized for some time, even more than a year, after prepucioplasty. They are instructed to avoid forced manipulation of the foreskin for several months after surgery.

TIP versus G-TIP

A variation on TIP is the grafted-TIP (G-TIP) incision or repair. Proponents claim several potential advantages: making a flat plate suitable for tubularization, less likelihood for urethral scarring, and/or better distal location of the meatus. Typically, the graft has been taken from the foreskin otherwise being discarded during circumcision. An alternative donor site would be needed when families wanted prepucioplasty.

No study has shown either increased or reduced complications from G-TIP versus TIP. We believe any advantage comes from encouraging surgeons to make the TIP incision deeply, in this case to place the graft. Our data in consecutive TIP repairs consistently show that the neomeatus is normally positioned, with an average glans fusion length of 4 mm.

Urethral Plate Configuration

Some surgeons have expressed concerns that a "flat" plate should either have G-TIP or an alternative repair. Others worry about TIP when the urethral plate measures <8 mm.[40,41] We published outcomes from distal TIP that are the same regardless of whether the plate is flat, "deep" or in between.[42] We also found that the urethral plate measured less than 8 mm in 85% of consecutive patients, but width did not correlate with outcomes.[43]

Results

A systematic literature review that included 23 publications with 1872 distal TIP repairs reported 4% fistulas and 3% meatal stenosis.[44] A subsequent meta-analysis included 49 studies and 3621 distal TIP repairs, finding fistulas in 6%, meatal stenosis in 4%, and urethral strictures in 1%. The reoperation rate for complications was 4.5%.[45]

We tallied complications reported by publications from 1994 to 2009, finding that they ranged from 0% to 24%. Of the 35 articles, 25 had overall complication rates of <10%.[46]

We also published our series of distal repairs in consecutive patients, using no other surgical technique. Complications occurred in 4%, comprising fistulas and glans dehiscence without meatal stenosis or strictures.[42]

Uroflowmetry may suggest obstructive voiding (Qmax less than 2 SD, with a plateau curve) after hypospadias repair, regardless of the technique used. A progressive increase in Qmax was documented during 10 years' follow-up in two studies, both of which observed no differences in uroflowmetry between TIP, Mathieu, and MAGPI.[47,48] Together, these add further evidence that the incised plate heals and grows without strictures.

Proximal Hypospadias Repair

We use TIP when the VC is <30° after degloving, although onlay prepucial flap is another option. When there is a

VC of ≥30°, STAG repair is done. Because the degree of curvature may not be apparent at the outset of the operation, initial skin incisions are made to allow any of these options—specifically by preserving most of the foreskin in the event that a graft, or flap, is needed.

TIP

The skin incision dorsally runs parallel to and 4 mm below the corona, and then extends ventrally immediately adjacent to the urethral plate, continuing through the scrotal midline (Figure 73.12a). Because deficient ventral dartos often results in shaft skin adhering closely to the wings of the corpus spongiosum, 1:100,000 epinephrine is injected in the incisions alongside the plate to reduce likelihood for bleeding.

The ventral skin is dissected immediately against its undersurface to further minimize risk for entry into the corpus spongiosum wings on either side of the urethral plate. Skin and dartos dissection continue until the root of the penis is visualized. Scrotal dartos extending up the penile shaft is released.

Then artificial erection is done. A VC of <30° is straightened by a midline dorsal plication using 5-0 polypropylene as described above.

Next, the glans width is measured, and glans wings are developed and dissected laterally to three and nine o'clock as described for distal TIP repair. When the glans is <14 mm wide, more extensive mobilization of the wings is done, continuing the dissection at three and nine o'clock another 4 mm on each side superiorly (Figure 73.12b). The insertion of corpus spongiousum into the wings is also released bilaterally. Our data indicate that complications are decreased by this maneuver for the smaller glans.

The urethral plate is incised deeply to the tunica albuginea of the corpora, extending from the distal tip proximally to within the meatus. As with distal TIP, this incision must be deep to gain the width needed for a normal caliber neourethra (Figure 73.12c).

The urethral plate is then tubularized in two layers. This begins distally with a 7-0 polyglactin stitch placed at approximately the midglans level, which is 3–4 mm below the end of the plate as in distal TIP. As in distal TIP repairs, the opening should be oval, and not rounded. Stitching continues proximally with interrupted subepithelial sutures. Then a second layer of 7-0 polydioxanone is run from proximally to distally (Figure 73.12d). Single-layer urethroplasties, or two-layer tubularizations that run the first layer, have greater risk for fistulas.

When the corpus spongiosum wings are well developed, these are freed sufficiently from the corpora to approximate over the neourethra. Next, the tunica vaginalis is harvested as a coverage flap. We have published that the tunica vaginalis is superior to the dartos in reducing fistulas in proximal hypospadias repair.

A testicle is grasped and then exposed through the scrotal incision using a 15 blade knife to enter its compartment. The tunica vaginalis is opened transversely. A 5-0 absorbable suture placed into the tissues just caudal to the lower pole of the testis provides traction to stabilize it, while 5-0 polypropylene stays lift the corners of the tunica vaginalis cephalad. Dissection proceeds on either side of the spermatic cord, releasing the flap to the external ring, reducing risk for tension on the penis subsequently during erection. Scrotal fat that connects to the flap medially is cut away (Figure 73.12e). Then the testis is sutured back into the dependent scrotum, and its compartment is closed to prevent migration medially toward the penis.

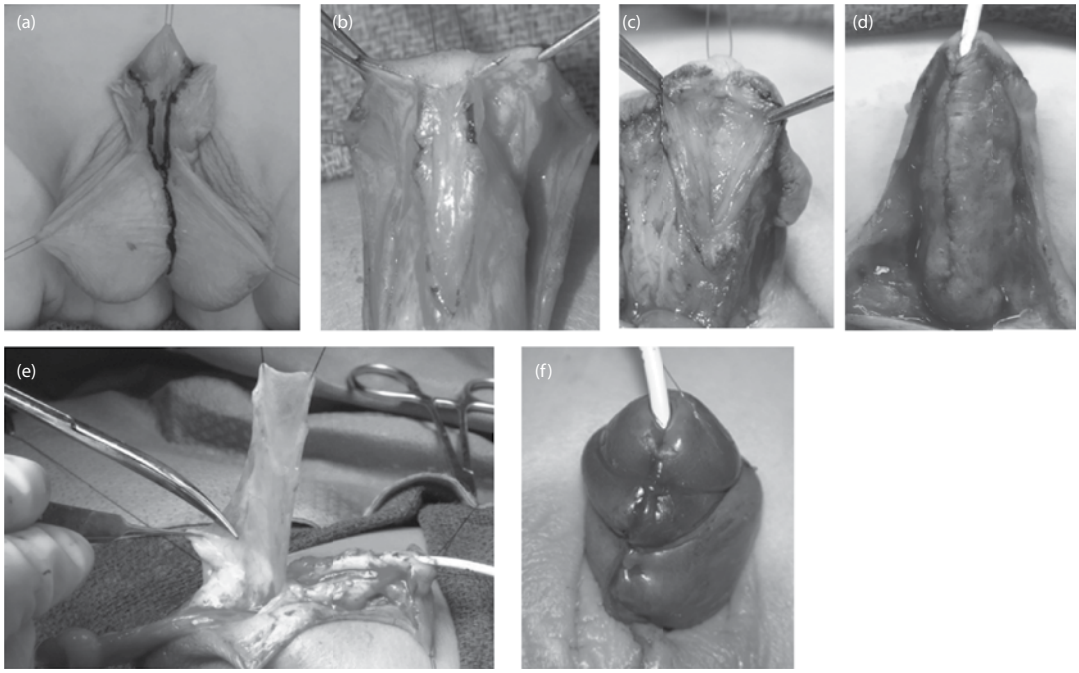

FIGURE 73.12 Proximal TIP repair. (a) Skin incision. Note that it extends alongside the urethral plate ventrally. (b) Extended glans wings dissection. (c) Deep incision of the urethral plate down to the tunica albuginea of the corpora cavernosa. (d) Two-layer subepithelial tubularization of the plate. (e) Preparation of a tunica vaginalis flap to cover the neourethra. (f) Completed repair.

The tunica vaginalis flap is sutured with the inner surface down over the neourethra using 7-0 polydioxanone, since braided sutures entangle the flap.

Glansplasty is done as for distal TIP described earlier, using three interrupted subepithelial 6-0 polyglactin sutures. The first approximates the glans wings distally to create the ventral lip of the neomeatus, and is placed at approximately the midpoint of the glans wings. The next two stitches continue proximally to the corona, with the second stitch including a bite of the tunica vaginalis flap to help keep it in place. The glans wings are not sutured to the underlying neourethra. Glans epithelial sutures are not needed and could create suture marks if used.

It is important in proximal cases to anchor the penoscrotal junction to the corpora on either side of the urethra. Most cases have some penoscrotal transposition, and the visible junction of shaft skin to the scrotum is cut on either side toward approximately three and nine o'clock (Figure 73.13), is pulled downward and medially, and is sutured to the corpora with 5-0 polydioxanone. This simple maneuver helps prevent the penis from "sinking" back into the scrotum and also resolves nearly all cases of scrotal transposition without creating scrotal flaps, which leave visible scars.

Releasing the shaft skin from the scrotum also facilitates cosmetic skin coverage around the penis. The dorsal foreskin is split down the midline to the lower edge of the inner prepucial collar and then sutured there using subepithelial 7-0 polyglactin. Next, the ventral median raphe is created, and finally, excess skin is removed (Figure 73.12f). The catheter provides urinary diversion for 2 weeks.

Results

We published 85% success using proximal TIP in our two most recent series.[49,50] However, our use of this procedure has significantly decreased since we stopped mobilizing the urethral plate for ventral lengthening when the VC was ≥30° to preserve the option to perform TIP urethroplasty. Today, we transect the plate in this common situation and instead do STAG repair due to a higher risk of urethral strictures with TIP when the urethral plate is elevated.

Uroflowmetry has shown progressive improvement in Qmax over time, especially during puberty. One study reported that there was no difference in Qmax 12 years after surgery between TIP, onlay, and tubularized prepucial flaps.[51]

Onlay Prepucial Flaps

The initial skin incision, ventral dartos dissection, and artificial erection with correction of a VC of <30° using plication, and glans wings dissection are the same as described above for proximal TIP.

In the example shown, a double-faced flap is created for urethroplasty and shaft skin coverage (Figure 73.14). 6-0 polypropylene stays are placed at the junction of the inner to outer prepuce, and then the vascular pedicle is dissected from the dorsal shaft skin proximally to the penopubic junction (Figure 73.14a).

Alternatively, the plane between dartos and shaft skin can be developed proximally near the penopubic junction and then dissected distally.

The prepucial flap then is either brought ventrally around the side of the penis in this case (Figure 73.14b), or passed over the glans using a buttonhole in the dartos pedicle.

Then the length of the flap needed to attach to the urethral plate is measured and the inner prepuce trimmed to that size. The proximal end of the flap is sewn to the spatulated native urethra using interrupted subepithelial 7-0 polyglactin. A 6 Fr stent is passed into the bladder and tied to the glans traction suture. Then the flap is gently stretched distally, trimmed as required to maintain uniform dimensions, and sutured to the urethral plate on either side, in the example shown, using a continuous 7-0 polyglactin (Figure 73.14c). The vascular dartos pedicle is used to cover the suture lines.

The flap edges are sutured to the glans wings by subepithelial 7-0 polyglactin. Glansplasty further approximates the glans wings to the corona using interrupted subepithelial 6-0 polyglactin (Figure 73.14d). Scrotoplasty and skin closure can be done as described above for proximal TIP.

In this example, the outer prepuce was maintained on the same vascular pedicle as the inner prepucial onlay flap ("double-faced" flap). This outer prepucial skin flap is sewn to cover the ventral penile shaft (Figure 73.14e).

Urinary diversion is maintained for 10–14 days.

Results

Urethroplasty complications developed in 27%–45% of patients in two series reporting proximal onlay flap repair.[52,53] A systematic literature review identified six studies with 309 patients undergoing onlay flap, which

(b) Lines for incision from six to ten o'clock and six to two o'clock through the penoscotal junction. (c) Scrotum is rotated down, correcting the transposition without need for scrotal flaps.

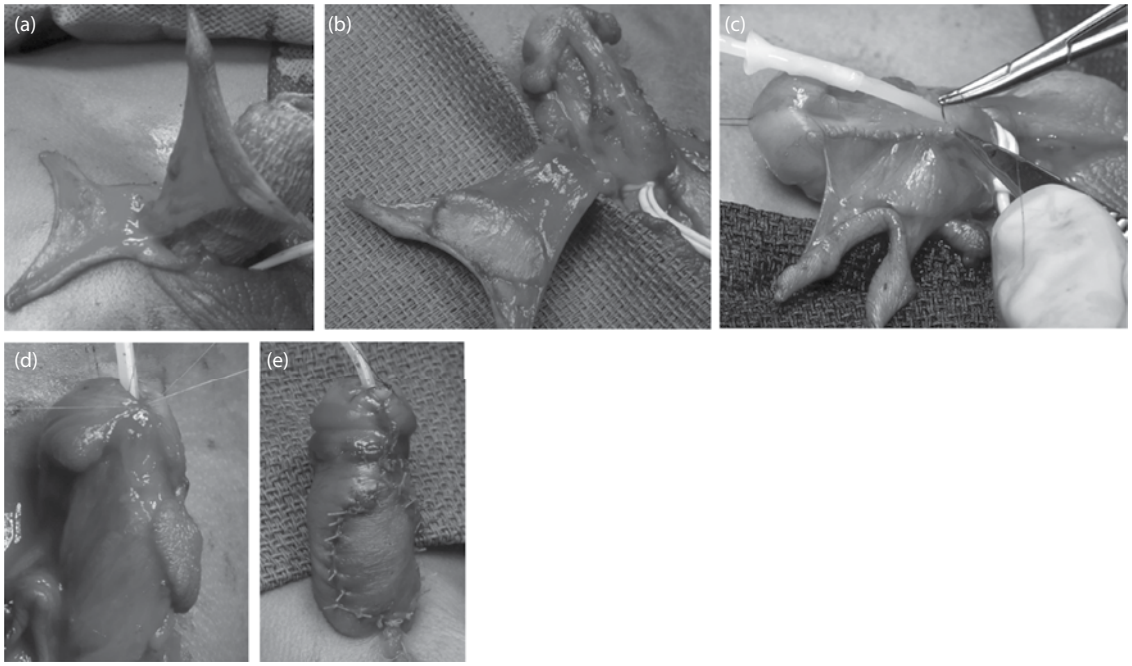

FIGURE 73.14 Onlay prepucial flap. (a) After degloving and correction of a <30° curvature, the prepuce is mobilized from the shaft skin still attached to the underlying dorsal dartos. (b) The flap, in this case with both the outer and inner prepuce, is brought ventrally. (c) The inner prepuce is sewn to the urethral plate to create the neourethra. (d) Glansplasty is done, sewing the glans wings to the end of the neourethra. (e) The outer prepuce is used in this case to provide ventral shaft skin. (Photographs courtesy of Antione Khoury.)

were compared with 262 repaired by TIP, finding no significant differences in their reported complications.[54]

First Stage

Degloving is done as described above for proximal TIP, beginning 4 mm below the corona to preserve most of the prepuce (Figure 73.15a and b). Dissection within the scrotum releases tissue attachments to the formed urethra, which in proximal hypospadias frequently lies superficially and tethered toward the anus. This moves the urethra to a normal location and gains length to reduce the distance to be grafted.

A VC of ≥30° results in transection of the urethral plate at the corona, with proximal dissection off the corpora, continuing past the junction to the formed urethra all the way to the external sphincter (Figure 73.15c and d). This step is also important to eventually gain length for the urethra.

Artificial erection is repeated. A persistent curvature of <30° is corrected by dorsal plication. A persistent VC of ≥30° is straightened by three transverse ventral corporotomies, as described above (Figure 73.15e). The corporotomies are not grafted.

A longitudinal midline incision is made and the glans wings opened widely. It is important that the wings be opened until flat, as this ensures an adequate width of graft to create a neourethra with normal caliber at the second stage. The remaining urethral plate (UP) is excised.

The urethra is gently stretched back distally and sutured back to the corpora using interrupted 6-0 polydioxanone, gaining approximately 1 cm in length. Some or all the UP is preserved, and the opening is spatulated. The distal end of this proximal urethrostomy is sewn to the corpora at twelve, two, and ten o'clock using 7-0 polyglactin.

Skin at the penoscrotal junction is incised from six to approximately three and nine o'clock to release the penile shaft skin (Figure 73.15f). The scrotum is rotated ventrally, reducing transposition, and then penoscrotal or scrotal skin adjacent to the proximal urethrostomy is sutured to the opening at five, six, and seven o'clock with 7-0 polyglactin. The scrotal incision is closed in layers.

Stay sutures hold the corners of the prepuce. The inner prepuce is elevated, and all dartos underlying the graft is excised (Figure 73.15g). Then the proximal shaft skin is brought ventrally around the penis and temporarily approximated at the penoscrotal junction to anchor it while sizing the graft. Next, distal skin is similarly wrapped around the glans, and the graft outline is marked—removing all skin distal to the mucosal collar (Figure 73.15h). These important steps ensure that there is sufficient skin for both the urethroplasty graft and shaft skin closure.

Penile shaft skin is sutured distally to the mucosal collar and proximally at the penoscrotal junction with subepithelial 7-0 polyglactin.

6-0 polypropylene stays are placed in the coronal edges of the glans wings. The widest distal portion of graft is first sewn to glans adjacent to these stays, using subepithelial sutures along the future meatus to avoid suture marks. The graft is next secured to shaft skin on either side using interrupted 7-0 polyglactin (Figure 73.15i). The proximal end of the graft is incised to extend to either side of the urethrostomy.

The graft is quilted to underlying corpora using interrupted 6-0 polyglactin sutures approximately 5 mm apart. The first row extends from the urethrostomy up the midline, with an additional row on either side (Figure 73.15j). Grafts are wider than the corporal bodies, and no attempt

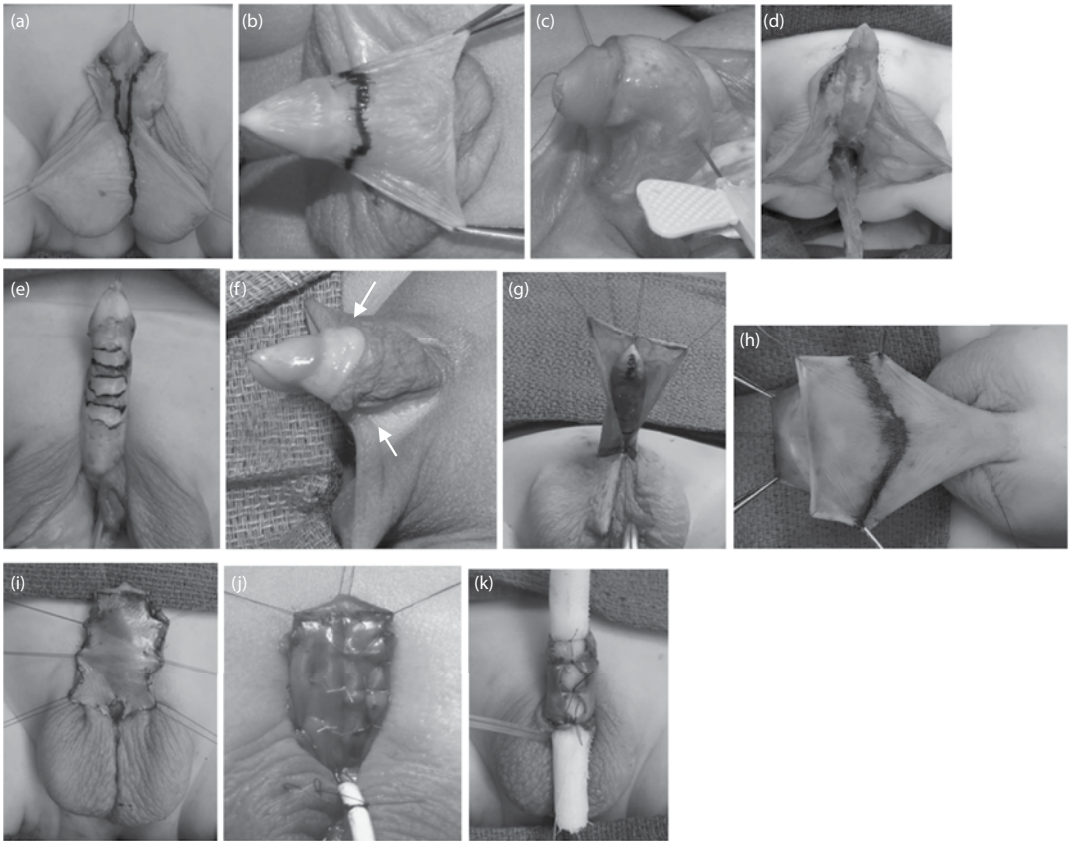

FIGURE 73.15 First-stage STAG repair. (a and b) Initial skin incisions preserving most of the prepuce. (c) Artificial erection after degloving shows a curvature of nearly 90°. (d) The urethral plate has been transected at the corona, and then dissected along with the formed urethra off the corpora to near the external sphincter. (e) Persistent curvature after plate dissection is straightened by transverse corporotomies. (f) Arrows point to the lateral penoscrotal junction, which is released on each side. (g) Dartos has been dissected from the foreskin, which enlarges it. Ventrally, the shaft skin at the penoscrotal junction is approximated temporarily to anchor it into place before harvesting the foreskin graft. (h) The line for removing the foreskin graft has been marked along the coronal margin. (i) The graft has been sewn into the gap from the proximal urethrostomy to the glans tip. Note that the glans is opened flat, like a book. (j) The graft has been quilted to secure it to the underlying corpora. (k) Tie-over bandage provides gentle compression to the graft.

is made to suture them to underlying structures lateral to the corpora to allow easier dissection at the second stage.

An 8 Fr Foley catheter is inserted. Then a rolled petroleum gauze is secured snugly over the graft with a tie-over bandage (Figure 73.15k). The catheter and bandage are removed 7 days postoperatively.

We now instruct caregivers to apply Aquaphor to the entire ventral penis with each diaper change for 3 weeks after bandage removal. Then, 1 month postoperatively, Aquaphor applications are stopped and 0.1% betamethasone ointment is applied ventrally to the graft and adjacent skin twice daily for 3 months. These maneuvers reduce graft contraction.

Second Stage

The second stage is done at 6 months or later. There is no documented advantage to waiting longer than 6 months.

Glans wings are injected with 1:100,000 epinephrine, and then mirror-image incisions are made, extending on each side down the edge of the neoplate and entering the proximal urethrostomy from five to seven o'clock to exclude shaft or scrotal skin sewn there at the first stage. The incision continues down the scrotal raphe (Figure 73.16a).

Glans wings are dissected laterally to three and nine o'clock, and then superiorly another 4 mm off the corpora on each side (Figure 73.16b).

A 6 Fr stent is inserted. Two-layer subepithelial neoplate tubularization is done, using interrupted 7-0 polyglactin and then continuous 7-0 polydiaxanone, as described for proximal TIP. As with TIP, the first suture was placed distally at approximately the midglans level, 3–4 mm below the future meatus, creating an oval, not rounded, opening (Figure 73.16c). Single-layer urethroplasties, or two-layer tubularizations that run the first layer, have greater risk for fistulas.

A tunica vaginalis flap is harvested and dissected proximally to the external ring. The testicle is pexed and its hemiscrotal compartment sutured closed. The flap covers the entire neourethra (Figure 73.16d).

Glans wings are approximated over the neourethra using three interrupted subepithelial 6-0 polyglactin stitches. The first is placed at approximately the midportion of the glans wings, and the last at the corona. As in TIP repair, glans wings are not sutured to the neourethra (Figure 73.16e).

The scrotal wall at three and nine o'clock is sutured to the corpora on either side of the neourethra to reduce transposition and prevent secondary concealed penis.

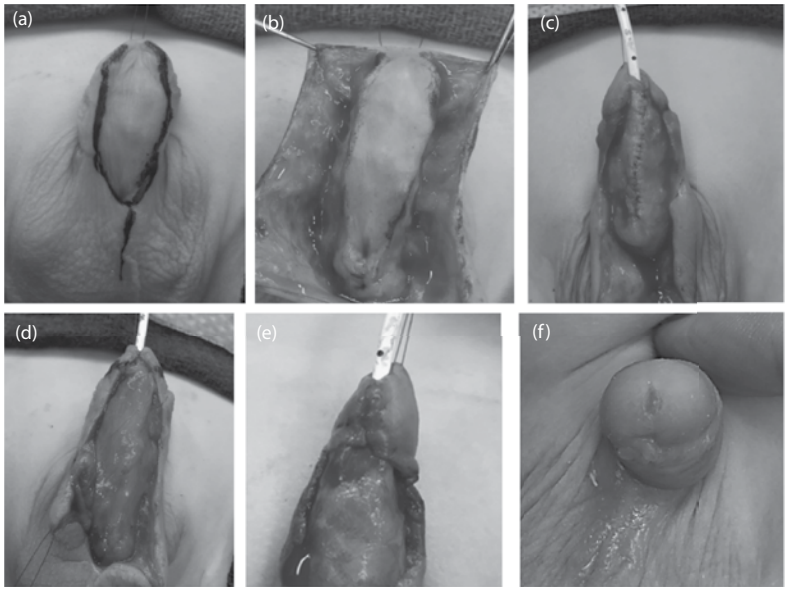

FIGURE 73.16 Second-stage STAG. (a) Line of incision along the graft and down the midline of the scrotum. (b) Extended glans wings dissection for later tension-free closure. (c) Two-layer subepithelial urethroplasty. The first layer is sewn with interrupted sutures, and the second using a continuous suture. (d) Tunica vaginalis, not dartos, covers the neourethra. (e) Completed glansplasty is done as described above for TIP. The neomeatus should be in the normal location. (f) Result 1 year after surgery.

Penile shaft skin is closed in the midline median raphe using interrupted subepithelial sutures. Catheter drainage continues for 2 weeks.

Results

We reported outcomes in 43 consecutive patients with proximal hypospadias,[50] of which 48% had a glans width <14 mm and the VC averaged 70° (30–120). All first stages were successful. Complications following the second stage developed in 24%, primarily glans dehiscence or fistulas that were subsequently corrected for overall 98% success (straight penis, opening at the tip). Glans fusion averaged 3.8 mm (2.5–6).

Others have similarly reported complications in 23%–33% using two-stage graft repairs for patients with a VC of >30°.[55–57]

One-Stage Tubularized Prepucial Flaps and Two-Stage Byars Flaps

Recent publications report complications in the majority of patients after proximal hypospadias repair using foreskin flaps. These ranged from 50% to nearly 85%.[4–6] Given this high rate of complications, the authors suggest that these procedures no longer be used.

Prepucial versus Oral Mucosa Urethroplasty Grafts

Some have expressed concern that there is not sufficient shaft skin and prepuce in boys with proximal hypospadias and a VC of ≥30° to both create a neourethra and cover the penile shaft. This observation may relate, in part, to experience estimating prepucial size before excising the underlying dartos, which definitely increases the epithelial surface area. We have found through experience that there is almost always adequate shaft skin and foreskin for both needs in even the most severe cases (Figure 73.17).

Because of this misperception, oral mucosa has been advocated for primary repair urethroplasty. There are several disadvantages to this approach. First, oral mucosa always heals more thickly than does prepuce, which makes it more difficult to enclose within the glans for a meatus in the correct location, particularly in patients with small glans width. In addition, while there are essentially no donor site complications from circumcision to obtain prepuce, some oral graft harvests will distort the lip and require scar release. If there is partial glans dehiscence after the second stage, the exposed distal urethra is much less noticeable when made of prepuce than oral mucosa, which results in a red meatus that then keratinizes and potentially distorts the urine stream. Finally, should complications develop that require a reoperative substitution urethroplasty, both the foreskin and lower lip will have already been harvested, leaving less optimal options.

We have vast experience using grafts in both primary and reoperative hypospadias repair, and strongly recommend that foreskin be used in primary operations, reserving oral mucosa for reoperations.

Grafts versus Flaps

Throughout the history of hypospadias repair, urologists have generally preferred flaps over grafts for urethroplasty. This is based on the assumption that transferring foreskin ventrally while still attached to the penis more likely ensures its vascularity than removing it and then sewing it back to the penis. These flaps preserve the dartos beneath the epithelium as the "pedicle," even though the dartos does not supply the skin like a mesentery. Duckett's innovation of mobilizing the dartos of his flaps off the

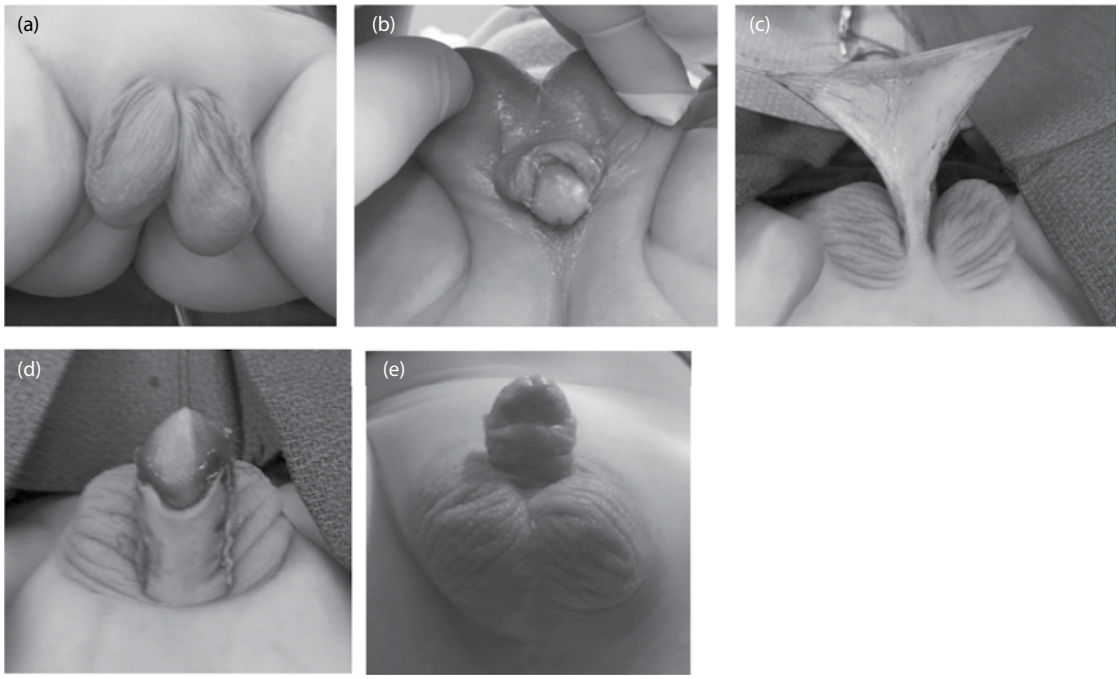

FIGURE 73.17 Perineal hypospadias resembling aphallia. (a and b) Aphallia-like appearance of the external genitalia. (c) Marked deficiency of shaft skin, which was absent ventrally. Note the large foreskin after dartos has been removed. (d) The foreskin graft was sufficiently large to provide tissue for both the neourethra and ventral shaft skin closure. The first-stage suture line of the graft runs along the lateral penis at three and nine o'clock. (e) 18 months after surgery.

dorsal shaft skin proved that dartos does not vascularize penile skin. On the other hand, Duckett commented that fluorescein illumination sometimes showed the ends of his flaps—with their dartos attachments—to be poorly vascularized.[58] Ischemia at the ends of a flap can result in meatal stenosis and/or a proximal anastomotic stricture.

Grafts remained on the fringes of hypospadias surgery, preserved by plastic surgeons who considered their revascularization both reliable and ultimately better than the vascularity of foreskin flaps, which lack a predictable blood supply. All published series of foreskin grafts report graft take after the first stage in 90%–100%. In addition, these series report almost no urethral stenosis, in contrast to meatal stenosis or strictures in 10%–15% of Byars flaps.

W.S. originally used Byars flaps for proximal repairs when VC required the urethral plate to be transected. Fifty percent of these developed a diverticulum, even though none had distal obstruction. In contrast, diverticula have rarely developed after STAG repair, even though both procedures use foreskin. Grafts adhere better to the corpora, like a normal urethra, than do flaps, whose dartos impedes this fixation and therefore promotes turbulent flow and distention of the neourethra (Figure 73.18).

Glansplasty in STAG is the same as in TIP, resulting in a normal ventral length from the meatus to the corona. This measurement has not been reported after flap repairs, but is likely less since the glans wings are stitched to the flap end, which is kept large to reduce meatal stenosis (Figure 73.19).

Finally, removing the dartos from the foreskin allows it to expand, making the graft long enough to reach from within the scrotum to the tip of the glans.

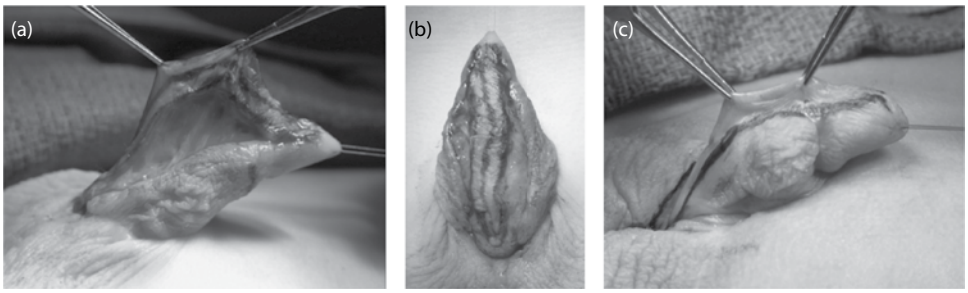

FIGURE 73.18 Byars flap vs. STAG graft. (a) Dartos underlying the Byars flap prevents adherence of the flap to the corpora. Quilting the flap to the corpora has not been reported to be effective. (b) Irregular shape of the flap before tubularization. (c) A graft adheres to the corpora, mimicking a normal urethra. The lateral edges of the graft easily roll together in the midline, creating a smooth neourethra.

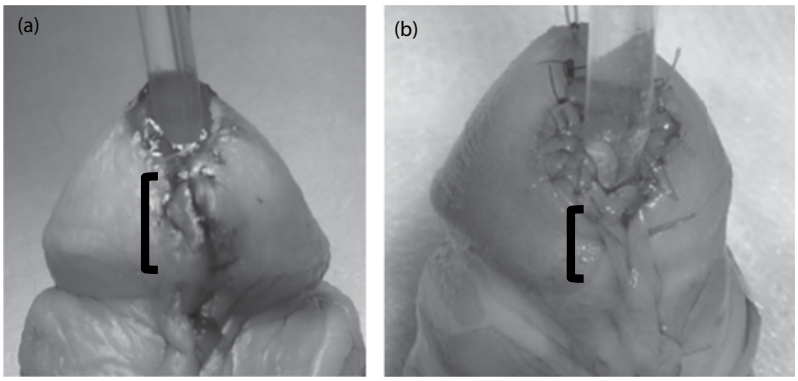

FIGURE 73.19 Glans fusion lengths after STAG vs. an onlay flap. (a) STAG repair creates a normal glans fusion distance from the meatal lip to the corona. (b) Flap repairs suture the glans wings to the end of the urethra, and may result in less, even subnormal, glans fusion.

POSTOPERATIVE MANAGEMENT

Urinary Diversion

There are no differences in urethroplasty outcomes following distal hypospadias repair done with versus without urinary diversion. However, toilet-trained boys are more likely to experience dysuria, urinary retention, and extravasation when diversion is not done.[59] We did distal TIP repairs without a catheter for a period of time, but encountered more secondary phimosis or other unsightly skin swellings, which appeared due to a less secure bandage leaving the distal penis exposed.

There are no trials published regarding need or duration of stenting in proximal hypospadias.

We only use urethral catheters. No study demonstrates a benefit of suprapubic tubes after hypospadias repair.

Bandages

Two studies reported no difference in urethroplasty complications related to bandages.[60,61] We use a "sandwich" bandage, wrapping a small Tegaderm around the penis, which is then gently compressed with a gauze held in place with a larger Tegaderm (Figure 73.20). This bandage falls off spontaneously. We discourage bandages that must be removed by the physician, especially under sedation.

Penile and scrotal hematomas are more likely in teens and adults following hypospadias surgery. We encountered them in nearly 50% of patients initially, which significantly decreased by loosely wrapping the penis with coban.

Hospitalization

Outpatient hypospadias repair became the standard of care in the United States in the mid-1980s. All primary and reoperative surgery can be done without postoperative hospitalization in prepubertal boys. Because of their increased risk for scrotal hematomas, teens and adults remain hospitalized overnight on bed rest.

The authors realize that decisions regarding outpatient versus inpatient repair are potentially influenced by cultural and healthcare system factors. Nevertheless, it is clear that hospitalization is not medically necessary, given that published results in the United States are among the best in the world. It is also clear that many or most caregivers would prefer to return home, if assured by their surgeons that hospitalization is not needed. Regardless, if hospitalization must be done, every effort should be made to minimize bother, fear, and discomfort for the child.

FIGURE 73.20 Typical postoperative bandage.

Preventing Erections

No medical regimen has been reported effective to prevent postoperative erections. We recommend oral diazepam at bedtime to reduce awareness and discomfort of nocturnal erections in older teens and adults.

It is commonly believed that erections in adults may increase the risk for urethroplasty complications. However, we reported outcomes in children and adults to be similar,[62] and boys also have erections following surgery.

Medications

We recommend alternating scheduled acetaminophen with ibuprofen every 3 hours for the first 36–48 hours after repair in infants. After age 1 year, we use hydrocodone

(which includes acetaminophen) rather than acetaminophen alone.

Boys over 1 year are also prescribed oxybutynin two or three times daily during urinary diversion, to reduce painful bladder contractions.

There are limited data regarding postoperative antibiotics to prevent urinary tract infection (UTI) or wound infection. We recommend sulfamethoxazole/trimethoprim during urinary diversion.

COMPLICATIONS

Many urethroplasty complications occur because of surgeon error, which emphasizes the responsibility to do the key steps of procedures according to descriptions with the best published outcomes. In contrast, complications are rarely due to the patient or caregivers.

In general, correction is delayed for 6 months after prior surgery, to allow tissue healing before additional surgery.

Fistulas

Prevention

Subepithelial, two-layer urethroplasty and coverage by a barrier flap have been shown to reduce likelihood for fistulas. We published a significant reduction in fistulas in proximal repairs using two-layer tubularization: the first layer interrupted and the second continuous. Similarly, the tunica vaginalis was more effective than the dartos in preventing fistulas in proximal repairs. With these maneuvers, fistulas should occur in <5% of cases.[49] Surgeons using other methods, such as single-layer urethroplasty, two-layer urethroplasty with a running closure reinforced with interrupted sutures, and/or dartos flaps, should review their results to be certain their fistula rate is not greater than 5%.

We have also found that recurrent fistulas after proximal repairs often indicate a persistent VC of ≥30°. These fistulas were noted within or just distal to the curvature, suggesting that tension during erections caused focal wound separation.[35]

Treatment

The first step in fistula closure is assessment for additional complications, including distal stenosis, diverticulum, and/or VC. Most fistulas, especially following distal repairs, are isolated; that is, there is no distal obstruction. Correction involves closure of the urethral defect and coverage with a flap. Traditionally, fistula repair has been done via a small incision around the defect with advancement of a skin flap over the closed urethral defect. We make a larger midline incision, which improves exposure, facilitates creation of a ventral dartos flap for coverage, and enables excision of redundant skin that often develops around the fistula with median raphe closure (Figure 73.21).

We also reported that subcoronal fistulas below an intact glans can be closed without redo glansplasty or urinary diversion with 95% success.[63] If the glans wings are dehisced with only a bridge of skin between them, fistula closure requires reoperative urethroplasty and glansplasty (Figure 73.21d).

Glans Dehiscence

This common complication is underreported. It is defined as complete separation of the glans wings with or without a bridge of skin between them (Figure 73.22). Glans dehiscence re-creates a hypospadias defect, with suboptimal aesthetic appearance and increased risk for a deflected or spraying stream.

Prevention

Mattress sutures do not prevent glans dehiscence, but do increase risk for suture marks or glans injury, and so should not be used. Glans wings dissection, as described in this chapter, opening laterally to three and nine o'clock and then superiorly an additional 4 mm bilaterally, effectively elongates the wings and reduces tension on their approximation over the neourethra.[18,50]

Treatment

Repair requires hypospadias reoperation as described below, most often by reoperative TIP. Secondary repair is

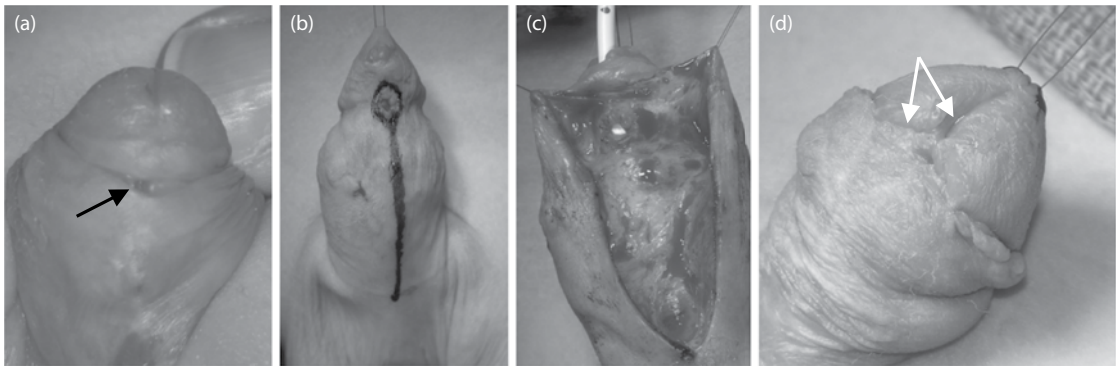

FIGURE 73.21 Subcoronal fistulas. (a) Subcoronal fistula with normal glans fusion. There is no need to reopen the glans to close the fistula. (b) Incision around the fistula and down the median raphe, giving exposure to close the fistula, create a dartos coverage flap, and revise any redundant ventral shaft skin. (c) Excellent visualization of the fistula, which can now be closed and covered with a dartos flap extending beyond it distally. (d) Subcoronal fistula with partial glans dehiscence. In this case, redo TIP repair is needed to both close the fistula and correct the dehiscence.

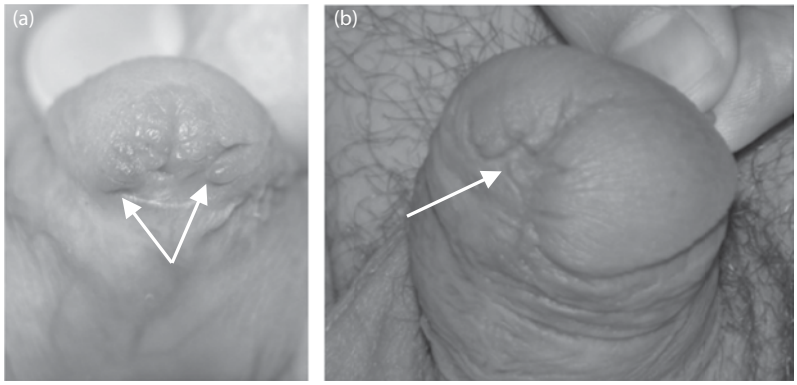

FIGURE 73.22 Glans dehiscence. (a) Complete separation of the glans wings indicated by the arrows. (b) Complete separation of the glans wings, with an intervening skin bridge (arrow) giving the false appearance of a glanular meatus.

successful in more than 75%. If glans dehiscence recurs, we do not do a third glansplasty, as success is less than 50% and there is risk for glans loss.

Meatal Stenosis

This complication is likely overdiagnosed. A small-appearing meatus with a fine stream most often does not indicate anatomic obstruction, especially early after surgery when there is edema of the neourethra (Figure 73.23). As discussed above, uroflowmetry after hypospadias repair may show an "obstructive" pattern initially, which improves progressively—indicating that there was no stenosis.

We define meatal stenosis as a caliber of <8 Fr with symptoms (persistent stranguria, urinary retention, and UTI).

Prevention

We reported no meatal stenosis after either primary TIP or STAG repair, and other similar series also found stenosis in 3% or less of cases. This suggests that meatal stenosis should first be considered a technical error: inadequate urethral plate incision and/or tubularization too far distally.

Treatment

There are no published data indicating that meatotomy is effective for true meatal stenosis after hypospadias repair. If meatotomy is done, the incision should be made dorsally, as a ventral incision may re-create the hypospadias.

Otherwise, relief of meatal obstruction requires hypospadias reoperation, generally a STAG repair with oral graft, as described below.

Neourethral Stricture

Strictures of the neourethra are defined as near-complete closure of the lumen. They are rare after TIP or STAG repairs, but were reported in 12% and 14% of two reports on Byars flaps.[4,5] Strictures are usually diagnosed due to stanguria, urinary retention, and/or UTI. We do not subject boys with these symptoms to urethrography, but rather rely on urethroscopy under anesthesia to establish the diagnosis.

Prevention

As stated, strictures are rare after TIP and STAG, and may be an inherent risk with prepucial flaps.

Treatment

Therapeutic dilation should not be used in boys. The treatment is not curative, and causes great anxiety and discomfort.

A single direct-vision urethrotomy is reported to have 25% effectiveness for hypospadias strictures of <1 cm long. Repeat urethrotomy for failures was not successful.[64]

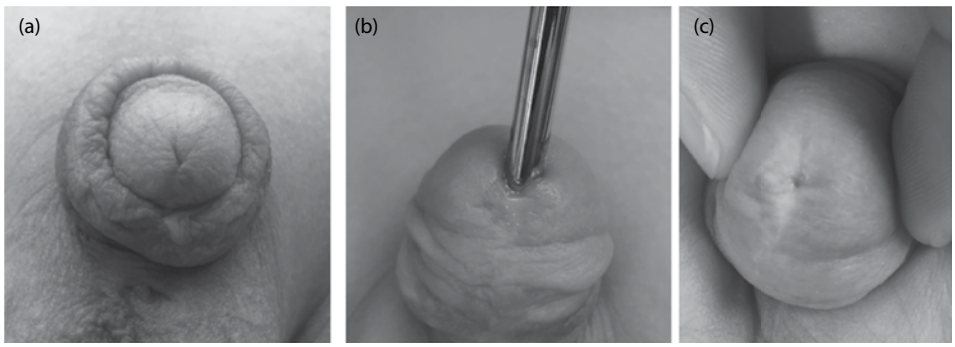

FIGURE 73.23 Meatal stenosis. (a and b) Small-appearing meatus is not meatal stenosis, as shown by easy passage of a 12 Fr sound. (c) True meatal stenosis is smaller than 8 Fr.

Therefore, strictures after hypospadias repair are best managed by open surgery, using an inlay graft if the stricture is not obliterative, and excision of the lesion with reoperative STAG when it is. These are discussed below.

Diverticulum

A diverticulum is visible ballooning of the neourethra during voiding (Figure 73.24). This complication is also rare after TIP and STAG, but more common following prepucial flap repairs. Despite widespread opinion, these indicate distal obstruction; most occur without distal obstruction.[65]

Prevention

We know of no technical maneuver to reduce the likelihood that a diverticulum will develop after a flap repair. This was the main reason W.S. stopped using Byars flaps.

Treatment

Although distal obstruction is uncommon, the first step in the procedure is to calibrate the urethra distal to the diverticulum. Then a ventral midline incision is made over the diverticulum, preserving the dartos for a coverage layer. The diverticulum is opened longitudinally, the excess tissue is excised, and then the urethra is closed in two subepithelial layers as described for proximal urethroplasties. The dartos is sutured as a barrier layer over the closure. We use urinary diversion for 1 week. Recurrences after repair are uncommon.[65]

FIGURE 73.24 Diverticulum.

Recurrent Ventral Curvature

A recurrent VC of ≥30° almost always indicates inadequate initial correction. Dorsal plications are not reliable for durable straightening of a VC of ≥30° (Figure 73.25). Excision of the urethral plate does not guarantee that the penis is straight. Ventral lengthening by three transverse corporotomies is the most reliable means for durable straightening.

Prevention

As discussed above, a VC of ≥30° after degloving should next lead to urethral plate transection at the corona, and its dissection from the corpora. A persistent VC of ≥30° after transection of the urethral plate should be straightened by three transverse corporotomies.

Treatment

A recurrent curvature of ≥30° requires the neourethra previously created to be excised, along with all other ventral scar tissue that is encountered. Repeat artificial erection may demonstrate straightening, or a VC of <30°, determined using a goniometer, that can be straightened by dorsal plication. However, a VC of ≥30° after excising the neourethra requires ventral lengthening using three corporotomies. Reoperative STAG repair is done using lower-lip mucosa for the urethral graft, which is described in the next section.

The fact that correction requires removal of the neourethra with two-stage reoperative grafting using oral mucosa emphasizes the critical importance of optimally straightening VC at the initial operation.

FIGURE 73.25 Recurrent VC. Curvature recurred despite dorsal plication. The plication suture is visible (arrow) and in the correct location.

HYPOSPADIAS URETHROPLASTY REOPERATIONS

Preoperative Assessment

Important factors to determine after failed hypospadias repair include the original meatal location, the means used to straighten the associated VC, the number of prior operations and date of the most recent one, and the techniques used. Generally, reoperations are delayed until 6 months after the last procedure. Even a single reoperation doubles the risk for additional complications, and if a patient has had three or more repairs, the complication rate increases to 40%.[7] The relative rarity of reoperations and the high risk for more complications indicates that these, like proximal hypospadias repairs, should be specialized to high-volume hypospadias surgeons.

Physical exam determines if the penis feels tethered, or is overtly curved, and the meatal location. All apparent complications, such a fistulas and glans dehiscence, are noted. The visible extent of scarring is recorded, as is deficiency of the shaft skin, especially ventrally.

We do not perform urethrography, or cystoscopy as a separate procedure, as sufficient evaluation to determine all complications can be made intraoperatively at the time of reoperation.

We also do not recommend androgen stimulation, given a lack of evidence that it reduces complications and the possibility that testosterone may increase the risk for poor outcomes.

Surgical Algorithm

Hypospadias reoperations should be approached systematically (8). As with primary repairs, VC drives decision making. When there is <30° after degloving and release of contracted scar, TIP is the first consideration. If there is a VC of ≥30°, the neourethra and all ventral scars must be removed, the penis straightened, and then STAG performed (Figure 73.26).

The most common indication for hypospadias reoperation is glans dehiscence. If the urethral plate appears supple, without gross scars, then a reoperative TIP repair is done. If prior surgery removed the urethral plate, then the skin neoplate is TIP incised dorsally, and the resulting defect grafted using the upper lip for one-stage repair. This inlay graft is a modification of TIP, essentially a G-TIP done using oral mucosa. Because the graft is sewn dorsally to the corpora and the lateral edges of the neourethra remain vascularized, one-stage tubularization can be done. Oral inlay grafts should be harvested from the upper, not the lower, lip—preserving the lower lip should there later be a need for a two-stage replacement urethroplasty.

Inlay grafts are also the first treatment for nonobliterative neourethra strictures. However, they are less effective for meatal stenosis, since it is difficult to place sufficient oral graft to open the narrowing at the meatus without placing graft distally onto the glans past the meatus. In these cases, STAG repair is needed to excise the scar and place a wide sheet of oral mucosa within the glans out to the meatus.

In addition to a VC of ≥30° and meatal stenosis, other indications for STAG reoperation include gross scarring of the neourethra, obliterative strictures, hair in the neourethra, and balanitis xerotica obliterans (BXO).

Some additional principles guide our approach to reoperations. For example, when Mathieu or onlay flaps have been used, we excise them and perform TIP. When there are indications for substitution urethroplasty, we completely remove the neourethra, even if a segment appears healthy, to create a continuous neourethra with uniform composition rather than a composite of various tissues. Otherwise, complications such as diverticulum potentially can result from the varying elasticity of the tissues incorporated together, or strictures may develop at the junctions of those tissues. We do not use skin flaps in reoperations, in part because there often is insufficient skin after prior surgery for both urethroplasty and shaft skin closure, and also because vascularity of previously operated tissues is not reliable.[66]

TIP

A Y-shaped incision is outlined extending along the visual borders of the glans wings to the urethral plate, joining approximately 2 mm below the meatus, and continuing down the median raphe toward the proximal shaft (Figure 73.27). It is usually not necessary to circumferentially deglove the penis in reoperations, which we do only when there is excess dorsal skin to revise or persistent curvature to straighten after the ventral skin incisions are made.

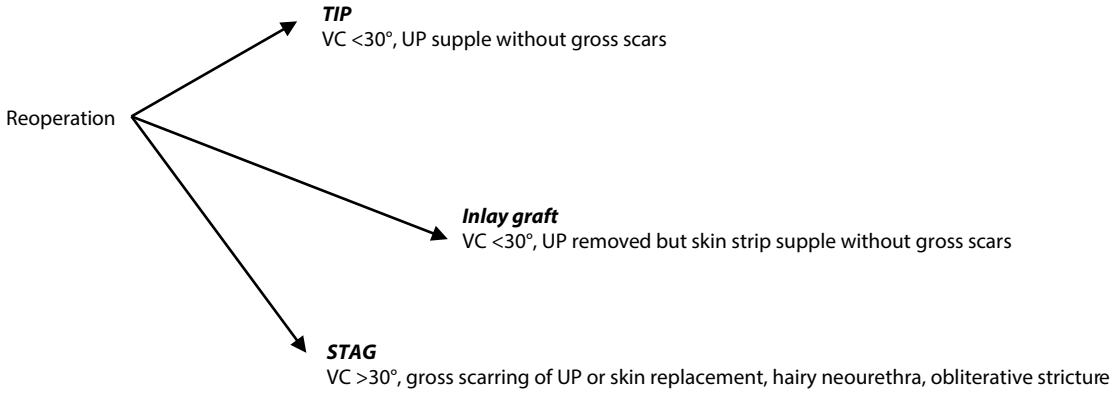

FIGURE 73.26 Algorithm for hypospadias reoperations. UP: urethral plate.

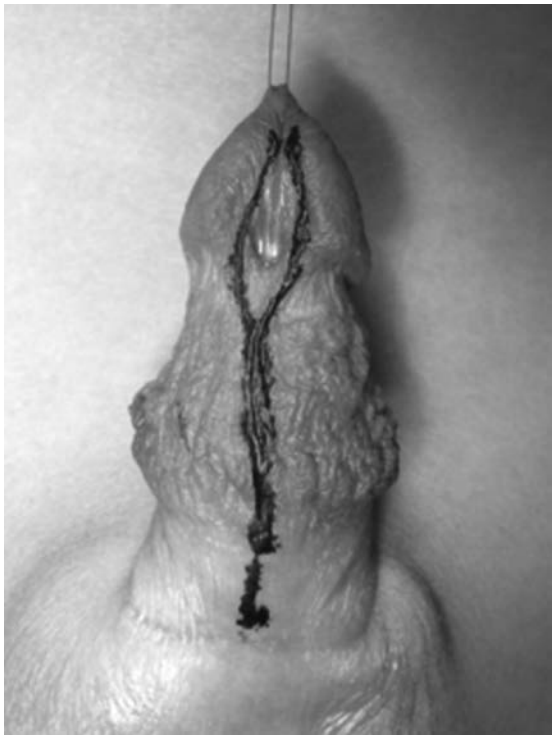

FIGURE 73.27 Incision for reoperative TIP repair.

The glans incision lines are injected with 1:100,000 epinephrine, and then the glans wings are developed. Since most reoperations have glans dehiscence, the extended dissection method is done first to three and nine o'clock, and then superiorly on each side another 4 mm.

Dissection down the median raphe is done immediately under the shaft skin to preserve ventral dartos for later flap coverage over the neourethra.

If a flap was previously used to supplement the urethral plate, as in Mathieu or onlay procedures, it is removed.

The urethral plate is next incised in the midline, deeply as for primary repairs, and a 6 Fr stent is passed into the bladder and tied to the glans traction suture. Tubularization is done in two subepithelial layers, using interrupted stitches for the first layer, followed by a continuous second layer. As in primary TIP, the first stitch is placed at approximately the midglans to avoid iatrogenic meatal stenosis.

A ventral dartos, or tunica vaginalis, barrier flap is created for distal and proximal repairs, respectively, and extended over the entire neourethra.

Glansplasty is done as previously described using three interrupted subepithelial stitches.

Excess ventral shaft skin, when present, is excised and the median raphe sutured closed with subepithelial 7-0 polyglactin interrupted stitches. The stent provides urinary diversion for 10 days.

Results

Reported complication rates range from 12% to 30%.[67–69] We published results in 69 patients with a mean of 1.1 (1–3) failed repairs, of which most originally had distal hypospadias. Complications developed in 19%.[67]

One-Stage Dorsal Inlay Grafts

The initial incisions, ventral shaft dissection, and glans wings development are done as described above for reoperative TIP. A first-generation cephalosporin is administered when oral graft harvest is anticipated.

The skin strip substituting for the urethral plate is incised dorsally in the midline as for TIP repair, extending into the native urethra. 7-0 polypropylene stays are placed laterally at its midpoint, providing traction to expose the dorsal defect. The visible margin of the upper lip is marked, and two 5-0 polypropylene stays are used to retract the lip open and upward. The needed graft is outlined, and then 1:100,000 epinephrine is injected before incision.

The graft is removed by dissection above the muscle, and then defatted. These smaller grafts are most easily handled by wetting an area on the drapes, which then holds the graft still. Tenotomy scissors cut the excess fat from underneath the epithelium. The donor site is not sutured and will reepithelialize.

We intentionally select the upper lip for inlay grafts, as they are thinner than cheek grafts. Although success with inlay grafts is high, the potential that a substitution urethroplasty might be needed in the future prompts us to preserve the lower lip. We strongly discourage harvest of small grafts from the lower lip.

7-0 polyglactin anchors a distal edge of the graft to the proximal end of the defect within the urethra. The graft is then sewn to the perimeter of the dorsal incision with interrupted epithelial 7-0 polyglactin stitches proceeding distally and trimming excess graft as needed. Finally, quilting sutures fix the graft to the corpora, first at 5 mm intervals down the midline and then to either side as needed (Figure 73.28).

FIGURE 73.28 Inlay graft reoperation.

A catheter is passed into the bladder and tied to the glans traction suture. Tubularization is done in two subepithelial layers, the first using interrupted 7-0 polyglactin and the second continuous 7-0 polydioxanone. The first stitch is placed distally at approximately the midglans so that the opening is oval, not rounded, to avoid iatrogenic stenosis.

A barrier flap is created from the ventral dartos, or tunica vaginalis if there is insufficient dartos or a proximal repair, placed over the entire neourethra, and sewn in place.

Glansplasty is done distally, creating the ventral lip of the neomeatus at the midpoint of the glans wings, and continuing proximally to the corona using interrupted subepithelial 6-0 polyglactin. Most often, three stitches are required. As with TIP repairs, the glans wings are not sewn to the neourethra. The second stitch incorporates the barrier flap to hold it in place.

Any excess shaft skin is next excised, and then subepithelial skin closure completed. Urinary diversion continues for 10 days.

Results

Three institutions all report complications in 15% of cases after inlay graft reoperations.[67,70,71] Of these, the mean number of prior operations was two in two series, and four in the other. Two of these noted postoperative strictures at the junction to the formed urethra, which likely emphasizes the need to incise the skin strip well into the urethra until healthy tissues are encountered.

Stag Reoperations

First Stage

A first-generation cephalosporin is administered intravenously when oral graft harvesting is anticipated. The orogastric tube is secured laterally to leave access to the lower lip, or nasogastric intubation is performed depending on anesthesia preference.

As with the other reoperations described above, the initial incision most often is ventral using a Y to create glans wings and open the skin down the median raphe. Complete degloving usually is not needed, although it is done when VC persists after the neourethra and surrounding fibrosed tissues are excised to better assess and correct the bending.

Next, the neourethra is opened from distally to proximally to normal urethra and then completely excised. All underlying scar tissues are removed down to the tunica albuginea of the corporal bodies. The visual margins of the glans wings are injected with 1:100,000 epinephrine before their incision. Glans wings are created and dissected laterally to three and nine o'clock. Extended dissection to additionally free the wings from the corpora distally is not done at the first stage, but the glans should be opened widely like a book in order to place a sufficient amount of graft into the glans. Prior surgery sometimes leaves the ventral glans flat, but excision of the neourethra and associated scar tissue reestablishes a deep groove between the wings so that the ultimate neomeatus will be vertical and slit after the second stage.

An artificial erection must be checked after excision of the neourethra; excision alone does *not* guarantee straightening. A persistent curvature of $\geq 30°$ after degloving and removal of the neourethra and ventral scar tissues is corrected by three transverse ventral corporotomies.

The normal urethra is spatulated ventrally, and proximal urethrostomy made by suturing adjacent skin to the urethra at five, six, and seven o'clock using 6-0 or 7-0 polyglactin in children and 5-0 in adults.

The visible border of the lower lip is marked with a pen, and two 5-0 polypropylene stays are placed into this line to retract the lip open and down, exposing the inner surface. A damp gauze is packed adjacent to the endotracheal tube to block blood from the throat. The graft is outlined running adjacent to the gum proximally, within 2 mm of the visible lip margin distally, and at a visible junction to cheek mucosa on each side laterally (Figure 73.29a). The goal is to remove all lip mucosa within these anatomic boundaries.

This graft will reach from the tip of the glans distally to deep within the scrotum proximally. Epinephrine (1:100,000), or bupivacaine with 1:200,000 epinephrine, is injected under the entire graft prior to harvest for hydrodissection. Then an incision is made first along the gum, then the lip, and finally the lateral edges by the cheek, so that blood running down does not obscure dissection. The correct plane to harvest the graft is above the muscle, limiting fat that is most abundant near the outer margin of the lip. The donor site is not sutured or otherwise treated. The wound heals by reepithelialization, leaving a fine transverse scar (Figure 73.29b).

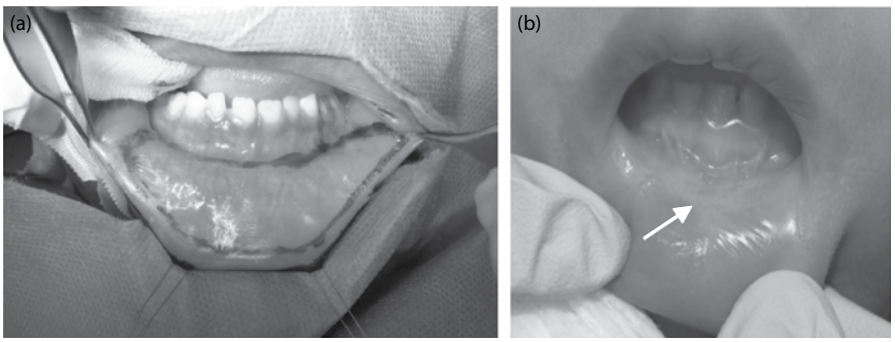

FIGURE 73.29 Lower-lip graft. (a) If a smaller graft is needed, harvest should be from the upper lip. The wound is not sutured, but allowed to heal by secondary intention. (b) Arrow shows the transverse scar after healing.

The graft is next defatted. There is no need to pin it to a board, as it is sufficient to simply drape the graft over the index finger. This allows the surgeon to sense the depth of the dissection and avoid holes.

Finally, the graft is sutured into place beginning distally. First, it is sewn to the coronal margin adjacent to the glans wings stays on either side with 7-0 polyglactin in children or 5-0 in adults, and then gently stretched further distally and stitched to the end of the glans. These most distal stitches are subepithelial on the glans side to avoid suture marks in the future neomeatus. Generally, the graft measures between 13 and 20 mm wide at the level of the corona. Not placing sufficient graft in the glans is a significant technical error.

Next, the graft is stretched gently proximally and sewn with interrupted polyglactin to shaft skin toward the meatus. The proximal end is split up the midline to place graft to either side of the urethrostomy, where it is stitched. Once the perimeter of the graft has been sewn into place, the graft is quilted to the corpora using 6-0 polyglactin in children, or 5-0 in adults, both on a RB1 needle, which we have found best penetrates the graft and secures it to the underlying tunica albuginea. Quilting is first done down the midline, and then to either side between the midline and perimeter, with interrupted stitches approximately 5 mm apart in children and 1 cm in adults.

Occasionally, the relative sizes of the lip graft and penis width are such that the usual graft will not entirely fill the defect in a single sheet of tissue. When more than one piece is needed, they should be joined on the shaft, below the coronal region, obliquely, to reduce chances for scar contracture. Lip graft is placed within the glans, since it is thinner than the cheek, which is used on the lower penile shaft.

5-0 polypropylene stays are placed at the graft perimeter adjacent to the meatus and at the middle section. A catheter is passed into the bladder, and then a rolled Vaseline gauze is laid onto the graft and tied snug, not tight, with the polypropylene stays.

The tie-over bandage and the catheter are removed in 1 week. In younger, active children, the polypropylene stays often pull loose and the bandage usually falls off spontaneously before 1 week. Those bandages that remain in place often develop an offensive odor, which has not indicated infection, graft loss, or other complications.

Teens and adults stay in the hospital for overnight bedrest after oral mucosa harvesting, primarily to reduce risk for scrotal hematomas. There can be significant mouth discomfort after oral harvest, which is diminished using Magic Mouthwash, a mixture of lidocaine, Maalox, and Benadryl.

After the bandage is removed, Aquaphor is applied to the graft and adjacent shaft skin several times daily to keep them moist. Beginning 1 month postoperatively, 0.1% betamethasone ointment is instead applied twice daily for another 12 weeks.

Oral mucosa keratinizes, when dry, create a superficial snakeskin appearance. This is of no consequence before the second stage.

Results

Graft contracture or loss requiring reoperation to repair or replace the graft occurs in <10% of cases.[8] Partial transverse contractures can be corrected during the second stage by either inlay grafting or inclusion of adjacent supple and non-hair-bearing skin into the urethroplasty.

However, longitudinal contraction causing penile bending of ≥30° requires staged graft repair or replacement. This most often occurs around the midshaft, where a transverse incision is made through the graft and then the remaining proximal graft and urethrostomy are mobilized off the corpora. Distal healthy graft on the distal shaft and within the glans can be preserved. Once the scar is all released and excised, the penis should be straight with artificial erection. A patch graft of oral mucosa from the upper lip or cheek is used to fill the gap between healthy distal graft and the now relocated proximal urethrostomy, which is quilted into place and further secured with a tie-over bandage. Second-stage urethroplasty is delayed another 6 months.

The most common donor site complication is contracture of the scar causing visible lip distortion. This usually resolves before the second-stage procedure, but if it persists, two or three longitudinal incisions can be made through the linear scar to release it.

Second Stage

Second-stage tubularization is done 6 months later. The desired neourethral plate appearance is seen in Figure 73.30. The border of the neoplate is outlined with a marking pen, creating a U shape. The glans wings are injected with 1:100,000 epinephrine, and then the incision made. Glans wings are dissected initially to three and nine o'clock. The proximal aspect of the incision just enters the urethrostomy, to exclude the skin previously sutured there, from five to seven o'clock. Then the incision continues below the urethrostomy, dividing the median raphe of the scrotum for later access to a testicle to harvest tunica vaginalis.

FIGURE 73.30 Appearance of oral mucosal graft prior to 2nd stage urethroplasty. Well-healed lower-lip graft. Note it appears relatively more thick than prepucial grafts.

There is little need to dissect under the edges of the neoplate, as they are most often sufficiently mobile for tubularization, and extensive dissection theoretically could devascularize that region.

Dissection of the glans wings laterally to three and nine o'clock, and then cephalad off the corpora bilaterally for approximately 4 mm, is done routinely in these cases for later tension-free approximation.

A catheter is passed into the bladder and tied to the glans traction suture as detailed above for second-stage STAG repair with prepucial grafts. The neoplate is tubularized in two layers, the first using interrupted subepithelial 6-0 polyglactin and the next continuous 6-0 polydioxanone in children, or 5-0 sutures in adults. The initial stitch is placed distally at approximately the midglans level to create an oval, not rounded, opening.

Next, a testicle is exposed and its tunica vaginalis covering dissected to the external ring. The testicle is pexed back into its normal location, and the scrotal dartos is sutured closed over it. The tunica vaginalis flap is placed with the inner portion over the neourethra and tacked into place with interrupted 7-0 polydioxanone stitches.

Glansplasty is completed beginning distally to establish the proximal lip of the neomeatus. Interrupted subepithelial 6-0 polyglactin is used in children or 4-0 in adults, and as in primary TIP repair, the glans wings are not sutured to the neourethra. The first stitch is at approximately the midglans. Closure continues proximally to the corona with two additional sutures, the second including a bite of the tunica vaginalis flap to hold it in place.

Glansplasty should enclose all the oral mucosa, as any exposed regions at the meatus will chronically keratinize, producing a snakeskin that the patient will peel off repeatedly, and which can deflect the stream.

Skin closure down the median raphe is then completed using 7-0 subepithelial polyglactin. A Tegaderm bandage is applied. The catheter provides urinary diversion for 2 weeks.

Results

Complications occur in nearly 40% of patients, most of whom are considered hypospadias cripples after failing an average of four repairs in our series.[8] In another series of STAG reoperations, one-third of patients had BXO,[72] which has a high rate for additional complications even after excision and staged oral grafting.[73] Our complications included glans dehiscence and fistulas, with no urethral strictures or diverticulum.

DURABILITY OF PREPUBERTAL REPAIRS

Most hypospadias repairs are completed during childhood. Of these patients, some will have no future problems, others will have persisting complications into adulthood, and a third group, considered successfully repaired, may present as adults with a "new" complication. Barbagli et al.[74] reported on 60 adult patients with childhood hypospadias repairs seen over a period of 9 years. Of these, some had visible penile deformities, that is, persisting complications, while others who appeared satisfactorily repaired presented with symptoms more than 10 years after surgery and were diagnosed with urethral strictures. The authors theorized that this latter group developed strictures after the onset of sexual activity from "repeated stretch and trauma" to the skin-made urethra lacking corpus spongiousum.

Subsequently, Ching et al.[75] reported their experience with 55 adults with hypospadias accumulated over 16 years, of which 16 were considered late failures. Their findings were not specifically described, but the authors also concluded that childhood repairs may not be durable.

These comments have found their way onto the Internet, and from there into layperson Facebook groups, raising questions of whether hypospadias should be repaired in childhood if the results do not last through growth and the onset of sexual activity during puberty. Consequently, some mothers now ask if surgery should be postponed until puberty.

Despite calls for routine long-term follow-up after repair of infants continuing through puberty, there is to our knowledge no study, even from countries with national healthcare systems, that captures the majority of patients operated on with periodic assessments for this duration of time.

It is also noteworthy that the majority of adult patients with hypospadias reported by adult reconstruction specialists had strictures, which is not surprising given that their centers are known for expertise in stricture repair. The duration of the anatomic lesion before diagnosis with symptoms is difficult to know with strictures, and certainly, it is possible that some of these men developed strictures before puberty. Even if all these strictures developed from sexual trauma, delaying surgery until puberty would not avoid the risk for future strictures unless patients are instructed not to have sexual intercourse indefinitely.

It is useful to place this discussion into context. Barbagli recently combined his experience with that of another center to report the largest series of adults with hypospadias, a total of 1176 men from a 19-year period, averaging 62 per year.[76] The authors did not state how many of these were considered to have late failures after beginning sexual activity. If all of them were, those 62 would represent less than 1% of the approximately 10,000 boys who undergo hypospadias repair each year in the United States alone.

The adults we see with complications after childhood repair each have had persisting complications, rather than new-onset ones.

IMPROVING HYPOSPADIAS REPAIR

Hypospadias repair is a complex operation, requiring precision. Dissection even 1 mm in the wrong plane during the key steps of a technique potentially increases the risk for complications. Current data reviewed in this chapter indicate that approximately 1 of every 10 distal repairs and more than 50% of proximal repairs will develop complications, requiring additional surgery. Furthermore, the risk for additional complications doubles with the first reoperation and rises to 40% by the third.

It is clearly important to achieve success with the primary repair. This section discusses the means for individual surgeons to improve their results.

Limit the Surgical Algorithm

It was previously believed that surgeons had to choose from among a variety of procedures for the one best suited to the specific anatomy of the patient. In fact, selection of the wrong technique, rather than technical error, was described as the leading cause of complications.[77]

In contrast, we discuss above that all repairs can be done by adapting TIP and STAG to the situation encountered, and emphasize that complications most often are the result of technical error. A limited algorithm simplifies decision making, and allows the surgeon to primarily focus on performing the key steps, optimally to reduce technical error. Even those surgeons who prefer other techniques can limit the total number of procedures they use to only a few and concentrate on their optimal performance.

Given that the average number of distal repairs done by U.S. pediatric urologists is only one a month, the advantage of using a single technique with published success in more than 90% of cases is clear—surgeons can gain expertise that is not as easily achieved and maintained if multiple techniques are each used a few times a year.

Perform the Key Steps Optimally

Every surgeon performing a hypospadias repair technique should do each key step according to the best published results. Failure to do so results in increased risk for complications, and reviews of operative records in patients presenting to us after failed repairs usually find at least one deviation from best practices. Some examples include no or partial TIP incision, single-layer urethroplasty, no barrier flap, single-stitch glansplasty or mattress suture glans wings approximation, and failure to check artificial erection after urethral plate transection.

For surgeons to optimally perform procedures, authors of articles and book chapters must describe key steps in precise detail so that readers can reproduce them.

Review Personal Results

Few surgeons know their personal results, instead assuming them to be similar to published outcomes or believing them to be low because they cannot recall the past patients they had with a problem like a fistula. The Dutch Hypospadias Study[3] suggests that both assumptions are often wrong. Similarly, we have found that nearly every time we review our results, they are not as good as we thought them to be.[18]

A simple chart review is sufficient to give an overview to a surgeon of his or her number of cases and complications. However, it is more efficient and accurate for individual surgeons to create a personal quality database using an Excel spreadsheet, and then maintain it prospectively. Information to be recorded includes patient name, date of surgery, primary or reoperative repair, technique used, date of follow-up, and complications (fistula, glans dehiscence, meatal stenosis, stricture, diverticulum, or recurrent VC). These data can be entered rapidly after surgery and postoperative clinic visits, and then reviewed periodically. Greater complications than the best published should then prompt a review of the surgeon's individual methodology to identify areas to improve. Review of subsequent patients confirms reduced complications.

We refer to this process as the three Ps: prospective data collection, periodic outcomes review, and practice changes to improve.[18] Other surgeons adopting this quality review have similarly told us that their results were not as good as they assumed, but improved once they realized the need to do better.

Specialized Proximal Hypospadias and Reoperations

Reviews of complex operations routinely find that the best results are achieved by high-volume surgeons. Certainly, the average of two proximal repairs done annually by U.S. pediatric urologists is not sufficient for the most complex forms of this condition, and likely explains, in part, the high complication rates reported by multiple centers.

There are only 1000 new male infants born in the United States with proximal hypospadias annually. There will only be approximately 1500 first-time complications each year (assuming 10% of distal and 50% of proximal repairs have a complication). While the complexity of reoperation varies, the fact that complications are greatly increased in patients undergoing reoperation suggests that these should also be considered high risk, similar to primary proximal repairs.

Therefore, we recommend that centers designate a single surgeon or surgical team to perform proximal repairs and reoperations, and then monitor their volume and results. Otherwise, few surgeons will have the volume needed to achieve and maintain expertise for these most challenging reconstructions.

CHAPTER 74

Pediatric Urethral Trauma and Stricture

Nadya M. Cinman, Jack W. McAninch, and Benjamin N. Breyer

INTRODUCTION

Urethral injuries in children are infrequent, accounting for 3.4% of children admitted with traumatic injuries of the genitourinary tract.[1] Significant morbidity may result from the impact on function and quality of life, with the need for specialized care and potential for multiple interventions. In general, the management of pediatric urethral trauma has followed treatment algorithms for adult urethral trauma.

ADULT VERSUS PEDIATRIC URETHRAL INJURY

Pediatric and adult urethral injury differ in several ways. Anatomic variation exists as the pediatric urethra is shorter, more mobile, and protected by an immature pubic bone. The bladder in a child is in a relatively intra-abdominal location compared with in the adult.

Pelvic fractures in children are more likely to be unstable and associated with a severely displaced prostatic urethra. Pediatric pelvic fractures occur with prostatic urethral displacement in 69%, whereas adult pelvic fractures are associated with a displaced prostatic urethra in 42%.[2] In children, concomitant bladder and urethral injuries occur in 20% of urethral injury, with coexisting anterior longitudinal urethral tears through the bladder neck and sphincteric complex. This is two times more likely to occur in children than in adults.[3] Similarly, in female children there is a higher likelihood that pelvic fractures have an associated urethral injury than in adult women.[4] Approximately 5% of pelvic fractures are associated with urethral injury, with higher rates of urethral injury in boys versus girls (7.4%–13.5% in boys and 4%–6% in girls).[5,6]

MALE URETHRAL INJURY

The male urethra can be divided into two segments, the anterior and posterior urethra. The anterior urethra includes the bulbar and pendulous (or penile) urethra. The posterior urethra includes the prostatic and membranous urethra, the latter of which is encompassed by the urogenital diaphragm. The pelvic floor separates the posterior and anterior urethra in both genders. The perineal membrane, which is the fascia of the urogenital diaphragm, signifies the extent of trauma as reflected by the amount of contrast extravasation above or below the urogenital membrane during a retrograde urethrogram.[7]

Classification of Urethral Injury

Anterior Urethral Injury

Anterior urethral injury in children is less common than posterior urethral injury.[8] It tends to result from blunt trauma, such as straddle injury to the perineum, occurring from a bicycle seat or crossbar, or from blows to the perineum from a fence or kick (Table 74.1). The bulbar urethra is most vulnerable to being damaged with straddle injury, representing the most common area of anterior urethral injury in boys (Figure 74.1).[9] The urethra gets compressed against the inferior aspect of the symphysis pubis. Straddle injuries do not typically occur with simultaneous pelvic fracture. However, blunt pelvic trauma with pubic rami fracture can occur in combination with bulbar urethral injury.

Posterior Urethral Injury

Posterior urethral injury is associated with pelvic fracture, tending to occur with motor vehicle collisions, crush injuries, and high-impact falls. The relative intra-abdominal location of a pediatric bladder and the more cranially placed prepubescent prostate predispose boys to complete posterior urethral disruption (Figure 74.2).[10] Prostatomembranous disruption occurs from major shearing forces at two fixation points of the posterior urethra. One point is the prostatomembranous junction, where the urogenital diaphragm is adherent to the ischiopubic rami. The second point is the fixation point of the prostatic urethra to the anterior pubic arch, the puboprostatic ligaments. The bladder and prostate are mobilized and displaced ("high-riding prostate") with this injury, with extraperitoneal urine leakage, and hematoma resulting from shearing of the dorsal venous complex (Figure 74.3a). The severe displacement of the pediatric prostate and nerve tissue disruption raise concern for future erectile dysfunction and incontinence.[11,12]

The risk of urethral injury occurring with a simultaneous pelvic fracture is directly related to the number of pubic rami fractures, degree of separation of the pubic symphysis, and presence of concurrent sacroiliac joint diastases.[13,14] Categories of fractures of the infant pelvis, according to Torode and Zieg, include types I, II, and III, which are stable fractures of avulsion, iliac wing fractures, and plain pelvic wing fractures, respectively.[15] Type IV fractures, also known as Malgaigne fractures, are anterior fractures through the rami or pubic symphysis coupled with posterior fractures of the ipsilateral ilium, sacrum, or sacroiliac joint, which typically occur from high-energy vertical forces transmitted to the pelvis via extended femurs. Malgaigne fractures carry the greatest risk of coexisting urethral injury (Figure 74.4).[16]

TABLE 74.1 Etiology of urethral injury

Condition	Cause
Anterior	
Blunt	Associated with straddle injury Falls Kick to perineum Horseback/bicycle riding Skateboarding/surfing
Penetrating	Gunshot wounds Impalement injury
Induced	Penile fracture Urethral foreign bodies
Iatrogenic	Urethral catheterization Circumcision Endoscopic evaluation
Posterior	
Blunt	Associated with pelvic fracture Motor vehicle accidents High-impact falls Crush injuries
Penetrating	Gunshot wounds Impalement injury
Induced	Urethral foreign body
Iatrogenic	Endoscopic evaluation Anorectal malformation repair

The Colapinto classification scheme defines posterior urethral injuries as determined with retrograde urethrography (Table 74.2). Type I injury is a stretched membranous urethra without rupture, type II injury is a complete rupture of the membranous urethra with an intact urogenital diaphragm, and type III is a membranous urethral rupture with urogenital diaphragm disruption.[17]

When a urethral injury and pelvic fracture are diagnosed concurrently, the risk of a coexisting rectal injury is present in 15% of children. While the role of pediatric digital rectal exam is controversial in accurately diagnosing a displaced prostate or rectal injury, it is recommended that radiographic and/or endoscopic modalities be used for rectal evaluation.[18] A missed rectal injury can result in significant morbidity, such as pelvic abscess, fistulization, osteomyelitis, and necrotizing fasciitis. When identified, rectal injury should be treated with temporary diverting colostomy.

DIAGNOSIS

Clinical Evaluation

Patients identified with pelvic fracture, straddle injury, or penetrating injury in the vicinity of the urethra should

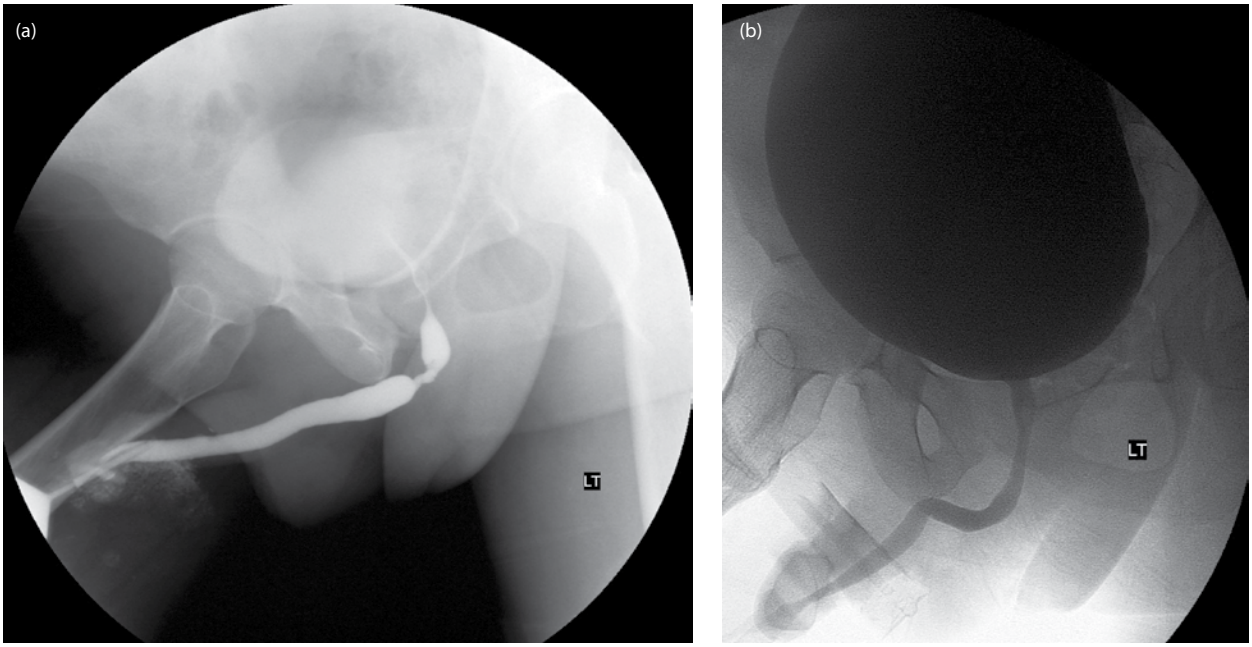

FIGURE 74.1 Radiographic images of a 16-year-old male with a bulbar urethral stricture that was a result of a straddle injury. (a) Preoperative retrograde urethrography demonstrates a 1.5 cm bulbar urethral stricture. (b) Six-month postoperative voiding cystourethrogram demonstrating the absence of the urethral stricture.

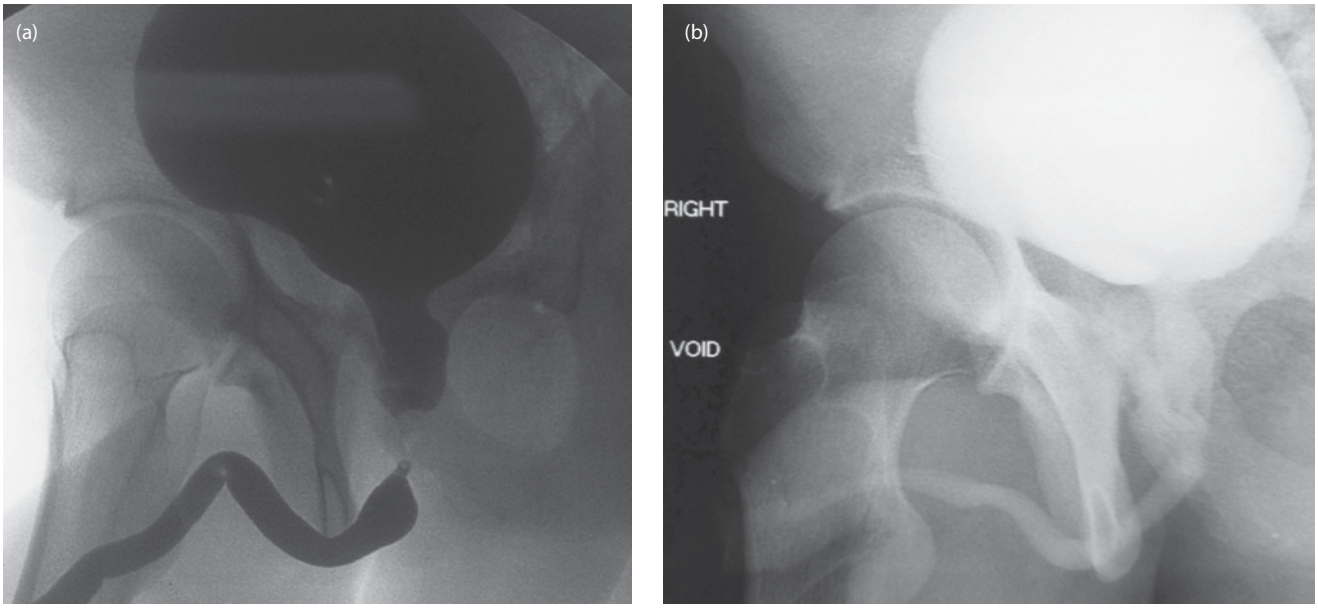

FIGURE 74.2 Radiographic images of a 15-year-old male who sustained posterior urethral disruption during a motor vehicle collision. (a) Simultaneous retrograde urethrogram and cystogram via a suprapubic tube delineate the urethral separation that has been filled in by scar. (b) Six-month postoperative retrograde urethrogram following posterior urethroplasty.

(b) Anterior urethral injury distal to the urogenital diaphragm with leakage represented within the borders of Colles' fascia.

be evaluated for urethral injury. The classic findings that should raise concern for urethral injury include perineal, penile, labial, or scrotal hematoma; a palpable bladder; blood at the urethral meatus; hematuria; and inability to void.[19] Evaluation to rule out urethral injury should occur when there is pelvic fracture with a pubic rami fracture or symphyseal diastasis, or when radiographic findings suggest bladder neck injury. Injury of the anterior urethra, distal to the urogenital diaphragm, results in a characteristic "butterfly hematoma," which represents hematoma of

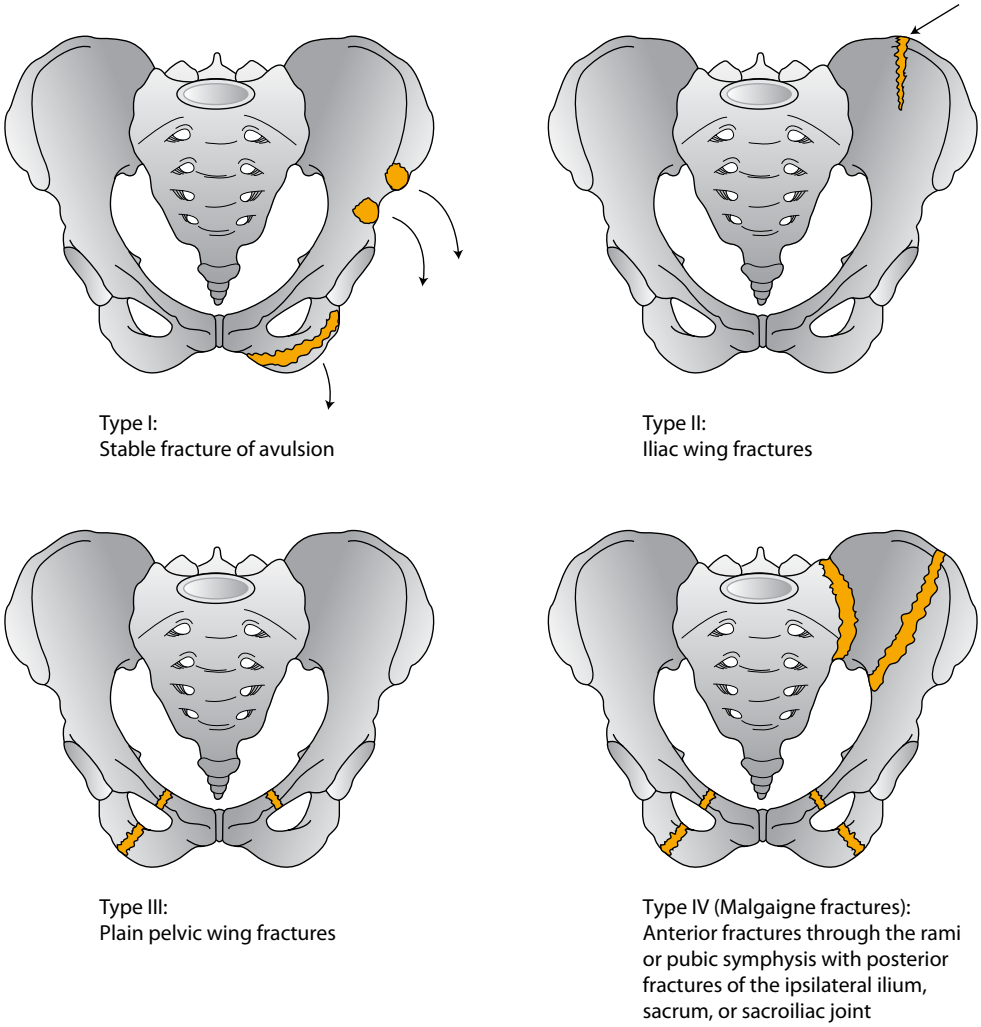

FIGURE 74.4 Torode and Zieg classification of fractures of the infant pelvis.

TABLE 74.2 Colapinto classification of posterior urethral injuries

Type	Description
Type I	Stretched membranous urethra without rupture
Type II	Complete rupture of the membranous urethra with an intact urogenital diaphragm
Type III	Membranous urethral rupture with urogenital diaphragm disruption

the superficial perineum that is contained by Colles' fascia (Figure 74.3b). Boys demonstrate scrotal enlargement from fluid extravasation through ruptured Scarpa's fascia, and its contiguous layer of the perineum, dartos fascia. Girls may exhibit labial swelling.

Radiographic Assessment

Significant lower genitourinary injuries were not found in stable pelvic fracture patients without gross hematuria, without multiple associated injuries, and with a normal genitourinary exam. Lower urinary tract radiographic evaluation of patients who fit these criteria may not be necessary.[1]

Retrograde Urethrography

Retrograde urethrography is considered the gold standard for the diagnosis of urethral injury, specifically male urethral injury. Proper technique includes patient positioning with the hips at an oblique angle, bottom leg bent, top leg straight, and the penis held on stretch. Scout imaging of the pelvis can demonstrate bony fractures of the pubic rami, pubic symphysis diastasis, and foreign bodies, including bullets and stones. A 6–8 French catheter is inserted into the fossa navicularis, and approximately 10 mL of undiluted contrast is injected transurethrally.

Computed Tomography

Urethral injury is typically associated with significant trauma; therefore, computed tomography (CT) scanning is the preferred initial radiographic modality to assess soft tissue injury, organs of the pelvis and retroperitoneum, and bony structures. While urethral injury is not always evident on CT, it does visualize the pelvic fracture and

associated hematoma. Radiographic literature suggests that CT provides an initial screening method for urethral injury, with a retrograde urethrogram to confirm male urethral injury and cystoscopy or vaginoscopy under anesthesia to confirm female urethral injury.[20]

Antegrade Urethrography

Posterior urethral injuries are typically managed by suprapubic tube urinary diversion. Antegrade urethrography via the suprapubic tube can be performed in conjunction with retrograde urethrography, to grade the extent and length of urethral injury or disruption and guide reconstructive planning.

Magnetic Resonance Imaging

MRI is generally reserved for the evaluation of urethral injury in preparing for delayed reconstruction, and is not typically used in the acute phase following injury. MRI can provide useful information about the location of the posterior urethral injury, length of the urethral obliteration, and degree of the external sphincter fibrosis.[21] While MRI offers the advantage of limited ionizing radiation versus CT, which is important in children, it does require the patient to be still. Therefore, sedation or general anesthesia may be required.

Cystoscopy

After suprapubic tube placement and radiographic demonstration of the urethral injury, cystoscopy may be performed to permit guidewire advancement into the bladder to facilitate primary urethral realignment. Due to the short female urethra, cystoscopic evaluation is noted to be of particular benefit.[22] Caution should be used in attempting cystourethroscopy in an injured pediatric urethra, especially without pediatric instruments and experience with pediatric urethroscopy, as manipulation may exacerbate the injury.

Preoperative Radiographic Evaluation of Urethral Stricture

The gold standard preoperative evaluation of a urethral stricture includes a combined retrograde and antegrade urethrogram to assess the length and location of the stricture and degree of stenosis. It is cautioned that the urethral defect that occurs after urethral distraction may be over- or underestimated by nonfilling of the fibrosed urethra distal to the verumontanum or by urinoma cavity formation that is in continuity with the end of the proximal segment.[23] Also, while Retrograde Urethrogram (RUG) can detect urethral stricture, it does not provide information on the extent of spongiosal fibrosis, which may bear significance in determining an operative plan. Therefore, it is recommended that urethrography be used in conjunction with other assessment tools, such as urethral ultrasonography.

Urethral Ultrasonography

Urethral ultrasonography is used intraoperatively at the case start to evaluate urethral stricture length and location, and provide details about spongiofibrosis that aid in deciding the optimal surgical approach. With retrograde saline instillation and a simultaneous suprapubic Crede maneuver, the urethral narrowing is evident adjacent to the distended urethra.[24] While the literature favors intraoperative urethral sonography for adult stricture assessment, reports show similar support for accurate measurement of adolescent anterior urethral stricture length and visualization of location.[25]

FEMALE URETHRAL INJURY

The female urethra develops to 4 cm in length, and pierces the urogenital diaphragm posterior to the pubic symphysis. It lies fixed against the anterior wall of the vagina, with a horseshoe-shaped, striated external urethral sphincter in the distal two-thirds of the urethra that fans out laterally along the inferior border of the pubic rami.

A high index of suspicion for urethral injury should occur in any female patient presenting with gross hematuria or blood at the introitus and a pelvic ring fracture. An estimated 40% of female urethral injuries are missed in diagnosis in the emergency department, with recommendation that proper assessment include adequate vaginal examination under anesthesia.[26] A delay may be required until pelvic fractures have stabilized, but a speculum exam and/or vaginoscopy should be performed, especially in the event of difficulty with urethral catheter placement.[27] While avulsion injuries are best diagnosed on physical exam or urethral catheterization, the best imaging modalities to aid the diagnosis of bladder neck or urethral injury include a CT cystogram and urethroscopy. Urethrography or voiding cystourethrography has been cited as less helpful.[22]

Female urethral injuries are typically associated with an unstable pelvic fracture. Disruption of the pubic symphysis occurs with a longitudinal laceration extending through the bladder neck and urethra, or by dislocation of a bony fragment that causes urethral laceration or transection. Urethroscopy and vaginoscopy are required for proper evaluation, and if clinically stable, it should be repaired. This includes primary bladder neck repair, end-to-end urethroplasty for distraction injuries, and longitudinal urethral lacerations repaired over a urethral catheter. Additionally, vaginal lacerations should be repaired, and a diverting colostomy should be performed for rectal injury. Delayed and multistaged approaches are associated with higher rates of failure, such as urinary incontinence, erosion, fistulization, or urethral obliteration. Approximately 30% of female pediatric patients with bladder neck or urethral injuries will need urinary diversion or continent catheterizable abdominal stomas secondary to high rates of complications.[3,28]

The female bladder neck is important for continence, and therefore should be repaired primarily via a transvesical approach and two-layer closure. Despite primary repair, variable rates of continence are reported in small series (48%–100%).[22,27] The midurethra should be closed primarily with a transvaginal approach and vaginal lacerations reapproximated over the urethra. This maintains urethral continuity, prevents urethrovaginal fistula, and prevents vaginal stenosis.[29] The distal urethra can be left hypospadiac, but some sutures may be needed for hemostasis.

Patients with female urethral injury are at risk for significant future sexual and lower urinary tract dysfunction.[27]

MANAGEMENT OF THE ACUTELY INJURED PEDIATRIC URETHRA

For suspected urethral injury, proper evaluation with urethral imaging, as earlier described, is necessary prior to attempting urethral instrumentation. To prevent infection that may occur from blood or urine extravasation, and accompanying inflammation, broad-spectrum antibiotics should be initiated. Additionally, urinary drainage should be established. In any trauma case, the patient needs to be stabilized, with priority given to treatment of life-threatening injury. In the acute setting, bladder drainage with suprapubic tube placement prevents ongoing urine extravasation and permits delayed urethral repair when the patient is regarded as ready. The goal of therapy, though, is to minimize the risk of fistulization (urethrocutaneous and vesicovaginal), periurethral diverticulae, stricture, incontinence, and impotence.

Generally, urethral repair may be performed immediately (within 3 days of injury) with primary realignment or primary sutured anastomosis, delayed (same modality done at 3–14 days postinjury), or performed late (more than 3 months following injury).

Posterior Urethral Injury

Controversy exists regarding the best method to initially treat posterior urethral injury. Most posterior urethral injuries are managed by suprapubic tube urinary diversion. Some advocate earlier repair at 7–10 days postinjury, while the periurethral and pelvic fibrosis is immature. The aim of earlier repair is not to prevent a stricture, but to make the developing stricture technically easier to treat.[30] However, for patients with more significant abdominal, pelvic, or life-threatening injuries, urethral repair can safely be postponed as needed. The completely disrupted bulboprostatic urethral segment will become scar through fibrosis.[31]

Primary open or endoscopic realignment attempts to bridge the disrupted urethral ends together using sounds or combination retrograde cystourethroscopy with guidewire advancement to reconnect the proximally displaced prostatic urethral stump. It has been shown to result in increased risk of impotence when compared with delayed repair (36% vs. 19%). This is believed to be related to periprostatic exploration and dissection.[32,33] Realignment may be particularly difficult in centers without sufficient pediatric endoscopic equipment.

Attempt at immediate repair of pediatric urethral disruption is cautioned against, given the associated high rates of complications, including stricture, restenosis, incontinence, and impotence.[34–36] Some suggest these complications result from the severity of the initial injury and not from surgical manipulation.[37]

Anterior Urethral Injury

For proximal anterior urethral injuries, stable patients can undergo primary endoscopic realignment over a guidewire. Alternatively, a suprapubic tube can be placed and assessment of the injury can be performed several weeks later by voiding cystourethrography. In the absence of urethral stricture or contrast extravasation, the suprapubic tube can be capped and subsequently removed if voiding is adequate. Immediate surgical repair can be performed for complete penetrating or open anterior urethral trauma that may occur with gunshot wounds or penile fracture; however, longer urethral defects or distracted ends require delayed reconstruction several months following the injury.[38]

Iatrogenic Urethral Injury

Iatrogenic pediatric urethral injury has been reported to occur with circumcision, urethral instrumentation, and repair of congenital anorectal malformation.[39] Potential injury from circumcision includes meatal injury, glans amputation with distal urethral injury, and development of urethrocutaneous fistula. Urethrocutaneous fistula can result from ischemic necrosis of the urethra, which can result from crush injuries by circumcision clamps, applied cautery, or sutures.[40] For injury sustained during urethral instrumentation, antibiotics should be administered along with urethral catheterization. Voiding cystourethrography can be performed between 1 and 3 weeks following the injury. Resulting strictures have traditionally been repaired when the child is over 1 year of age, given the concerns regarding general anesthesia. For children over the age of 1, waiting at least 3 months after injury provides sufficient urethral rest to permit stricture maturation.

The risk of urethral injury during repair of congenital anorectal formation is believed to occur when either no urethral catheter is placed during the rectal dissection or the urethral catheter is misplaced into the rectum via a rectourethral fistula. Accurate catheter placement with bladder drainage should be ensured before anomalous anatomical dissection is performed.[41]

Endoscopic Techniques

Popular in the late 1980s as a minimally invasive approach to treating obliterative posterior urethral strictures, the "cut-to-light" procedure combines retrograde and antegrade urethroscopy to open the urethra with knife incision or laser. Long-term stricture-free success is cited near 0%, with patients needing either daily catheterization to maintain luminal patency or urethroplasty. Therefore, the popularity of this procedure has diminished in favor of more durable approaches.[42]

Management of anterior urethral strictures is controversial in both pediatric and adult populations. Some reserve direct vision internal urethrotomy (DVIU) for short (<1 cm) nonobliterative anterior urethral strictures, claiming relatively high rates of stricture-free recurrence (75%–100%) following the procedure. Long-term follow-up shows stricture-free recurrence rates of 20%–35% at 5 years.[43,44] Others advocate initial DVIU regardless of preoperative stricture length, reserving urethroplasty for cases in which one endoscopic attempt has failed.[45] Endoscopic attempts may worsen the stricture severity, with more subsequent scar tissue and increased surgical difficulty.

Surgical success rates have been shown to decline with increased previous procedures.[46] Longer, denser strictures are likely better treated with open techniques.

Anastomotic Urethroplasty

In general, excision of the urethral stricture and primary anastomosis in pediatrics follows the same principles and steps as for adult urethroplasty. Anastomotic urethroplasty includes complete excision of scar tissue, widely spatulated urethral ends, and a tension-free anastomosis with urethral mucosal approximation. Typically, pediatric distraction injuries less than 2 cm can be performed in an end-to-end fashion, while urethral gaps of more than 3 cm will need adjunctive maneuvers to permit adequate anastomosis. Urethral mobilization distal to the penoscrotal junction risks penile shortening and chordee, so other techniques to aid in reducing tension on the urethral anastomosis include pubectomy, splitting or rerouting the penile crura, and a combination perineal and suprapubic approach. Since pediatric posterior urethral injury tends to occur with prostatic urethral displacement off of the pelvic floor, posterior urethroplasty in a child is more likely to need these maneuvers than adult urethroplasty.[47] Some advocate pediatric posterior urethroplasty with an initial transpubic approach.[10]

Using a mallet and osteotome, partial pubectomy permits access to the posterior urethra and bladder neck. Partial pubectomy has not been shown to affect bone growth, posture, or gait, and can safely be performed in children.[48–50] While it is rare to need total pubectomy in a child, close monitoring with periodic plain radiography can assess theoretical medial pubic bone regrowth, which risks impingement on the rerouted urethra. A reduction in the need for pubectomy may be related to improved visualization by use of high lithotomy positioning in candy-cane stirrups and use of a self-retaining ring retractor with flexible hooks.[51]

While coronal splitting has been described in pediatric urethroplasty,[52] select surgeons prefer not to split or reroute the pediatric urethra.[53] Controversy exists as to whether corporal spongiosal splitting procedures affect rates of erectile dysfunction.

Substitution Urethroplasty (Flaps, Grafts, and Multistage)

Traumatic pediatric urethral strictures greater than 3 cm in length are often approached in a single-stage flap procedure using prepucial or penile shaft skin (Orandi procedure and McAninch fasciocutaneous flap for long defects). Alternatively, if local skin is unavailable, a graft urethroplasty using a free skin flap or buccal mucosa can be performed.[47,54] Single-stage repairs involve opening the urethra on one side, where onlay placement of the graft or flap will permit maximal imbibition and inoscultation. For pendulous urethral strictures, dorsal onlay grafts are used, whereas bulbar urethral grafts can be placed either dorsally or ventrally. Ventral onlay bulbar urethroplasty avoids the need for lateral urethral dissection, is technically easier, and permits graft support from the thicker dorsally located bulbar spongiosum. However, a dorsal onlay bulbar urethroplasty may be preferred since it avoids incising the thicker area of the bulbar spongiosum. If the urethral defect is large enough that a flap or graft may need to be tubularized, the recommendation is to stage the procedure to reduce the risk of recurrent stricture. Staging the procedure by performing a classic two-stage Johansen urethroplasty or multistage flap or graft urethroplasty permits evaluation of graft survival, time for neovascularity, and assessment of the urethral plate for possible hair-bearing skin before urethral closure. Generally, urethral stricture length, the availability of well-vascularized excess adjacent skin, and the health of the donor bed determine single- or multistage approaches.

Bladder Neck Incompetence Following Posterior Urethral Injury

Urinary incontinence is a result of either concurrent bladder neck and urethral injury or damage to the pelvic or pudendal nerves with resultant sphincteric complex denervation.[38] Therefore, bladder neck injury should be fixed to restore urethral continuity. This is of fundamental importance to reduce the likelihood of urinary incontinence. If urinary incontinence results, an artificial urinary sphincter or bladder neck sling can be placed. However, with previous bladder neck reconstruction, artificial urinary sphincter placement risks urethral erosion. Artificial urinary sphincter mechanical life span is a further limitation for pediatric use. Alternative options include a continent catheterizable stoma with the Mitrofanoff principle, without an attempt to restore urethral continuity, or neourethral reconstruction using a bladder flap.[55]

Repair of Female Urethral Injury

Female urethral injury involves primary repair. Postponement of definitive repair in the female is believed to result in an obliterated urethra, and dense scar tissue of the anterior vagina that risks vaginal stenosis.[56] In combination with primary urethral repair, vaginal lacerations should be repaired.[57] For acute injuries so severe that there is an inability to identify or reapproximate urethral ends without tension, or with widely displaced pelvic fractures, suprapubic urinary drainage can be obtained with delayed definitive repair.[58] Approaches to repair include transvaginal, abdominal-vaginal, retropubic, or transpubic means.

For injuries associated with urethral loss as a result of pelvic fracture, neourethral reconstruction can be performed by tubularizing a segment of the bladder wall, in a manner similar to that of a Boari flap.[59] Delayed urethral reconstruction following complete urethral disruption after pelvic fracture has been associated with stress incontinence. In a small series of girls (median age of 6 years) treated with delayed retropubic urethroplasty with end-to-end anastomosis, 43% (3/7) demonstrated mild stress incontinence at a median 3 years' follow-up.[60] It is believed that the detrusor tone of the tubularized bladder flap contributes to continence, in addition to intraoperative bladder neck suspension.[61]

LONG-TERM FOLLOW-UP

Long-Term Follow-Up of Pediatric Urethral Strictures

There are limited published data reporting long-term outcomes of pediatric urethral stricture.

Rates of stricture recurrence have been reported to be the same at all anatomic levels of injury, with 39% of male pediatric patients with posterior urethral injury requiring a repeat surgery for urethral stricture recurrence and at a mean of 8 months following the initial surgery.[62] Urethral reconstruction using long-segment grafts or flaps may develop recurrent stricture, most commonly at the proximal or distal end of the urethral graft, or urethral diverticula. The recommendation is that the repair procedure should be individualized per patient, depending on the anatomy and extent of the urethral injury, patient stability, and presence of additional injuries.

Long-Term Functional Outcomes

Many reports on the long-term functional outcomes following urethral injury cite the injury itself as primarily responsible for the loss of potency and urinary symptoms.[63,64] Urinary incontinence is evident in 3.7%–20%, and erectile dysfunction is listed between 16.2% and 72%.[64] The evaluation of erectile function in a prepubescent male is limited, and requires long-term follow-up that is difficult to maintain with consistent data acquisition. Reports have shown that posttraumatic posterior urethral rupture in children poses risk to their psychological well-being. While nonoperative treatment of pediatric pelvic fractures with posterior urethral injury has been quite successful, repeated operations, the presence of long-term urologic complications, and frequent and long hospitalizations risk psychological harm. In one study of 49 children with posterior urethral disruption who were followed for a mean of 12 years (range 4–17) and an average age of 8 at the time of injury, development of psychological disease was more likely to occur with greater than three urologic procedures, the presence of long-term complications, and greater than three hospitalizations. Psychological disability occurred in 43% (dysthymic disorder, social phobia, posttraumatic stress disorder, anxiety, and depression). The authors recommend a multidisciplinary approach that includes physicians and mental health professionals for the treatment of these children.[65]

CHAPTER 75

Abnormalities of the Penis and Scrotum*

Gregory P. McLennan, Kevin M. Feber, and Evan J. Kass

INTRODUCTION

Anomalies of the genitalia are common and, as a group, comprise the most frequent cause of birth defects in males. However, other than cryptorchidism and hypospadias, the majority of congenital malformations of the testis and scrotum are extremely rare and often associated with anomalies of other organ systems. Fortunately, most of these anomalies are identified at birth, and some are occasionally detected in utero.[1] Many other developmental abnormalities affecting the genitalia, such as patency of the processus vaginalis (hernia and/or hydrocele), varicocele, and the bell clapper deformity of testicular suspension, may not be apparent for many years but have the potential for significant long-term morbidity. For most genital defects, the etiology remains unknown. Congenital and acquired pediatric abnormalities of male genitalia, excluding intersex disorders, hypospadias, and cryptorchidism, are reviewed here.

NORMAL DEVELOPMENT OF THE PENIS AND SCROTUM

The external genitalia, including the genital tubercle and labioscrotal swellings, are indistinguishable in the male and female before the ninth week of human gestation.[2] The genital tubercle is formed by the migration of the mesodermal mesenchyme to the cranial portion of the cloacal membrane between the fourth and seventh weeks of gestation. Under the direction of the SRY gene and downstream processes, dihydrotestosterone causes subsequent development into the male phenotype in a proximal-to-distal fashion. The urethral groove deepens, and the urethral folds become distinct and then fuse in the midline. Recent work suggests that creation of the glanular urethra also occurs by fusion of the urethral plate, via the mechanism of epithelial–mesenchymal interaction, and not by the previously suggested ingrowth of surface glanular epithelium.[2–6] The paired labioscrotal swellings attain a more ventral position, either by actual migration or by relative change in position due to lengthening, and are anterior to the genital tubercle by 11 weeks of gestation. Fusion of the urethra up to the coronal sulcus is complete by 12 weeks. Developmental penile curvature is lost, and scrotal positioning is complete by 13 weeks. Fusion of the urethral folds within the glans proceeds as described for urethral closure in the shaft, and is accompanied by distal growth of the prepuce. By 24 weeks, the meatus is at the glans tip and the prepuce completely covers the glans, to which it is largely adherent.

PENILE ABNORMALITIES

Prepuce

Normal Development

At birth, the normal prepuce is usually unretractable because of physiologic adherence between the glans and inner preputial skin and/or tightness of the preputial ring. Ease of retractability of the prepuce increases with age, with complete retraction possible in at least two-thirds of 11- to 15-year-old and 95% of 16- to 17-year-old uncircumcised males.[7–10] Therefore, true phimosis is present in childhood only in cases of secondary fibrosis or balanitis xerotica obliterans of the prepuce, which occur in 0.8%–1.5% of uncircumcised boys.[11]

Circumcision

The prevalence of routine neonatal circumcision in the United States has dropped from close to 90% in the mid-1960s to an estimated 61.4% in 2002.[12,13] Epidemiologic data indicate that there are marked differences in circumcision rates based on socioeconomic class, ethnicity, and religious affiliation. The most recent American Academy of Pediatrics (AAP) Task Force on Circumcision report[14] stated that the risks of circumcision and now outweighed by the benefits of elective circumcision. However, the policy does state that the preventative benefits of circumcision are not enough to recommend routine elective circumcision in newborn males.

It is estimated that one in three uncircumcised men will experience a foreskin-related medical condition at least once in their lifetime.[15] In the most recent report, the AAP Task Force acknowledges potential medical benefits to

* Revised from MacDonald, M. F., Barthold, J. S., and Kass, E. J. Abnormalities of the penis and scrotum. In Docimo, S. G., Canning, D. A., and Khoury, A. E., eds., *The Kelalis–King–Belman Textbook of Clinical Pediatric Urology*, 5th ed. (Boca Raton, FL: CRC Press, 2007), 1239–70.

neonatal circumcision but concludes that these do not warrant its routine use. Benefits include reduction in the risk of urinary tract infection (UTI) in infant males and development of penile cancer as an adult. Data support an increase in the risk of symptomatic and asymptomatic UTI in uncircumcised male infants, probably because of an increased rate of periurethral and inner preputial bacterial colonization.[14,16] Similarly, penile cancer occurs almost exclusively in uncircumcised males. However, penile hygiene, including foreskin retraction with periodic cleansing, may also be preventative. Nevertheless, both of these conditions are rare, and their prevention by routine circumcision may not be justified. There is evidence that routine circumcision reduces the risk of acquisition and transmission of human immunodeficiency virus (HIV) in studies performed in underdeveloped countries.[17] The argument that the risk of sexually transmitted disease is reduced by circumcision is not supported by available data.[15,17,18]

Similarly, the risk of penile problems of sufficient severity to require circumcision is low.[8,14,11] Balanitis and balanoposthitis, characterized by erythema, edema, and purulent preputial discharge involving the glans and/or prepuce, occur in 3%–10% of uncircumcised boys. Paraphimosis, or retraction of a tight preputial ring with consequent severe glanular edema, is rare. Circumcision may be necessary only when these problems are severe or recurrent. However, even in these boys the use of topical steroids can significantly reduce the need for circumcision.[19] Since circumcision in older boys requires general anesthesia and may be associated with morbidity,[20] it should not be performed without discussing the option of medical therapy.

Newborn circumcision is performed with the Mogen or Gomco clamp or the Plastibell device.[21] Contraindications include hypospadias, chordee, penoscrotal fusion, buried penis, micropenis, and bleeding disorders. Complete separation of the prepuce from the glans with circumferential visualization of the corona is essential for adequate and safe newborn circumcision. Since significant physiologic response to pain has been documented in neonates undergoing circumcision, local anesthetic should be used.[14] Choice of anesthetic technique depends on the skills and experience of the surgeon, although penile ring block may be the easiest and most effective alternative.[22]

Older infants and children are circumcised under general anesthesia using a freehand sleeve resection technique with approximation of the penile shaft skin to the corona. Use of electrocautery in this technique has been deemed safe and effective for incision and hemostasis.[23,24] The choice of closure for freehand sleeve circumcision has traditionally been absorbable suture. Recently, 2-octyl cyanoacrylate (Dermabond) without the use of suture has become an option for closure of the shaft skin to the corona with good reported outcomes.[25,24] This technique avoids the irritation of the dissolving sutures and decreases the anesthetic time of the infants.

Complications of Circumcision

The risk of complications after circumcision is 0.2%–5%.[21] Bleeding is most common, occurring in 0.1% and more often in older boys, but is usually self-limited. Infection typically responds to local care but in rare cases may be associated with sepsis, necrotizing fasciitis, or death. Other complications of varying severity may occur, some of which may require further surgical intervention. Partial denudation of the penile shaft due to removal of an excess amount of skin will heal uneventfully with local wound care alone. Further intervention is required only to correct secondary chordee or phimosis. Conversely, excess or "redundant" preputial skin remaining after circumcision is often a source of concern for parents, but surgical intervention is rarely required. Resolution of physiologic adherence between the remaining skin and the glans will occur spontaneously after puberty, as in uncircumcised boys. Contracture of the healing edges of skin over the glans may produce secondary phimosis, also known as a trapped penis (Figure 75.1a). Correction requires excision of scar and, in some cases, penile skin flaps or Z-plasty for closure. Skin bridges (Figure 75.1b) between the shaft and glans may cause chordee and should be sharply incised. Inclusion cysts (Figure 75.1c) comprising retained subcutaneous epithelium should be completely excised. More severe injuries include glans amputation (Figure 75.1d), which can often be repaired acutely with success. However, subsequent meatal stenosis may require delayed urethroplasty.[26] Total penile necrosis (Figure 75.1e) is a rare but devastating complication of circumcision that is usually the result of using an electrocautery in combination with a metal clamp, such as a GOMCO. The use of electrocautery for circumcision is safe as long as it is not used in combination with a metal clamp.[23] Some investigators have recommended gender reassignment[27] for children with penile necrosis. However, male gender identity may be a consequence of testosterone imprinting, suggesting that gender conversion might be unsuccessful.[28] The decision of gender reassignment is difficult and should involve an experienced multidisciplinary team.[29]

Meatal stenosis occurs almost exclusively in circumcised boys. The proposed etiologies include frenular devascularization or chronic meatitis from exposure of the unprotected meatus to diaper irritation.[30,31] The incidence of symptomatic meatal stenosis after neonatal circumcision appears to be <10% based on limited available data, and possibly as high as 20% in asymptomatic patients.[32,30,33] Nonspecific symptoms, such as urethral bleeding, dysuria, or other voiding complaints, may be present, but the pathognomonic finding is upward deflection of the urinary stream as a consequence of an acquired ventral web (Figure 75.2).[34] Urinary tract imaging is unlikely to disclose significant pathology in the absence of incontinence or UTI. Meatoplasty or meatotomy can be performed under a brief general anesthetic or in the office after a generous application of EMLA cream.[35]

Defects of Number or Position

Penile Agenesis

Penile agenesis, or aphallia, is complete absence of the penis in an otherwise normal phenotypic and genotypic male (Figure 75.3).[36,37] Rudimentary erectile tissue is occasionally present. The estimated incidence is 1 in 10–30 million, and the presumed etiology absence or failed development of the genital tubercle. The majority

FIGURE 75.2 Upwardly deflected urinary stream in a boy with significant meatal web.

(54%) of patients have other genitourinary anomalies (e.g., cryptorchidism and renal and/or ureteral malformations) with or without gastrointestinal, musculoskeletal, and cardiovascular anomalies. Skoog and Belman[37] classified patients based on the relationship of the urethral meatus to the anal sphincter, noting increased additional anomalies and mortality with more proximal location of the meatus. The three variations that they described, in decreasing order of frequency, include postsphincteric with anterior perianal urethra, presphincteric with urethrorectal fistula, and urethral atresia with vesicorectal fistula. Treatment for these patients is controversial. Surgical intervention during infancy, including urethral transposition and bowel vaginoplasty via a posterior sagittal approach plus orchiectomy and scrotoplasty, has been advocated.[38,39] However, gender reassignment in other contexts and detailed psychosexual data may not support this recommendation.[29,36,37,40–45] In addition, since phallic reconstruction is feasible, however imperfect, in prepubertal boys,[46] maintenance of male gender should be considered an option in discussions with the patient's family.

FIGURE 75.3 Aphallia in a patient with a perianal urethral opening identified by sound.

Diphallia

Penile duplication or diphallia occurs in an estimated 1 in 5–6 million births.[47,48,49] The proposed etiology is branching or splitting of the genital tubercle soon after the fifth week of gestation. A balanced genetic translocation involving chromosomes 1 and 14 has been reported in one case.[50] Variants include partial and complete forms of true diphallia and bifid phallus. In the bifid variant, which is more common, the penis is branched at any point along its length, with each shaft containing a single corpus cavernosum. The designation of true diphallia is reserved for cases in which an accessory tricorporal penis (both cavernosa and spongiosum present), which may be hypoplastic, is present. The accessory organ may be located in the perineum or upper thigh. Ultrasound may be useful to characterize corporal anatomy.[47] Associated malformations are usually present and may include urethral duplication or agenesis, bladder duplication or exstrophy, hypospadias, epispadias, widened symphysis, cryptorchidism, and/or anorectal, renal, or scrotal anomalies. Also, cardiac and musculoskeletal anomalies have been reported.[51] Surgical repair involves excision of one completely duplicated penis or fusion of the bifid penis with urethral reconstruction.

Abnormal development

Penile Torsion

Rotational deformity of the penis (Figure 75.4a), usually in a counterclockwise direction, is most often associated with hypospadias and chordee but may occur as an isolated abnormality.[52] The incidence in a cohort of normal newborn males was 1.5%, with curvature of at least 90° seen in 0.7%.[53] Deviation of the median raphe without torsion was noted in 10% of newborns. Although a functional abnormality is absent if the penis is straight, penile torsion can be corrected in most cases by penile skin degloving and realignment. For more severe cases, this may be ineffective, and other procedures, such as a dorsal dartos flap rotation, may be utilized.[54,55]

Penoscrotal Fusion

Foreshortening of an otherwise normal ventral penile shaft occurs when the ventral penoscrotal junction is located distal to its normal position (Figure 75.4b).[56,57] This abnormality is called penoscrotal fusion or webbed penis, and may be congenital, due to removal of excess ventral skin during circumcision, or associated with hypospadias. Large, bilateral hydroceles in infancy may cause apparent penoscrotal fusion, which disappears with resolution of the hydrocele.[56] Lengthening of the ventral shaft

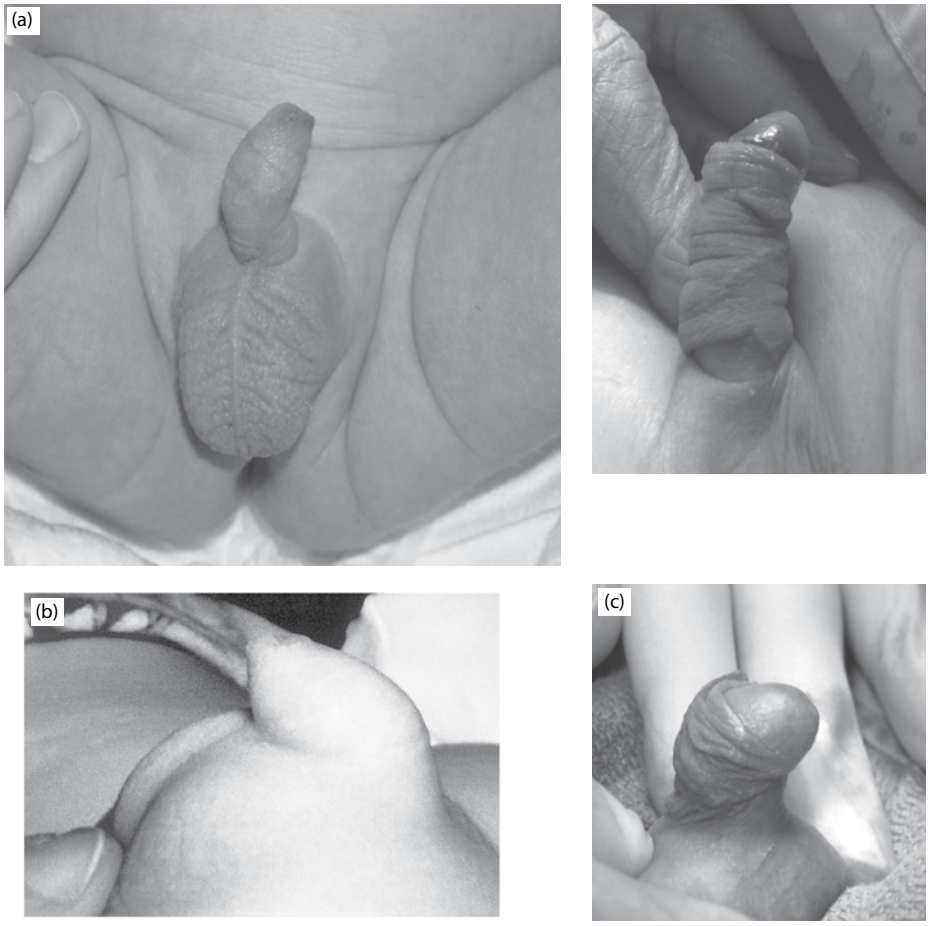

FIGURE 75.4 (a) Penile torsion, (b) Penoscrotal fusion, and (c) Chordee.

is most simply accomplished by preputial unfurling with or without ventral transfer of dorsal preputial skin. If the foreskin is not tight, use of the inner preputial skin for ventral shaft coverage during circumcision may be all that is necessary to correct the defect.

Chordee

Congenital chordee is a varying degree of curvature of the penis that is commonly observed in the presence of hypospadias (Figure 75.4c). It can be observed in 4%–10% of cases in the absence of hypospadias.[58] Ventral curvature is most commonly observed with the proposed mechanisms being related to skin chordee, fibrotic Buck's or dartos fascia, or in the case of lateral chordee, corporal disproportion.[59,60]

Assessment of curvature can be done at the time of repair by placing a fine-gauge needle into one of the corporal bodies and injecting saline to create an artificial erection. Standard repair was described by Nesbit in 1965, which involved degloving of the penis, excision of wedges from the tunica albuginea, and closure of these wedges in a vertical fashion in order to plicate the penis at the point of maximal curvature.[61] Anatomical studies have led to dorsal plication being performed in the twelve o'clock position in order to avoid the nerve fibers coursing along the penile shaft.[62] More recently, techniques using grafts and penile disassembly have been described.[58] However, these studies are small and lack long-term follow-up. For further discussion of chordee, refer to Chapter 73 on hypospadias.

Concealed Penis

An otherwise normal penis that appears to be small is called a concealed, buried, or inconspicuous penis (Figure 75.5).[63] Measurements of stretched penile length and penile diameter are normal. Etiologic factors include a prominent prepubic fat pad, generalized obesity, and/or poor fixation of the subcutaneous tissue of the penis to Buck's fascia. Most commonly, the patient is asymptomatic and spontaneous resolution can be anticipated with change in body habitus at puberty.[64,65] The extent of psychological distress in the untreated patient is unclear, and when surgical intervention is elected, results are poorly documented. Cromie et al.[63] reported prolonged (median 5 years) follow-up, with durable improvement in most cases using a preputial unfurling and degloving procedure similar to techniques used to correct penoscrotal fusion. Others have described simple anchoring of the penopubic skin to the prepubic deep fasica without degloving the penis, with good results.[66] However, the power of the study was low. The use of more complex procedures, such as prepubic liposuction or lipectomy, and closure with Z-plasties or skin flaps not only is rarely indicated but also may cause unnecessary scarring. Many reported early

FIGURE 75.5 Concealed penis in an obese prepubertal boy with normal stretched penile length.

failure in as many as 35% of cases, and long-term results are unknown.[64,67,68]

Micropenis

A penis that measures more than 2 or 2.5 standard deviations below the mean in stretched length for age, but is otherwise normally formed, is called a micropenis.[69,70] In newborns, a stretched length of less than 2.0 cm is considered abnormal. Normal development of the urethra and prepuce implies normal first-trimester development, with impaired penile growth occurring in the second and third trimesters. Cryptorchidism may also be present. The most common etiology is gonadotropin deficiency with or without panhypopituitarism.[69] Other endocrine causes include growth hormone deficiency, testicular dysgenesis or regression, and rarely, 5-alpha-reductase deficiency[298] or partial androgen insensitivity.[299] Micropenis may be present in gonadal determination disorders, such as Kleinfelter's syndrome and XX sex reversal, or in Prader–Willi, Lawrence–Moon–Biedl, Robinow, and other rare syndromes, or it may be idiopathic.[69,70]

Evaluation of patients generally includes karyotype; determination of serum glucose, serum electrolytes, cortisol, and growth hormone levels; and thyroid function tests and pituitary imaging as indicated.[69,70] Testicular function can be determined by measuring serum luteinizing hormone (LH), follicle-stimulating hormone (FSH), and testosterone before and after human chorionic gonadotropin (hCG) stimulation.[71] The dose of hCG is 500–1500 international units (approximately 3000 IU/m^2) every other day for 5–7 days, with serum testosterone measurements before and 24–48 hours after the last dose. Newborns can be evaluated for the normal spontaneous surge in serum gonadotropins and testosterone within the first few weeks of life; absence suggests a central (pituitary or hypothalamic) defect.

After diagnostic studies are complete, androgen stimulation therapy using intramuscular depot testosterone, 25 mg every 3–4 weeks for several months in infants, has been recommended to assess penile growth potential.[69,70] Unfortunately, response to testosterone does not always correlate with adequate penile size in adulthood, and may vary with the etiology of micropenis.[72,73] In this regard, patients with palpable testes[74] and significant response to gonadotropin-releasing hormone (GnRH) and hCG stimulation tests[75] appear more likely to have adequate long-term penile growth. Limited data suggest that treatment with dihydrotestosterone cream may be an effective alternative to parenteral testosterone, particularly in peripubertal males and in some patients who have failed testosterone therapy.[76] In patients with isolated growth hormone deficiency, growth hormone replacement appears to be sufficient for adequate penile growth.[77] Concerns that early androgen therapy might itself limit long-term penile growth potential are not supported by observations of males with early androgen excess syndromes.[78]

Until recently, routine gender reassignment was recommended for patients who showed no penile growth response to testosterone.[69,70] However, the advisability of routine gender reassignment in genetic males with functioning testes has been questioned in other contexts,[28,42–45] and the long-term results of reassignment for micropenis are not known. Adequate sexual functioning and clear male gender identity in adulthood have been reported in some patients raised as males with persistent small penile size in adulthood,[300] but not in others.[73] Additional long-term follow-up data are critically needed to facilitate clinical decision making in these patients. Therefore, gender reassignment should be performed with caution and should be accompanied by expert ongoing patient and family counseling, including a discussion of the risks and benefits of penile reconstruction.

Priapism

Priapism is defined as a prolonged, frequently painful penile erection not sustained by sexual activity. The most common pediatric cause is homozygous sickle cell (SS) disease, but other possible etiologies include other hemoglobinopathies, leukemia, local malignancy, viral infections, pelvic infections or appendicitis, trauma, diabetes, amyloidosis, and Fabry's disease.[79,80] Low-flow priapism (ischemic) is usually present in affected boys with sickle cell disease, while a high-flow state (nonischemic) is typically present in trauma-induced priapism, but may rarely also be present in sicklers.[81,301] The incidence of priapism in males with sickle cell disease is 2%–35%.[82–87,302] The pathophysiology has been thought to be vascular blockage caused by deformed red blood cells, but a component of endothelial inflammatory activation has also been suggested.[88] Stuttering episodes usually lasting less than 24 hours are common in both pediatric and adult patients. Initial episodes may occur in early childhood.

Priapism can be characterized by the site and degree of blood flow or stasis in the erectile tissues. Tumescence is usually limited to the corpora cavernosa but, in some cases, may also involve the corpus spongiosum, a situation termed tricorporeal priapism.[302] Spongiosal involvement, described in postpubertal individuals, is characterized

by a firm, tender, engorged glans. Voiding difficulty may occur in some patients. Studies used to characterize degree of blood flow include analysis of aspirated penile blood, technetium-99m (99mTc) penile flow studies, and color Doppler ultrasonography. However, appropriate radiological support is necessary to perform the latter two imaging studies.

Low-flow priapism is characterized by acidosis, hypercarbia, and hypoxemia on penile blood gas analysis. The usefulness and reliability of penile nuclear scans and Doppler studies in children remain unclear. Miller et al.[85] reported that nuclear scans did not predict outcome in a series of pediatric patients with sickle cell–associated priapism.

In the past, the initial treatment of patients with priapism due to sickle cell disease was hydration, analgesia, and transfusion to achieve a target hemoglobin S concentration of 30% or less.[82,83,85,303] However, in 2003 the Erectile Dysfunction Guideline Update Panel on the management of priapism[89] recommended that intracavernosal treatment should be administered concurrently with the above treatment if the priapism lasts longer than 4 hours. Intracavernosal therapy includes aspiration with irrigation and/or intracavernosal injection of a sympathomimetic drug. Prepubertal boys appear to respond more commonly to medical therapy than older patients.[84] Exchange transfusion has been associated with acute neurologic events characterized by reversible or irreversible cerebral ischemia, termed the ASPEN syndrome (association of sickle cell disease, priapism, exchange transfusion, and neurologic events).[304] Morbidity from this complication may be reduced by gradual or partial exchange transfusion, recognition of prodromal headache, and close monitoring.

With a total lack of response to medical and intracavernosal therapies, the next step should be surgical intervention.[82,85,87,89–91] The older view that surgical intervention in prepubertal patients with sickle cell priapism is unnecessary, if not contraindicated,[303] appears unjustified based on documented erectile dysfunction in boys following prolonged episodes of priapism.[90,92] For low-flow priapism, distal shunts (e.g., Winter, Ebbehoj, and Al-Ghorab procedures) should be attempted prior to proximal shunts (e.g., Quackels and Grayhack procedures), because the distal shunts have fewer complications and are easier to perform.[89,91] These usually produce detumescence. A modification to the Winter's shunt, using a large-bore needle with multiple punctures through the glans into the corpora cavernosa, has been suggested in the pediatric population with good postprocedure potency.[93] Available long-term follow-up data suggest that potency is more commonly preserved in prepubertal patients after episodes of shorter duration and when successful intervention occurs early.[90,94,95]

For the patient with high-flow priapism, diagnosed by history, corporeal aspiration, and blood gas analysis, the Erectile Dysfunction Guideline Update Panel on the management of priapism[89] recommends observation, along with ice packs and site-specific compression, as the initial management. High-flow priapism is not associated with ischemia and will often resolve without treatment.[96] Selective arterial embolization of the ruptured artery is the next step if observation fails or treatment is requested by the patient and/or family.[89,91]

A variety of other treatments have been suggested for patients with sickle cell disease and priapism; however, data are anecdotal or limited. Alpha-adrenergic agents such as etilefrine[97,98] have been given orally or intracavernosally with some success. Detumescence with hydroxyurea has been reported[99] but not confirmed in a large series. Other options include treatment with sildenafil,[100] GnRH analogues,[101] or antiandrogens,[102] but the latter two are not recommended in patients who have not achieved full sexual maturation and adult stature.[89]

Persistent, apparently painless penile erection has also been observed in newborns.[103] This condition resolves spontaneously in 2–6 days with no adverse sequelae. Associated, possibly contributing factors include polycythemia and birth trauma, although many reported cases are idiopathic.

SCROTAL ABNORMALITIES

Two main types of scrotal pathology occur in the pediatric population: the commonly observed acute swelling of a normal scrotum (discussed under the "Inguinoscrotal Disease" section) and the rare abnormalities of scrotal development.

Defects of Number or Position

Scrotal Agenesis

Complete absence of the scrotum is an extremely rare anomaly, with only six reported cases in the modern literature.[104–106,305] One case of hemiscrotal agenesis has also been reported.[305] Localized androgen insensitivity, localized 5-alpha-reductase deficiency, or labioscrotal fold formation failure have all been suggested etiologies for this condition.[305] The penis was normal in all the cases, the perineum was smooth with a median raphe present, and both testes were superior to the expected scrotal site. Successful repair using preputial skin was performed.

Accessory Scrotum

Ectopic scrotal tissue in addition to a normally developed scrotum is designated accessory scrotum or, in females, accessory labioscrotal fold. This anomaly is very rare, with just over 30 cases identified in the literature.[107,108] The accessory tissue is located on the perineum in the majority of cases and associated with a perineal lipoma and no other genitourinary anomalies. A case of isolated penile accessory scrotum has also been reported.[109] In the absence of a perineal lipoma, accessory perineal scrota are usually associated with other anomalies, including hypospadias, diphallia, defects of scrotal position, anorectal anomalies, and the VACTERL (vertebral, anal, cardiac, tracheoesophageal, renal, and limb anomalies) association.[306] Sule et al.[107] hypothesize that when present, the lipoma disrupts the continuity of the developing labioscrotal fold, and the etiology in other cases is generalized perineal maldevelopment.

Ectopic Scrotum

Ectopic positioning of the scrotum is usually unilateral, with the ectopic tissue usually suprainguinal but in

some cases infrainguinal (femoral) or on the thigh.[110–112] The ipsilateral testis is usually present within the ectopic hemiscrotum, although associated cryptorchidism has been reported. Ipsilateral renal and ureteral anomalies are common, so patients should be evaluated for upper tract anomalies. Associated skeletal defects, penile torsion or chordee, hypospadias, and cleft palate have also been reported. Chowdhary et al.[113] reported a case associated with a patent urachus. The etiology is uncertain, but may be related to a gubernacular defect failure of migration of the labioscrotal fold, or fetal deformation secondary to limb compression (foot). Treatment is generally simply achieved by flap scrotoplasty and orchidopexy.

Bifid Scrotum

Incomplete fusion of the labioscrotal folds may produce a partial or complete separation of otherwise normally positioned hemiscrota in patients with severe hypospadias or chordee. The defect may be corrected by excision of the abnormal tissue and creation of a new scrotal raphe with reapproximation of the hemiscrota in the midline.

Penoscrotal Transposition

In cases of penoscrotal transposition, part or all of the scrotum is located superior to the penile shaft. The spectrum of findings ranges from a normal-sized penis with confluent scrotal tissue both anterior and posterior (shawl or doughnut scrotum) to complete transposition of a rudimentary penis to the perineum behind an intact scrotum, a phenotype similar to that of penile agenesis.[114] The posterior aspect of the scrotum may be bifid and/or hypoplastic, and hypospadias and chordee are frequently present (Figure 75.6). However, multiple other anomalies of diverse organ systems have also been identified. These include renal, central nervous system (CNS), developmental, gastrointestinal, respiratory, limb, vertebral, cardiovascular, facial, and ocular anomalies.[114] Three types of chromosomal defects have been identified: trisomies 8 and 18, and distal deletions of the long arm of chromosome 13.[115] Correction of the defect may be performed during or subsequent to hypospadias repair by mobilization of the anteriorly placed scrotal skin with ventral transposition and closure, as described by Glenn and Anderson.[116] In some cases, ventral penile tethering may occur postoperatively that may be corrected by interposition of thigh-based neurovascular flaps.[117]

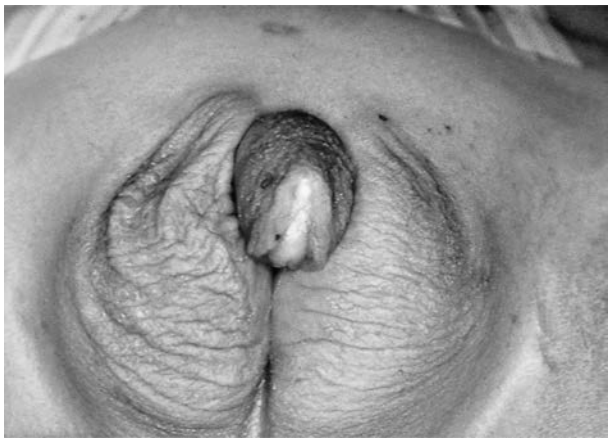

FIGURE 75.6 Partial penoscrotal transposition and bifid scrotum in a patient with proximal hypospadias.

Median Raphe Cysts

Midline cysts may arise anywhere along the median raphe between the urethral meatus and anus.[118,307,308] Their origin is believed to be epithelial or endothelial rests trapped in an aberrant subcutaneous location during developmental approximation of the urethral and genital folds. They may be large and elongated and appear translucent. Histologically, they are lined with cuboidal or squamous epithelium and contain sebacious material. Rarely, the proximal portion of the cyst may traverse the urogenital diaphragm and extend into the pelvis. Magnetic resonance imaging may be useful to define the extent of the lesion preoperatively if pelvic extension appears likely. Treatment is complete excision of the cysts with midline closure.

Inguinoscrotal Disease

Varicocele

Population studies have confirmed the observation that a varicocele first becomes clinically evident between the ages of 10 and 15 years,[309] and once a varicocele is present, it will normally persist for the remainder of that individual's life.[119] The varicocele that has its origin in adolescence may be a major cause of infertility in adults. However, if one waits until adulthood to treat varicocele-induced infertility, success is unlikely for the majority of men.[120] Because of this experience, recent efforts have focused on identifying teenagers with an asymptomatic varicocele in an attempt to identify individuals at risk, intervene earlier, and hopefully improve results. Although this approach seems reasonable, the problem for the clinician has been establishing uniform criteria for treatment. The observation that a varicocele occurs in 15% of men adds to the difficulties in deciding when treatment is indicated. Do we treat all men with a varicocele or just selected ones?

The vast majority of teenagers with a varicocele are discovered during a routine school physical, are asymptomatic, and are unaware of the presence of the varicocele. As a consequence, most of the teenagers identified with a varicocele have a grade II (mass or veins 1–2 cm in diameter) or grade III (large mass or veins easily visible and greater than 2 cm in diameter) varicocele. A child with a small varicocele (veins 1 cm or less in diameter) can only be detected by a skilled examiner, and most will escape early detection. No investigators have reported using color Doppler ultrasound to detect a subclinical varicocele in a teenager, and therefore this entity appears to have no clinical significance in the teenage population at the current time.

Since most teenagers with a varicocele are detected during a routine physical examination by a primary care physician, it is reasonable to assume that a teenager with a large varicocele is more likely to be diagnosed. Dubin and Amelar[121] concluded that the size of a varicocele was not a significant fertility variable. However, Fariss

et al.[122] and coworkers demonstrated that in adult men found to have a varicocele on routine physical examination, there was a greater chance of a man with a large varicocele having a sperm count of less than 20 million/mL than a man with a small varicocele. Several other studies have reported that in men with a large varicocele, there is greater impairment in semen parameters.[123,124,310] Steeno et al.[309] noted that with increasing varicocele size, there was progressively more volume loss of the testis ipsilateral to the varicocele. Other studies[311] have also demonstrated lower testicular volumes in men with a large varicocele than those with a small one. This loss of testicular volume may be significant because the seminiferous tubules comprise greater than 50% of the testicular mass, and in adult men, total sperm count correlates with testicular volume.[125,312] Therefore, it is reasonable to conclude that an individual with a large varicocele may be at greater risk for testicular injury.[126]

The mechanism by which a varicocele induces testicular injury is still unresolved, although many theories have been proposed. Investigators have also noted that a varicocele, both clinically and experimentally, results in an increase in scrotal and testicular temperature.[127] An increase in testicular temperature has been shown to be toxic to the testis in humans, as well as other mammals with scrotal testes.[128,129,313] Agger[130] reported that following varicocele correction, there was a good correlation between the fall in left testicular temperature and the improvement in spermatogenesis. Kass and Salisz[131] measured scrotal temperatures in adolescents with grade II and III varicoceles and reported that there was a significant bilateral elevation in scrotal temperature when compared with control subjects without a varicocele. They also noted that the higher the left scrotal temperature, the greater the volume loss of the left testis. Following successful varicocele correction, scrotal temperature normalized.

In an infertile adult male with a unilateral left varicocele, abnormal testicular histology can be demonstrated in both testes and involves all cell types, although the changes are typically more pronounced in the left testis (Figure 75.7).[132–134] Similar histopathology has been demonstrated bilaterally in the adolescent with a unilateral varicocele, but the abnormalities are less severe.[135,136] It is important to note that while the pathologic changes in the seminiferous tubules, blood vessels, and Sertoli cells are present to varying degrees in infertile men with a varicocele, the relative severity of the abnormality in these cell types is not the key prognostic variable. Investigators have reported that it is the severity of the Leydig cell pathology that is most significant in determining the potential for reversibility of the varicocele-induced testicular injury.[137] Luo et al.[138] showed apoptosis and suppression of StAR mRNA as the process through which Leydig cell injury occurred, which, in turn, caused a significant decrease in the intratesticular testosterone levels.[138] Individuals with Leydig cell hyperplasia have a very poor prognosis, while those with Leydig cell atrophy have a better prognosis for fertility following varicocele correction. The prognosis for return of fertility is independent of the degree of tubular pathology and more likely dependent on the pathologic changes in the Leydig–Sertoli cell interrelationship.[139] Hadziselimovic et al.[140] reported that Leydig cell atrophy was the predominant pathologic finding on testicular biopsy in teenagers undergoing varicocele surgery (74%) when compared with adults in whom Leydig cell hyperplasia was more common. These various histologic studies taken as a whole suggest that varicocele-induced histologic abnormalities occur in adolescents and are progressive. The pathology is potentially reversible early on, but once Leydig cell hyperplasia is present, surgical correction of the varicocele will be unlikely to have beneficial effects.

Varicoceles also induce endocrinologic abnormalities that parallel the histopathology. Weiss et al.[141] measured the in vitro synthesis of testosterone from testicular biopsy material and noted that there was a significant reduction in testosterone formation in 90% of infertile men with a varicocele. In these same individuals, peripheral levels of testosterone and LH were normal. Other investigators have also reported significant varicocele-induced Leydig cell dysfunction and noted that the abnormalities are progressive.[142,143,314] Furthermore, several studies show improved testosterone levels in adult men after varicocelectomy, possibly adding another indication for varicocele repair.[144,145]

An exaggerated gonadotropin response to the administration of GnRH has been demonstrated in infertile men with a varicocele and is thought to be the result of a primary testicular injury. The excessive release of LH following GnRH stimulation is an indicator of Leydig cell dysfunction, and the exaggerated FSH response is an indicator of an abnormality of the seminiferous tubules. Nagao et al.[146] measured the response to GnRH stimulation and noted that semen and hormonal abnormalities can be observed in both fertile and infertile men with a varicocele, suggesting that there may be some degree of testicular dysfunction in all men with a varicocele, regardless of their fertility status. They suggested that perhaps with increasing age, the varicocele-induced testicular injury could become clinically evident in more men. Several investigators[147–151] demonstrated that the excessive gonadotropin response to GnRH stimulation in infertile men was reversible after varicocele correction only in those individuals whose spermiograms also improved. Individuals who did not demonstrate an improved postoperative gonadotropin

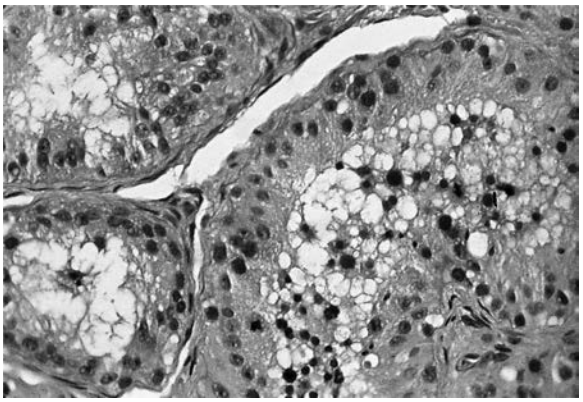

FIGURE 75.7 Testicular histology in a patient with a varicocele showing Sertoli only tubules and severe maturation arrest. Only 25% of tubules were normal in this patient (× 250).

response pattern did not show any improvement in their spermiogram.

The gonadotropin response to GnRH stimulation has been shown to be a useful diagnostic tool for evaluating testicular function in teenagers.[152,153] Kass et al.[154] measured the gonadotropin response pattern to GnRH stimulation in adolescent males with a varicocele and compared it with that of a group of normal teenagers without a varicocele. They noted that an abnormal gonadotropin response was present in almost one-third of teenagers with a varicocele, and that this test may be useful in identifying those varicocele patients with early evidence of testicular injury.

Barwell (1885)[155] was the first to report volume loss of the testis ipsilateral to a varicocele in a teenager, and noted that the testis "became harder and regained some of its dimensions" following surgical correction. In adult men with infertility, both testes tend to be smaller than those of aged-matched control groups without a varicocele. Kass and Belman[156] performed varicocele ligation on adolescent males with grade II or III left-sided varicocele and volume loss of the left testis. Significant catch-up growth of the left testis was noted in 80% of patients. Subsequent studies have confirmed their findings and indicate that a varicocele can be responsible for testicular growth retardation, and early successful correction can reverse this process.[157–160] In the majority of adolescents with a varicocele, testicular volume loss is the most common indication of testicular injury, and therefore the most significant indication for intervention. Normal testicular size correlates with stage of sexual maturity.[161,162] Testicular volume progressively increases from approximately 4 to 25 mL during pubertal development, making it difficult to calculate a normal testis volume in any individual before adulthood. A 20% volume loss on the ipsilateral side of the varicocele has traditionally been considered significant testicular volume loss (Figure 75.8). However, Li et al.[163] have shown that surgical intervention may reduce testicular hypotrophy for adolescent boys with a 10% size discrepancy. Fairly accurate testicular volume measurements are possible with a standard Prader orchidometer (Figure 75.9), but more accurate measurements may be possible with scrotal ultrasound using the Lambert (Length × Width × Height × 0.71) or Hansen (Length × Width × Height × 0.52) formula adjustments.[164] However, scrotal ultrasound is very dependent on the technician performing the study.

FIGURE 75.8 Left testicular volume loss in a patient with a left varicocele.

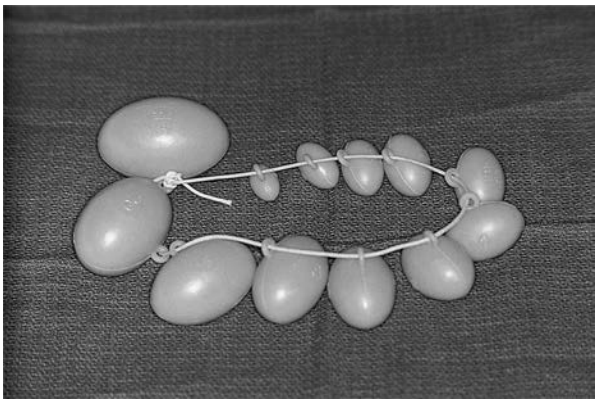

FIGURE 75.9 Prader orchidometer.

In adults with a varicocele, the assessment of a semen sample is a reasonable first step in the evaluation process since there are established normal parameters. Unfortunately, in adolescents it is often difficult to obtain such samples, and even when available, normal adult values for semen volume, spermatozoa concentration, and morphology are not achieved until 2–3 years after the onset of puberty.[165] It is important to remember that a single normal semen analysis does not predict future normality, since the effect of a varicocele may increase with time.[132] Although semen analysis is not practical in the adolescent population, at least one report has shown improvement in semen parameters after adolescent varicocele repair.[166] The establishment of normal semen analysis controls in the adolescent population and more routine use of this measure of the effects of varicocele could be useful in determining the need for surgical intervention. It is recommended that every adult with a palpable varicocele should have a semen analysis on an annual basis until the completion of his family in order to ensure that abnormalities do not develop.

Current data indicate that it is important to identify and evaluate all teenagers with a varicocele. Certainly no one can predict with absolute certainty whether any adolescent with a varicocele will be fertile or infertile; however, based on existing information, it can be expected that many will develop a fertility problem that becomes progressive if left untreated.[167–169] Individuals with volume loss of the testis ipsilateral to the varicocele appear to have a greater likelihood of having a normal semen analysis if treated as a teenager than if left untreated.[170,171,315] Similarly, individuals with large varicoceles may be at future risk for developing testicular volume loss and abnormal semen parameters. Although there are concerns that an abnormal GnRH stimulation test may be associated with similar long-term risks,[172] that hypothesis is not generally accepted as an indicator for intervention when other parameters are normal. Similarly, it is unclear whether intervention in otherwise normal individuals with bilaterally palpable varicoceles or scrotal discomfort is reasonable, and should be considered routine. Persistently abnormal semen parameters in older teenagers and adults are of significant concern and should be considered an indication for intervention.

Multiple techniques have been proposed for correction of a varicocele in a teenager.[173,174] Selective transvenous embolization of the internal spermatic vein[175–177,316] is a complex, invasive procedure with a significant recurrence and nonocclusion rate. Conventional inguinal[178] and retroperitoneal approaches with attempted preservation of the testicular artery are simple and relatively complication-free procedures but have an unacceptably high risk for failure.[179] Current data suggest that the above techniques are not the best choice for varicocele correction in teenagers. The Palomo technique,[180] with mass ligation of the internal spermatic vessels,[178,179,181–183,317] and the inguinal[184] or subinguinal approach,[185] with microscopic ligation[186–188] of all venous channels, are the procedures with the highest success rates and fewest complications, and are the procedures of choice for varicocele correction in teenagers. Secondary hydrocele may occur in 30% of patients undergoing mass ligation of the spermatic vessels, but only 5% of these patients require further surgical intervention.[189] Also, potential risk for testicular atrophy, should vasectomy be carried out in the future, must be considered. However, preservation of a single lymphatic vessel may prevent hydrocele. Laparoscopic ligation[190–194] of the spermatic vessels can also be done with good success (Video 75.1). This procedure requires intubation and bladder catheterization, and has the rare potential for significant intra-abdominal complications. However, the use of isosulfan blue injected into the scrotum can allow a lymphatic-sparing procedure to be performed, decreasing the hydrocele rate observed with the traditional Palomo varicocelectomy.[195]

Acute Scrotal Disease

Testicular torsion must be considered in any patient who complains of acute scrotal pain and swelling. Torsion of the testis is a surgical emergency because the likelihood of testicular salvage decreases as the duration of torsion increases. Conditions that may mimic testicular torsion, such as torsion of a testicular or epididymal appendage, epididymitis, trauma, hernia, hydrocele, varicocele, and Henoch–Schonlein purpura, generally do not require immediate surgical intervention. The cause of an acute scrotum can usually be established based on a careful history, a thorough physical examination, and appropriate diagnostic tests. The onset, character, and severity of symptoms must be determined. The physical examination includes inspection and palpation of the abdomen, testis, epididymis, scrotum, and inguinal region. Urinalysis should always be performed, and scrotal imaging is necessary when the diagnosis remains unclear.

History

The history and physical examination can significantly narrow the differential diagnosis of an acute scrotum. Testicular torsion is most common in neonates and postpubertal boys, although it can occur in males of any age. Henoch–Schonlein purpura and torsion of a testicular appendage typically occur in prepubertal boys, whereas epididymitis most often develops in postpubertal boys.

Testicular torsion usually begins abruptly in the early morning, and the pain is often severe from the onset. Moderate pain developing gradually over several hours or days is more suggestive of epididymitis or appendiceal torsion.

A history of scrotal trauma is common and does not exclude the diagnosis of testicular torsion. Minor scrotal trauma incurred during sports activities or rough, boisterous play typically causes severe pain of short duration. Pain that persists for more than 1 hour after scrotal trauma is not normal and merits investigation to rule out testicular rupture or acute torsion. Pain that resolves promptly after scrotal trauma only to recur gradually a few days later suggests traumatic epididymitis.

Many patients with testis torsion describe previous episodes of similar pain that lasted for only a short time and resolved spontaneously. Acute on-and-off pain associated with or without scrotal swelling suggests intermittent torsion with spontaneous detorsion. Voiding dysfunction, congenital genitourinary anomalies, and urethral instrumentation can predispose patients to bacterial UTIs and secondary epididymitis.

Physical Examination

A general abdominal examination should be performed, with particular attention given to flank tenderness and bladder distention. The inguinal regions should be examined for obvious hernias, swelling, or erythema. The spermatic cord in the groin may be tender in a patient with epididymitis, but typically is not tender in a patient with acute testicular torsion.

The scrotum should be assessed for discrepancies in size, degree of swelling, presence and location of erythema, thickening of the skin, and position of the testis. Unilateral swelling without skin changes suggests the presence of a hernia or hydrocele. A high-riding testis with an abnormal (transverse) lie may suggest torsion (Figure 75.10a), but this diagnosis is unlikely if the pain has been present for more than 12 hours and the scrotum has a normal appearance. In both epididymitis and testicular torsion, the affected hemiscrotum typically displays significant erythema and swelling after 24 hours.

The cremasteric reflex should always be assessed. One study[196] found that the cremasteric reflex was intact in 100% of boys aged 30 months to 12 years but was not consistently normal in infants and teenagers. The cremasteric reflex is rarely intact in patients with testicular torsion but is usually present in patients with torsion of a testicular or epididymal appendage.[318]

In early torsion, the entire testis is swollen and tender, and is larger than the unaffected testis. Tenderness limited to the upper pole suggests torsion of a testicular appendage, especially when a hard, tender nodule is palpable in this region. A small bluish discoloration representing the necrotic torsed appendage, known as the "blue dot sign," may be visible through the skin at the upper pole. This sign is virtually pathognomonic for appendiceal torsion when tenderness is also present. In early epididymitis, the epididymis exhibits tenderness and induration, but the testis itself is not tender. Swelling to the degree that the epididymis is no longer palpable can indicate testis torsion if the symptoms have been present for only a few hours. With both appendiceal torsion and epididymitis, loss of testicular

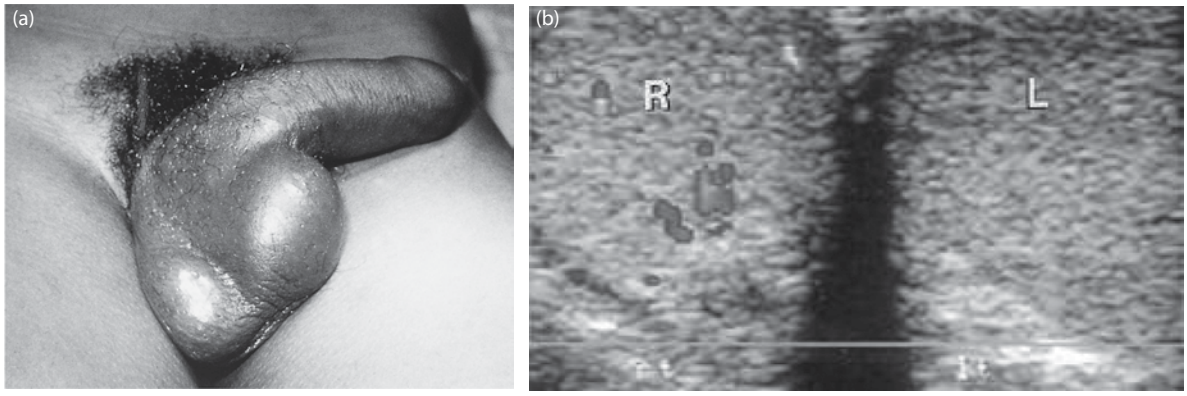

FIGURE 75.10 (a) High-riding, swollen left testis in a patient with acute spermatic cord torsion. (b) Ultrasound showing flow in right testicle and lack of flow in left testicle.

landmarks occurs later in the clinical course. The testis may be elevated to elicit Prehn's sign. Lack of pain relief (negative sign) may contribute to the diagnosis of testicular torsion. If torsion is suspected, manual detorsion can be attempted by rotating the testis away from the midline.

Diagnostic Studies

Urinalysis is performed to rule out UTI in any patient with an acute scrotum. Pyuria with or without bacteruria suggests infection and is consistent with epididymitis.

Historically, it was thought that no imaging studies were useful in confirming the cause of an acute scrotum. Immediate surgical exploration was thus the standard approach when torsion was suspected. However, studies conducted in the past few years have shown that only 16%–42% of boys with an acute scrotum have testicular torsion.[197–200] Therefore, routine exploration of all children is not reasonable if tests are available to improve diagnostic accuracy.

Initially, Doppler stethoscopes and conventional gray-scale ultrasonography were used to diagnose or exclude the presence of torsion, but these tests lack sensitivity and specificity.[201] Nuclear testicular flow studies are helpful, and when performed by experienced personnel, they can reliably identify children with torsion, epididymitis, and late torsion. However, since it is strictly a blood flow study, a testicular scan is not helpful when a hydrocele or hematoma is present because these conditions may mimic the findings of torsion. In addition, it is of critical importance to localize the exact position of the testis; otherwise, no reliable test is possible. In addition, most centers do not have personnel experienced in the performance or interpretation of nuclear medicine scrotal scans.

Color Doppler sonography has become the most popular diagnostic modality to evaluate a child with an acute scrotum because it is noninvasive and has a diagnostic accuracy at least equal to that of nuclear scanning. It can semiquantitatively characterize blood flow, distinguish intratesticular and scrotal wall flow, and also be used to assess other pathologic conditions involving the scrotum (Figure 75.10b).[202–204] Proper technique is essential. When color Doppler examinations are not performed correctly, false-positive or false-negative studies may occur. Certain caveats are important to remember. It may not be possible to demonstrate a Doppler signal in the small testes of very young boys. Just seeing color dots does not mean that flow is present; one must see a waveform within the substance of the testis. Reduced flow in a painful testis relative to the normal testis may indicate torsion, and exploration is indicated.

Spermatic Cord Torsion

The suggested protocol for the evaluation of a child with an acute scrotum (Figure 75.11) states that when the history and physical examination strongly suggest that testicular torsion is present and the duration of the pain is less than 12 hours, urgent surgical intervention is indicated.[205] With the widespread availability of color Doppler ultrasound, prompt triage and ultrasound can be performed without significant delay in treatment. When pain has been present for more than 12 hours or the diagnosis is unclear, ultrasound examination can be equally as helpful in making clinical decisions. It is important to remember that most patients with an acute scrotum do not have testicular torsion.

The "bell clapper" deformity is the underlying cause of testicular torsion in older children. In this deformity, the testicle lacks a normal attachment to the tunica vaginalis and therefore hangs freely. As a result, the spermatic cord can twist within the tunica vaginalis (intravaginal torsion).

Surgery is performed to correct torsion in the affected testis and to anchor the other testis to prevent future torsion. Surgical exploration can usually be accomplished through a single, small, midline incision in the scrotal raphe. Testes that are unequivocally necrotic should be removed. Viable testes should be fixed to the scrotal wall with multiple nonabsorbable sutures.

Testicular torsion can also occur perinatally before the entire testis complex has fused to the scrotum. In this type of torsion, the testis, spermatic cord, and tunica vaginalis twist en bloc (extravaginal torsion) (Figure 75.12). Clinically, extravaginal torsion generally appears as a hard asymptomatic intrascrotal swelling in the newborn. Erythema or a bluish discoloration of the scrotum is also frequently seen and may be confused with a hydrocele.

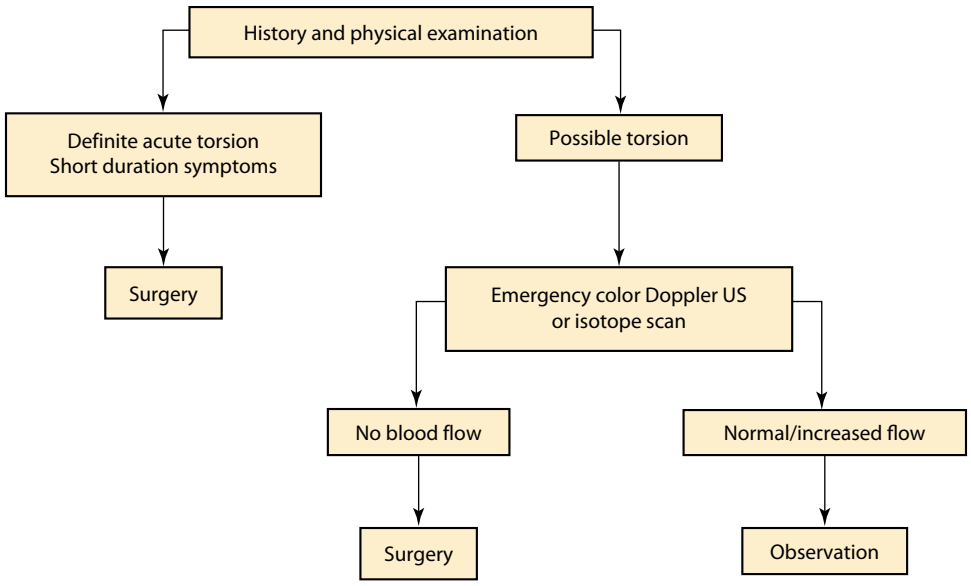

FIGURE 75.11 Algorithm for evaluation and treatment of patients with acute scrotal pain. (US = ultrasonography.)

The management of perinatal torsion remains controversial. Some surgeons advocate a nonoperative approach because of the poor potential for testicular salvage. Others argue that leaving a neonatal testis in place may have adverse effects on the contralateral testis and note that cases of bilateral neonatal torsion have been reported.[206] Also controversial is the question as to whether the remaining solitary testis should be fixed in place, although risk of torsion of that testis is no greater than that for the general (adult) population.

Torsion of an Appendix of the Testis or Epididymis

The appendix testis, a Mullerian duct remnant located at the superior pole of the testicle, is the most common appendage to undergo torsion (Figure 75.13). The epididymal appendix, located on the head of the epididymis, is a Wolffian duct remnant and may also become twisted. Torsion of either appendage produces pain similar to that experienced with testicular torsion, but the onset is more gradual. The cremasteric reflex is not lost with torsion of an appendage. Color Doppler ultrasonography often demonstrates increased blood flow that may be indistinguishable from epididymitis. Occasionally, a hypoechoic mass near the upper pole of the testis, the torsed appendage, may be visualized.

Torsion of a testicular appendage may be misinterpreted as epididymitis. However, if the urinalysis is

FIGURE 75.12 Extravaginal torsion (twisted cord – arrow).

FIGURE 75.13 Torsion of appendix testis (arrow). Note accompanying enlargement and hyperemia of the epididymis.

normal, no antibiotic therapy is required. Management entails symptomatic treatment to minimize inflammation and edema. Normal activity may both worsen and prolong the symptoms. Nonsteroidal anti-inflammatory drugs (NSAIDs) may offer symptomatic relief to some patients. The inflammation usually resolves within 1 week, although the testicular examination may not be completely normal for several weeks, with induration in the region of the head of the epididymis persisting for that interval.

Epididymitis or Orchitis

Epididymitis in adolescents and young adults is often unrelated to sexual activity and does not present with a UTI. In prepubertal boys, however, bacterial epididymitis is often associated with a urinary tract anomaly.[319] Any episode of epididymitis and UTI should be investigated with a renal bladder sonogram and a voiding cystourethrogram (VCUG) to rule out structural problems. However, the cause of epididymitis in the majority of young men can often not be determined.

Treatment includes empiric antibiotic therapy until the results of a urine culture are known. If the culture is negative, the symptoms are most likely to be due to abacterial chemical epididymitis caused by the retrograde reflux of urine into the vas deferens. Bed rest and scrotal elevation are often helpful. Symptoms may be alleviated with NSAIDs and analgesics. As with appendiceal torsion, the pain and swelling generally resolve within 1 week. Resolution of epididymal induration may require several weeks (Figure 75.14).

Scrotal Trauma

Severe testicular injury is uncommon and usually results from either a direct blow to the scrotum or a straddle injury. Damage generally occurs when the testis is forcefully compressed against the pubic bones. A spectrum of injuries may occur. Traumatic epididymitis is a noninfectious inflammatory condition that usually occurs within a few days of a blow to the testis.[207] Treatment is similar to that of nontraumatic abacterial epididymitis. Scrotal trauma can also result in intratesticular hematoma, hematocele, or laceration of the tunica albuginea (testicular rupture). Color Doppler ultrasonography is the imaging technique of choice (Figure 75.15). Testicular rupture is a surgical emergency requiring debridement of devascularized tissue and closure of the tunica albuginea. Isolated hematomas and hematoceles are managed on an individual basis.

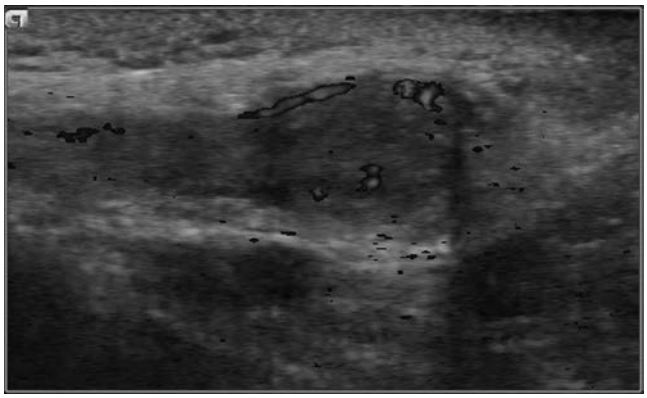

FIGURE 75.14 Epididymo-orchitis: Color Doppler ultrasound showing increased flow to a heterogeneous left testis and enlarged epididymis.

Lacerations of the scrotum itself are a fairly common occurrence in active boys, usually the consequence of bicycle accidents or getting caught on a fence. Most are superficial and do not involve the tunica vaginalis, requiring only minor suturing with sedation and local anesthesia. Deeper injuries may require a trip to the operating room.

Other Acute Scrotal Disease

Acute idiopathic scrotal edema is another cause of an acute scrotum (Figure 75.16). This condition is characterized by the rapid onset of significant edema without tenderness. Erythema may be present. It typically occurs in boys between the ages of 5 and 10, and can relapse in 20% of patients.[208] The patient is usually afebrile, and all diagnostic tests are negative. The etiology of this condition remains unclear. Treatment consists of bed rest and scrotal elevation. Analgesics are rarely needed.

Henoch–Schonlein purpura, a systemic vasculitic syndrome of uncertain etiology, is characterized by nonthrombocytopenic purpura, arthralgia, renal disease, abdominal pain, gastrointestinal bleeding, and occasionally, scrotal pain and swelling.[209] The onset can be acute or insidious. Hematuria may be present. The syndrome has no specific treatment.

The overriding need in the child with scrotal edema is to rule out testicular pathology. Color Doppler sonography may be helpful, but it may also be possible to make this determination clinically. If the testes can be manipulated gently into the superficial inguinal pouches and palpated, their noninvolvement in the inflammatory process may be proven and no further diagnostic studies need be carried out.

Hernia and Hydrocele

Inguinal hernia and hydrocele in childhood are most commonly due to patency of the processus vaginalis, an extension of the peritoneum that forms in the first trimester in proximity to the gubernaculum of both sexes.[210] In males, the processus vaginalis migrates distally through the inguinal canal with the masculinized gubernaculum, facilitates descent of the testes, persists distally as the tunica vaginalis, and normally becomes obliterated proximally. In females, the processus vaginalis develops but does not enlarge substantially. In both sexes, failure of closure of the processus creates a potential site for clinical hernia formation, characterized by passage of fluid or intra-abdominal viscera into the persisting sac.

The timing of closure of the processus vaginalis and its relationship to clinical hernia formation can be inferred from data obtained at autopsy, inguinal exploration, and intraoperative laparoscopy, and from studies of patients requiring ventriculoperitoneal shunts. These studies suggest that the processus is open in more than 80% of individuals at birth, and closure is most common in the

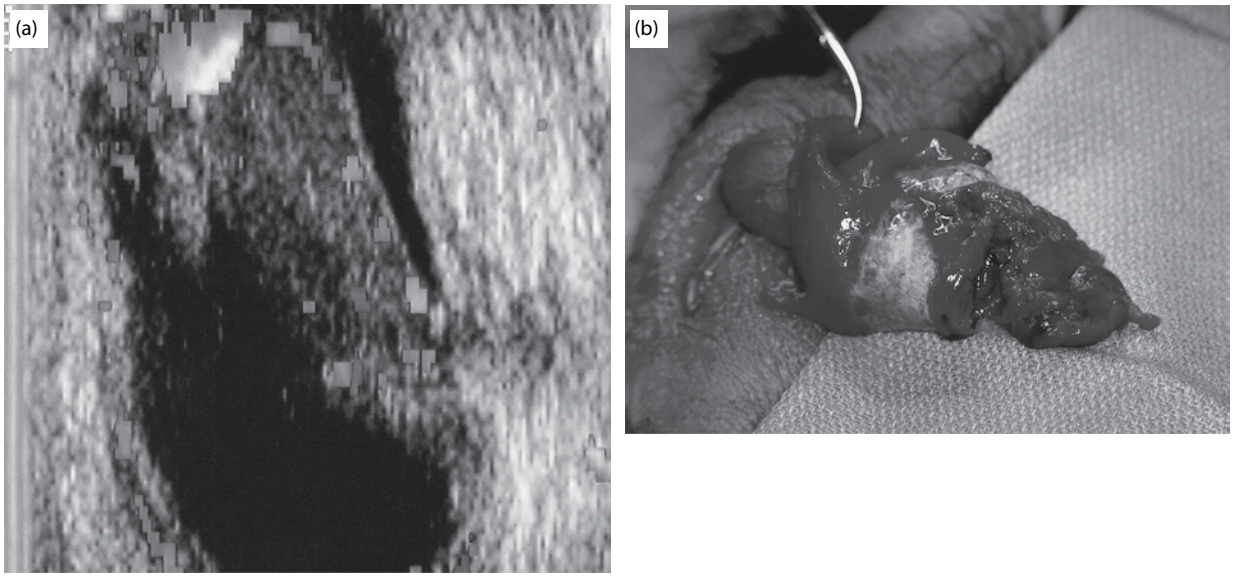

FIGURE 75.15 Testicular trauma: (a) color Doppler ultrasound showing discontinuity of testis and anechoic area at site of hematoma (asterisk); (b) intraoperative photograph showing disrupted testis with hematoma.

first year of life but may occur much later. Patency persists in 15%–30% of adults.[211,320] However, clinical hernias develop in fewer than 30% of newborns and 10% of 1-year-olds after placement of a ventriculoperitoneal shunt.[212] Similarly, contralateral patency of the processus vaginalis has been reported to be as high as 40%–50% of children with unilateral inguinal hernias.[213] However, only 7% of children who undergo unilateral hernia repair subsequently develop a clinical hernia on the opposite side.[214] Therefore, not all potential hernias manifest themselves clinically, even in the presence of increased intra-abdominal pressure.

FIGURE 75.16 Idiopathic scrotal edema.

The incidence of pediatric hernia is 10–20 per 1000 and is greater in premature infants (7%), in males (85% of total), and in the first 6 months of life (30% of total).[211,320] Clinical hernias are more frequent on the right side and are bilateral in approximately 10% of both male and female children. Incarceration occurs most frequently in the first year of life. Patients may present with an inguinal bulge and/or enlarged scrotum or labium, irritability, vomiting, and obstipation. In the absence of incarceration, a hernia may be diagnosed during the Valsalva maneuver (crying or blowing up a balloon) or by observation of inguinal asymmetry and palpable thickening of the spermatic cord distal to the external ring. These findings may be facilitated by examining the patient in the upright position. The spectrum of anatomic findings is shown in Figure 75.17.

Surgical repair is indicated when the clinical history and physical findings suggest visceral involvement or when fluctuation in size is observed. Prompt repair is also advised in infancy to reduce the risk of incarceration. If an incarcerated hernia requires reduction, surgical repair should be urgent, or emergent, if peritoneal signs suggest that bowel strangulation is present. The question of contralateral inguinal exploration at the time of repair of the symptomatic hernia is controversial. Some surgeons base their decision on laparoscopic evaluation of the contralateral internal ring.[213] However, while this may reduce the incidence of routine inguinal exploration, the data cited above suggest that the majority of patent processus vaginales will remain asymptomatic. Routine contralateral exploration may be reasonably limited to situations associated

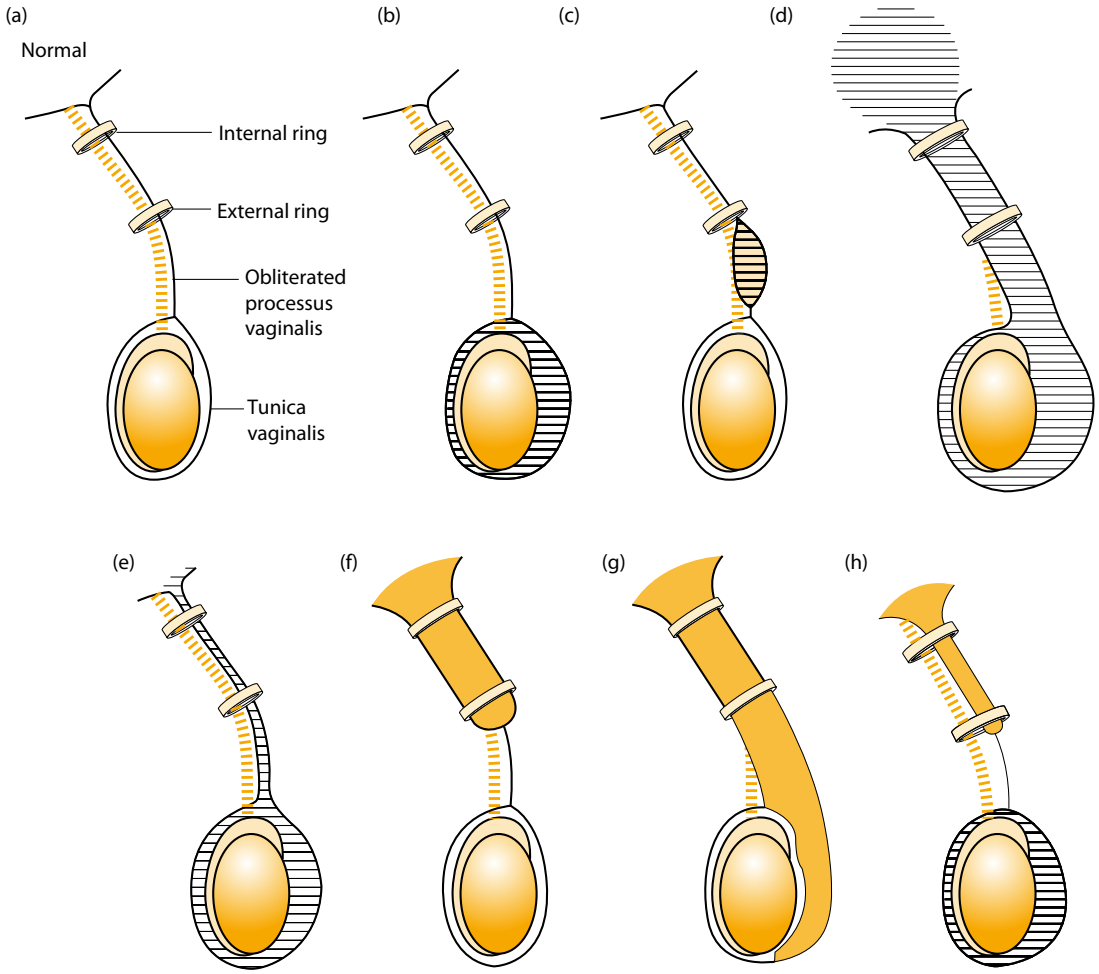

FIGURE 75.17 Possible findings in patients with hernia and/or hydrocele. Hatched black areas represent fluid and dark orange areas represent intra-abdominal contents: (a) normal findings; (b) scrotal hydrocele without hernia; (c) hydrocele of the cord; (d) abdominoscrotal hydrocele; (e) communicating hydrocele; (f) inguinal hernia; (g) inguinoscrotal hernia; (h) inguinal hernia and scrotal hydrocele.

with a higher risk for metachronous hernia and/or morbidity, such as age less than 1 year, history of prematurity, and increased abdominal pressure from shunts, dialysis, or ascites.

Principles of repair include a small, transverse incision over the inguinal canal, isolation of the sac with minimal handling of cord structures, reduction of any abdominal viscera, and high ligation of the hernia sac. Formal repair of the internal ring or floor of the canal is rarely needed in children. Generous windowing of an undrained hydrocele, which may be loculated, should be performed after transection and ligation of the hernia sac. The testis should be replaced in its normal position in the scrotum.

Scrotal hydroceles without associated patency of the processus vaginalis are common in newborns and may be quite large. Diagnosis is made by transillumination, and the inability to reduce the mass, forcing the fluid back into the peritoneal cavity, rules out hernia. Most resolve spontaneously, and treatment is not recommended.

Persistence of a simple scrotal hydrocele beyond 18 months of age may be an indication for surgical correction. However, there is no evidence that a simple hydrocele risks testicular damage. Treatment is generally cosmetic, although some boys will complain of discomfort if the mass is particularly large.

Fluid may also be trapped within the tunica vaginalis of the spermatic cord. The diagnosis is made by identifying a nondecompressible, transilluminatable mass above and separate from the testis.

Treatment of simple hydroceles or hydroceles of the cord is similar to that in adults; however, an inguinal approach is recommended to rule out associated patency of the proximal tunica vaginalis at the level of the internal inguinal ring. Excision or plication of the enlarged tunica vaginalis is generally effective.[215]

Finally, hydroceles may occur acutely following minor scrotal trauma or a viral illness associated with coughing or vomiting. The acute rise in intra-abdominal pressure associated with coughing or vomiting may force peritoneal fluid through a minimally patent processus vaginalis. Many of these will resolve spontaneously, and a period of observation for several weeks before recommending surgical intervention is advised.

Many unusual structures have been observed within hernia sacs:[216]

- Abscess
- Adrenal hemorrhage
- Adrenal tissue and adrenal tumor
- Appendix
- Bladder
- Dystic dysplasia of testis
- Dermoid cyst
- Ectopic renal tissue
- Ectopic testis
- Epidermoid cyst of testis
- Epididymal cysts, nodules, structural anomalies, and tumors
- Fat necrosis of scrotum
- Fibrous adnexal pseudotumor
- Free nodules and calculi
- Funniculitis (thrombosis of pampiniform plexus)
- Gonad or genital structure of opposite sex
- Granulomas (talc, etc.)
- Glaucomatous disease (acidosis, etc.)
- Hemangioma
- Intussuscepted processus vaginalis
- Lymphangioma
- Meckel's diverticulum (Littre's hernia)
- Meconium granuloma
- Mesenchymoma
- Neuroblastoma
- Parasitic disease
- Paratesticular cyst
- Paratesticular rhabdomyosarcoma
- Pedunculated body
- Peritonitis pseudotorsion
- Pneumoscrotum
- Polyarteritis nodosa
- Polyorchidism
- Richter's hernia
- Scrotal calculi
- Spermatic cord tumors
- Spermatocele
- Splenogonadal fusion
- Testicular infarct
- Tunica albuginea cyst
- Tunica vaginalis tumor
- Ureter
- Uterus
- Vas deferens agenesis
- Vasitis nodosa
- Venous thrombosis
- Wilms' tumor
- Xanthogranuloma (juvenile)

Preoperative clinical findings will suggest the presence of some of these structures, such as spermatic cord tumors. Previously unsuspected discoveries in the inguinal canal become clinically significant in the context of hernia repair if they suggest an additional diagnosis that requires treatment, are confused with normal tissue, or are removed inadvertently, producing morbidity. Additional diagnoses of significance include persistent Mullerian duct syndrome (usually associated with cryptorchidism), Meckel's diverticulum, intersex abnormalities in phenotypic females, and testicular, vasal, or epididymal anomalies (see below). Since androgen insensitivity syndrome is present in about 1% of girls undergoing hernia repair,[217] routine exposure of the ovary and/or vaginal examination under anesthesia is warranted in these cases.

Incompletely developed portions of vas or epididymis have been identified by microscopic analysis of excised hernia sac tissue in 1.5%–4% of cases and may cause concern of vasal injury. These can be differentiated from normal vas and epididymis by their small mean diameter of 0.17–0.26 mm, versus >0.7 mm for normal ducts.[218,321] Serious injury to the normal vas, bladder, ureter, or testis during hernia or hydrocele repair is uncommon (2%).[57,211,219] Even in the subset of boys requiring hernia repair in infancy for incarceration, the rate of testicular atrophy is low[321] (2%). Hernia recurrence is also rare (<0.5%). Postoperative (new or persistent) hydrocele may be found in 1.5%–3.5% of cases, but the majority resolve spontaneously within 1 year.

A more severe and unusual form of hydrocele is the abdominoscrotal hydrocele (ASH), which extends from the scrotum to the retroperitoneum but has no demonstrable communication with the peritoneal cavity.[220,221,322] Presentation is usually unilateral but may be bilateral. Bimanual examination confirms an abdominoscrotal mass that transmits a fluid wave; ultrasound may be useful to confirm the diagnosis in some cases. Often present at birth, the ASH may become quite large, extending laterally to the level of the umbilicus or higher. They often do not regress and may enlarge with time. They may rarely cause pain, lower extremity edema, hydronephrosis, and testicular atrophy.[221,222]

Proposed etiologies include isolated closure of the processus vaginalis at the internal ring with gradual upward extension of the hydrocele retroperitoneally, or incomplete proximal obliteration of the processus producing a one-way valve mechanism with continued accumulation of fluid.[220,322] Associated undescended testis may be present. ASH repair is generally performed through a standard inguinal incision, although imbrication of the wall transcrotally may be safer.[223] The sac is transected, the distal portion opened widely, and the retroperitoneal portion excised completely to prevent recurrence. Extreme care must be taken to avoid injury to local retroperitoneal structures, such as the vas or ureter, which may be difficult to identify in the folds of the large hydrocele wall.[322] For this reason, the scrotal approach may be preferable. Concomitant orchidopexy is performed, if indicated.

Testicular Abnormalities

Congenital testicular anomalies other than cryptorchidism are rare but are often found in association with abnormal testicular descent. Those associated with intersex disorders are reviewed elsewhere (see Chapter 70).

Defects of Number and Position

Anorchism and Monorchism

The absence of one or both testes in otherwise normal phenotypic males is identified in as many as 35% of patients

evaluated for nonpalpable testes.[224–226] In the majority, the vas and spermatic vessels are present but end blindly distal to the internal inguinal ring, a condition called vanishing testis. Several observations indicate that the likely cause of vanishing testis is antenatal torsion. These include the presence of hemosiderin or calcification in 15%–85% of specimens examined histologically,[224–226] the absence of developmental abnormalities in the contralateral testis,[227] and sonographic confirmation of prenatal testicular disappearance in a patient with extravaginal torsion.[228] The diagnosis of anorchism can be made after the first 3 months of age if both elevation of plasma gonadotropins and lack of testosterone response to hCG stimulation are present.[229] However, testosterone levels are elevated until about 2 months of age in the normal male. Therefore, the absence of measurable levels in this age group suggests anorchia. During mid-childhood, gonadotropin levels may be normal in anorchid boys, but a GnRH stimulation test will reveal an exaggerated gonadotropin response. Contralateral testicular enlargement and elevated FSH levels are present in some, but not all, patients with monorchism.[230,231] Therefore, diagnosis must be based on laparoscopic and/or surgical findings of blind-ending spermatic vessels. Reduced levels of serum Mullerian inhibiting substance may also prove useful in the diagnosis of anorchism.[232]

Polyorchidism

Supernumerary testis is a rare entity, with fewer than 100 case reports in the literature.[233–236] The proposed etiology is complete duplication of the genital ridge or separation of the ridge into two or more parts. The extra testis is most commonly located in the scrotum (75%), but may be inguinal (20%) or retroperitoneal (5%). The condition is rarely bilateral (5%). Associated ductal structures on the affected side may be single or duplicated. The anatomic variants described in the literature include shared epididymis and vas (47%), duplicated epididymis and common vas (33%), duplicated epididymis and vas (11%), and the absence of both adjacent to the accessory testis (5%). Associated genital anomalies are common and, in decreasing order of frequency, include inguinal hernia, undescended orthotopic testis, spermatic cord torsion, hydrocele, testicular tumor, and varicocele. The diagnosis is suspected by physical findings and can often be confirmed sonographically (Figure 75.18). Surgical intervention is indicated for torsion, hernia or hydrocele, suspected tumor, or cryptorchidism.

Testicular Exstrophy

Congenital extrusion of one or both testes outside the scrotum is one of the rarest testicular anomalies.[237,238] There are inadequate data to support any specific etiology, but theories include gubernacular malfunction, scrotal ischemia, or local mesodermal abnormality. No associated anomalies are reported. Treatment is simple scrotal orchidopexy and closure.

Transverse Testicular Ectopia

The presence of both testes on the same side, each with an intact ipsilateral blood supply, epididymis, and vas, is an uncommon malformation.[239,240] A fused vas deferens has also been reported in four cases in the literature.[241] The most frequent associated anomalies include inguinal hernia (98%) and persistent Mullerian duct syndrome (30%). The absence of a normal attachment of the gubernacular remnant suggests that anomalous development of this structure may predispose to transverse ectopy. Laparoscopy may be useful for both diagnosis and management.[242–245] Depending on presentation, orchiectomy or orchidopexy is performed with partial excision of Mullerian remnants as required to facilitate scrotal placement of the testis.

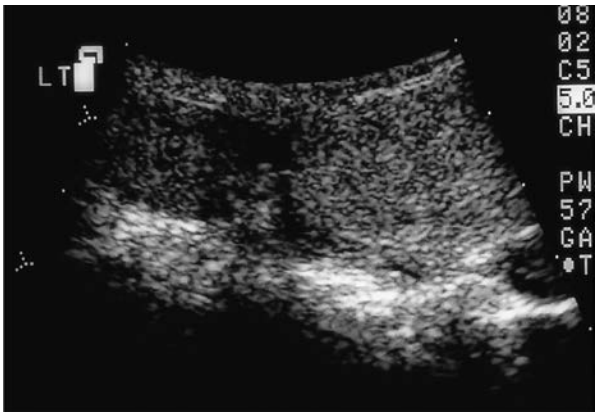

FIGURE 75.18 Polyorchidism: ultrasound image showing two normal testes on the left side.

Other Testicular Anomalies

Gonadal Fusion Anomalies

Splenogonadal fusion is a rare anomaly characterized by an abnormal attachment between the left gonad or its internal ductal system and the spleen or accessory splenic tissue.[246–249] Almost 150 cases have been reported, with the majority occurring in males. Patients most commonly present with a scrotal mass, inguinal hernia, or undescended testis. Rare presentations include bowel obstruction, ambiguous genitalia, and acute enlargement or traumatic rupture of the scrotal spleen. Two variants are described: a continuous form characterized by a fibrous connection between the gonad and spleen, which may contain accessory "spleenlets," and a discontinuous form, with no connection between the gonad and the orthotopic spleen. These subtypes occur with similar frequency. Other congenital anomalies are present in about one-third of cases, including limb, skull, or cardiac defects; micrognathia; diaphragmatic hernia; imperforate anus; spina bifida; and hypospadias. Proposed etiologies include adhesion between splenic and gonadal tissue at 5–9 weeks' gestation due to simple fusion or inflammation[246] and migration of splenic cells into a persistent diaphragmatic gonadal ligament.[248] Treatment is based on associated findings, but care should be taken to avoid injury to the associated normal testis.[246]

Two cases of hepatogonadal fusion have appeared in the literature.[250,251] One patient presented with a right

inguinal hernia, and had a histologically proven liver nodule attached to the upper testicular pole with a fibrous attachment to the porta hepatis. No other anomalies were present. The second patient had a fibrous cord-like structure containing hepatic tissue along its length connecting the liver and right testis in a patient undergoing right inguinal hernia repair.

Testicular Hypertrophy and Macroorchidism

Testicular volume is usually less than 2 mL prior to puberty.[252,323] After the age of 9–10 years, testicular size is markedly variable but correlates with Tanner stage.[323] Unilateral or bilateral enlargement of the testis has many etiologies. Malignant lesions, including primary testicular tumors and leukemia, are rare but should be ruled out initially. Benign causes of increased testicular size include asymmetric pubertal enlargement,[253,254] compensatory hypertrophy in some cases of monorchism or cryptorchidism,[255] macroorchidism associated with fragile X and other mental retardation syndromes,[256,324] nodular enlargement in patients with congenital adrenal hyperplasia,[325] and isosexual precocity due to CNS lesions, excess gonadotropins, testotoxicosis, hypothyroidism, and other syndromes.[257]

Testicular size discrepancy at puberty in otherwise normal boys is an uncommon finding. If a history of previous inguinal surgery or testicular injury is absent, the proposed cause is asymmetric response of the testis to normal maturational stimulation.[254] Exaggerated bilateral, benign testicular enlargement is also reported.[253] These patients should be evaluated with testicular sonography, and if a tumor is not identified, no further steps are indicated. Over time, the size discrepancy in unilateral cases may persist or resolve.[254]

Microlithiasis

Microlithiasis is a condition usually reported in adult men, but also found in children.[258] It is characterized by ultrasonic and/or histologic evidence of multiple calcifications within the testicular parenchyma (Figure 75.19).[326] Adult men with microlithiasis often present with other testicular disease, and associated germ cell tumors have been reported in as many as 40%.[259] By contrast, the prevalence of microlithiasis in men who have had testicular sonography for other reasons is 0.6%.[260] However, recent studies have failed to show the suggested link between microlithiasis and increased cancer risk.[261] The exact incidence in the general population is unknown, but a study of 1504 young asymptomatic men 10–35 years old found a 5.6% prevalence of testicular microlithiasis.[262] A study by Wasniewska et al.[263] revealed a high prevalence of testicular microlithiasis in males with McCune–Albright syndrome.

Microlithiasis identified by pathological examination is not always evident by sonography. However, the histologic type may be helpful in determining the significance of the lesion.[326] Hematoxylin bodies are associated with germ cell tumors, while laminated calcifications may be present in association with testis tumors but also occur in normal boys and in other diseases affecting the testis, including cryptorchidism, epididymitis, inguinal hernia, and Kleinfelter's syndrome.

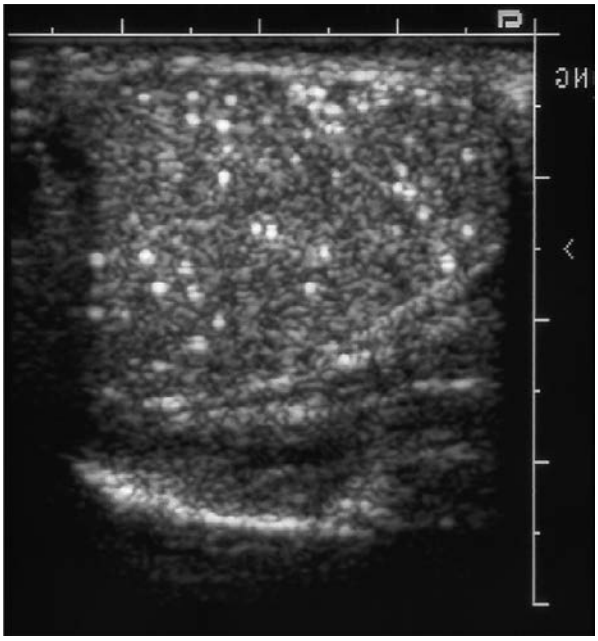

FIGURE 75.19 Testicular microlithiasis: typical appearance on ultrasound image.

Histological microlithiasis is even rarer in the pediatric population, identified in only 1 of 2100 autopsies and 1 of 600 testicular biopsies.[264] In a multi-institutional series, Furness et al.[258] studied 26 patients aged 6 months to 21 years (mean 12 years) in whom microlithiasis was diagnosed incidentally by sonogram. Reasons for evaluation included hydrocele, epididymitis, varicocele, trauma, testicular or appendix torsion, testicular mass, and unilateral testicular enlargement. There were no cases of clinically evident tumor during a mean follow-up period of slightly more than 2 years. Additionally, long-term data are required to identify the clinical significance, if any, of testicular microlithiasis in children. For the present, the subject of surveillance of these patients is controversial. In the abscence of risk factors such as history of testicular tumor or cryptorchidism, some would only recommend self-examination.[261] Others advocate evaluation every 6 months with examination and ultrasound, but do not recommend routine biopsy.[265]

Abnormalities of Accessory Organs

Cystic Dysplasia of Rete Testis

Cystic dysplasia of the rete testis (also called cystic dysplasia of the testis) has been reported 48 times in the literature.[266–269] This lesion is believed to be due to a defect in fusion between the rete testis and efferent ducts. Cystic dysplasia is usually unilateral but may be bilateral, and patients often present in childhood with a testicular or scrotal mass. The diagnosis may be made by identifying multiple small cysts on the medial aspect of the testis, although most of the testicular parenchyma may be compressed by the mass. Associated genitourinary anomalies

are common, suggesting that an associated Wolffian duct anomaly may be present. Almost all cases are associated with renal anomalies. The most common are agenesis, dysplasia or hypoplasia, or hydronephrosis. Abdominal cryptorchidism is seen in one-third of patients. Preferred treatment is local excision, but an inguinal approach with control of the cord vessels is recommended to rule out tumor. Orchiectomy is preformed if testis sparing is not possible. Some advocate a more conservative approach with serial ultrasonography.[269,270]

Wolffian Duct System

Since the mesonephric or Wolffian duct is the precursor of both the ureteral bud and the internal genital ducts, including vas, epididymis, and seminal vesicles, anomalous development frequently affects both the kidney and reproductive tract.[271] The caudal segment of the Wolffian duct, or common mesonephric duct, is the site of the origin of the ureteral bud. The middle segment, or common vas precursor, becomes the vas and seminal vesicles, and the upper mesonephric duct becomes the distal vas and epididymis.[272] It is proposed that defects that appear before the seventh week of gestation (onset of ureteral bud differentiation) may interfere with normal renal and reproductive tract development, and after that time, the reproductive tract alone is affected.[271] The timing and extent of the development defect probably influence the eventual phenotype.

Agenesis

Absence of the vas deferens is the most common finding in patients with agenesis of Wolffian duct derivatives.[271,273–275] The lesion may be bilateral or unilateral and, in either form, occurs in less than 1% of males. Vasal agenesis is usually discovered in adult patients with infertility or at the time of planned vasectomy, but may also present during inguinal exploration at any age. Both the unilateral and bilateral forms are associated with agenesis of the epididymis, seminal vesicle, and/or kidney, but the association is more frequent in unilateral cases. The caput epididymis almost always persists. This observation supports other clinical data indicating similarities between the caput epididymis and the efferent ducts, with the implication that the caput arises from the gonadal ridge rather than the Wolffian duct. Mutation of the transmembrane conductance regulator (CFTR) gene is the only known genetic etiology of vasal agenesis. CFTR gene mutations are more common in bilateral (64%) than unilateral (25%) disease and have not been found in patients with bilateral vasal agenesis in association with renal anomalies.[271] When vasal agenesis is diagnosed in childhood, renal and pelvic sonography and, if abnormal, VCUG should be preformed. Vasal agenesis may be found in patients with cystic fibrosis, even when clinical evidence of the disease is absent.

Anomalies of Epididymal Attachment

Abnormalities of fusion or suspension of the epididymis are known to be common in patients with cryptorchidism. Turek et al.[276] studied epididymal anatomy in a group of boys undergoing inguinal or scrotal exploration primarily for hydrocele and reported normal anatomy in 96%. However, two other studies have shown a higher incidence (31%–39%) of mild suspension or fusion anomalies of the epididymis in boys with hernia or hydrocele, with a greater frequency in those patients with a patent processus vaginalis.[277,278] The clinical significance of partial epididymal detachment or a long looping epididymis in patients with a normally positioned testis is unclear.

Epididymal Cysts

Cysts of the epididymis (spermatocele) (Figure 75.20) usually appear during puberty or adulthood and are asymptomatic. The etiology is unknown, but proposed theories include dilated efferent ducts that have failed to fuse with the epididymis[271,279] and/or part of a testicular dysgenesis syndrome caused by an endocrine abnormality.[280,281] Conditions associated with a higher incidence of epididymal cysts include cryptorchidism, von Hippel–Lindau disease, and fetal exposure to diethylstilbestrol. Intervention is not usually required, but both excision[282] and sclerotherapy[283,284] have been used successfully in symptomatic patients. Two cases of torsion of an epididymal cyst have been reported.[285]

Other Vasal Anomalies

Ectopy of the vas deferens,[272,286,287] also called persisting mesonephric duct,[327] is characterized by ectopic insertion of the vas into the urinary tract. Most commonly, fusion of the vas and ureter occurs proximal to the bladder (vasoureteric insertion),[288] but direct entry of the vas into the bladder (vasovesical insertion) may occur. Approximately 30 cases are reported in the English literature. Ectopic insertion into a prostatic utricle is also possible (Figure 75.21).

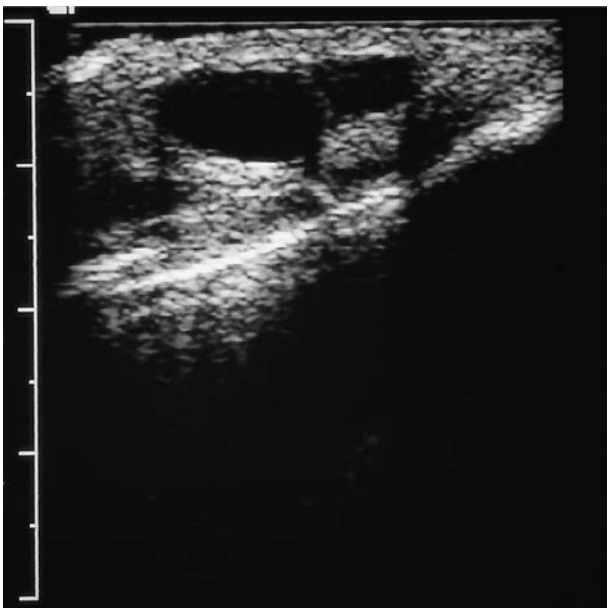

FIGURE 75.20 Epididymal cysts in a patient with polyorchidism.

FIGURE 75.21 VCUG of patient with prostatic utricle showing insertion of vas deferens into utricle.

Proposed mechanisms include ectopic insertion of the ureteral bud and/or aberrant development of the proximal vas precursor.[272,327] Patients are asymptomatic or present with UTIs and/or epididymitis. Other congenital anomalies are common, including agenesis of the seminal vesicles, imperforate anus, hypospadias, ureteral reflux and/or ectopy, and renal anomalies. The triad of imperforate anus, hypospadias, and ectopic vas was reported in 21% of cases.[289] The diagnosis may be made by cystourethrography or retrograde ureterography, or at the time of ureteroneocystostomy. Treatment is based on anatomic findings and clinical indications.

True duplication of the vas deferens is extremely rare. Binderow et al.[290] reported a single case found at the time of inguinal hernia repair in a boy with a normal urinary tract. The authors proposed Wolffian duct duplication or ductal bifurcation in the region of the proximal vas precursor as the etiology.

Seminal Vesicle Cysts

Seminal vesicle cysts are another rare manifestation of anomalous Wolffian duct development.[291,292,328] They may be congenital or acquired.[293] Most are associated with renal agenesis with or without ureteral ectopy. Presentation is predominantly in adulthood, with pain during micturition, defecation or ejaculation, UTI, or infertility. A palpable mass is appreciated on rectal examination. The diagnosis may be confirmed by abdominal or transrectal sonogram. A computed topographic scan may be useful to visualize the seminal vesicle and confirm renal agenesis (Figure 75.22). Excision is indicated in symptomatic patients, either using an open technique, such as a transtrigonal approach,[292] or laparoscopically or robotically.[294–296]

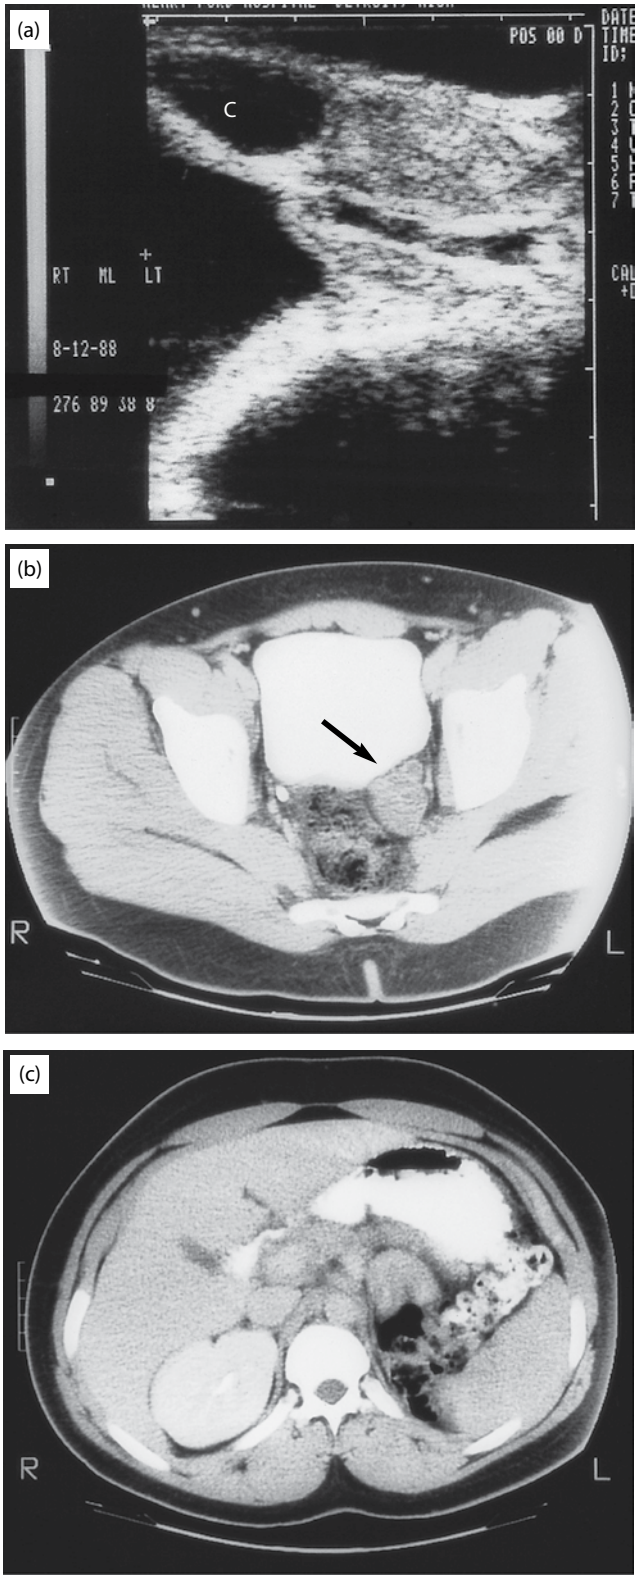

FIGURE 75.22 Seminal vesical cyst in an adolescent presenting with voiding symptoms and urinary tract infection: (a) sonogram showing a cystic structure posterior to the bladder in the left sagittal view (C); (b) computed tomographic (CT) scan confirming a fluid-filled structure (arrow) in the region of the left seminal vesicle; (c) absence of the left kidney on CT scan.

CHAPTER 76

Penile Replacement Surgery

Piet Hoebeke and Stan Monstrey

INTRODUCTION

The biological male without a penis or with a very insufficient penis remains a major challenge to the reconstructive surgeon. Next to congenital conditions in which the penile development failed, traumatic events, medically necessary penile amputations, and failed reconstructions of congenital anomalies are the main reason for penile insufficiency.

Severe penile insufficiency and absence of a penis are devastating conditions for men with a significant psychological and physical impact, and thus are a challenging lesion to treat.

Possible treatment options are gender reassignment, tailoring of the penile stump, penile replantation, phallic reconstruction (phalloplasty), and most recently, penile transplantation.

In the past, sex reassignment to the female gender has been offered, based on the principles applied to newborns with disorders of sex development (DSDs) and ambiguous genitalia. There is no evidence to show that the outcome of this policy is satisfactory. Indeed, long-term evaluation of a few patients shows contradictory results, which have triggered great controversy of this therapy.[92]

Today, sex reassignment is no longer considered a treatment of choice.

Tailoring of the penile stump by means of penile degloving, division of the suspensory ligament and rotational skin flaps, or skin grafts combined with buccal mucosa grafts for glans reconstruction has been reported. However, this can only be applied in cases of moderate penile injuries with still a reasonable penile stump.

Penile replantation can be attempted in the acute phase of traumatic amputation of the penis. The survival of the replanted penis depends on the viability of the amputated segment and the condition of the residual penile stump. Replantation must take place within 24 hours. Current replantation techniques rely on microsurgical approximation of the dorsal structures and cavernosal arteries with uniformly good results. In traumatic amputation, salvage of the amputated segment with replantation is the primary treatment option. The outcome of erectile function after replantation is not very clear.

Recently, one case report has been published on penile transplantation.[93] It is feasible due to microsurgical techniques with anastomosis of neurovascular structures, corporal bodies, and urethra, and due to our knowledge in immunosuppressive medication from other transplant surgery. Unfortunately, the transplanted penis was cut off 14 days postoperatively because of psychological problems of both the patient and his partner. This technique is still experimental and is not a current treatment option. Future options like tissue engineering are at present not science, but rather science fiction.

Nowadays, reconstructive surgery for severe penile insufficiency is performed within the context of a genitourinary reconstructive team, which includes urologists and plastic surgeons. The essence of a reconstructive team is reflected in this chapter, which mainly is the collaborative work of both these specialties. Plastic surgery techniques and traditions continue to play an important role in the reconstructive armamentarium of all who aim to repair genital defects. As the urethra is part of the genitals, the role of the urologist is essential in this reconstruction, as it is for erectile function.

In this chapter, we focus on penile replacement surgery for congenital and traumatic conditions with severe penile insufficiency and provide an overview of state-of-the-art approaches for this condition.

INDICATIONS FOR PENILE REPLACEMENT SURGERY

Congenital Genital Defects

Aphallia

Aphallia is an extremely rare condition in which a normally developed 46 XY male presents without a penis at birth. The scrotum is normally developed and the testes are also normal. The urethra ends in the perineum or in the anterior wall of the rectum (Figure 76.1).

Disorders of Sex Development

After standardization of the terminology, intersex conditions are nowadays defined as DSDs.[11] The conditions in which penile replacement could be a possible option include 46 XY DSD, chromosomal DSD, and some rare congenital anomalies. Where in the past an underdeveloped phallus could be an indication for female gender assignment, in modern times, with the actual state of penile replacement surgery, this assignment approach is no longer justified.

1. *46 XY DSD*: Undervirilization in males. Testosterone synthesis defects and partial androgen receptor insensitivity are among the causes. Patients in this group present genital ambiguity with varying degrees of

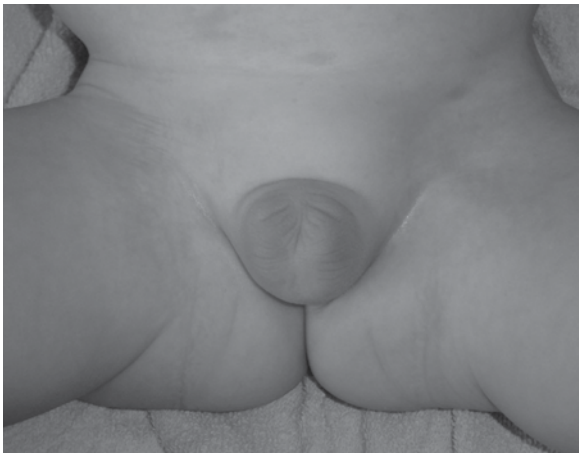

FIGURE 76.1 Aphallia. (Courtesy of Dr. R. De Castro.)

hypospadias, penoscrotal transposition, and cryptorchidism. Surgical treatment early in life consists of hypospadias repair, correction of penoscrotal transposition, and orchidopexy. In rare cases, the penis is so underdeveloped that penile replacement surgery can be an option.

2. *46 XY/46 XX DSD*: Consists of varying degrees of genital ambiguity and the presence of both male and female or dysgenetic gonads. Reconstruction is done after gender assignment, which is not always clear. Multidisciplinary teams with expertise in these pathologies are needed to guide the diagnosis and treatment in these children.
3. *Genital conditions*: This DSD classification includes conditions like penile agenesis, extreme penoscrotal transposition with rudimentary penis (Figure 76.2), cloacal exstrophy, idiopathic micropenis, and other genital malformations with normal chromosomes and gonads. All these conditions will eventually require genital reconstruction, although due to their low prevalence, these should be treated in centers of excellence by a multidisciplinary team with a lot of expertise in this field.

FIGURE 76.2 Complete penoscrotal transposition with rudimentary penis.

Traumatic and Iatrogenic Genital Defects

Penile Insufficiency after Failed Reconstruction for Exstrophy, Severe Hypospadias, and Cloacal Exstrophy

The main goal of initial closure for exstrophy is to reconstruct a functional genitourinary system. This is carried out by direct closure of the bladder and reconstitution of the pelvic ring. Different techniques have been described for penile reconstruction,[6,8] and although the results of the urethral closure have drastically improved, the ideal surgical approach is still controversial: neonatal versus delayed closure and one-stage versus multistage repair. Phallic length mainly depends on antenatal development, and the majority of these patients end up with a small and underdeveloped penis, despite the best efforts of their treating surgeons. As they pass through their postadolescent period, many of these young men will benefit from further lengthening procedures or even complete penile reconstruction. In some patients, correction of unaesthetic scars and further release of insufficiently released corpora can help to gain length (Figure 76.3).

In some boys, there is not enough skin to cover the penis after lengthening. For these cases, the thick split-thickness skin graft is the mainstay of reconstruction. The graft should be pliable, placed onto a flat bed, and secured with a tie-over bolus pressure dressing to reduce the risk of hematoma or seroma formation. Successful skin graft "take" is directly related to a well-vascularized wound bed, meticulous hemostasis, infection-free environment, and adequate immobilization.

The donor site should be close to the genitalia, large enough to produce a sheet skin graft, and well hidden. Ideally, the skin graft should be at least 0.018–0.02 inch in thickness and large enough to cover the whole breadth of the penile shaft or scrotum. The skin graft should be sutured circumferentially around the penile shaft with a ventral suture line. The graft is then fixed to the surrounding skin, the underlying Buck's fascia, and the tunica with dissolving sutures. Fixation with tissue sealant has been reported to improve skin graft fixation and skin graft take in this difficult area.[16]

Widely meshed split-thickness skin grafts should never be used on the penile shaft. However, with the so-called "reversed mesh graft" (nonexpanded or 1:1 meshed skin grafts), only puncture-type perforations are made with a V1 carrier (Humeca Ltd., Enschede, the Netherlands) (Figure 76.4), which allows for a better fluid evacuation, and thus a better skin graft take, while still avoiding poor scarring and an unaesthetic mesh pattern in the long term. These nonexpanded meshed split-thickness grafts have also become a mainstay of complicated, staged urethral

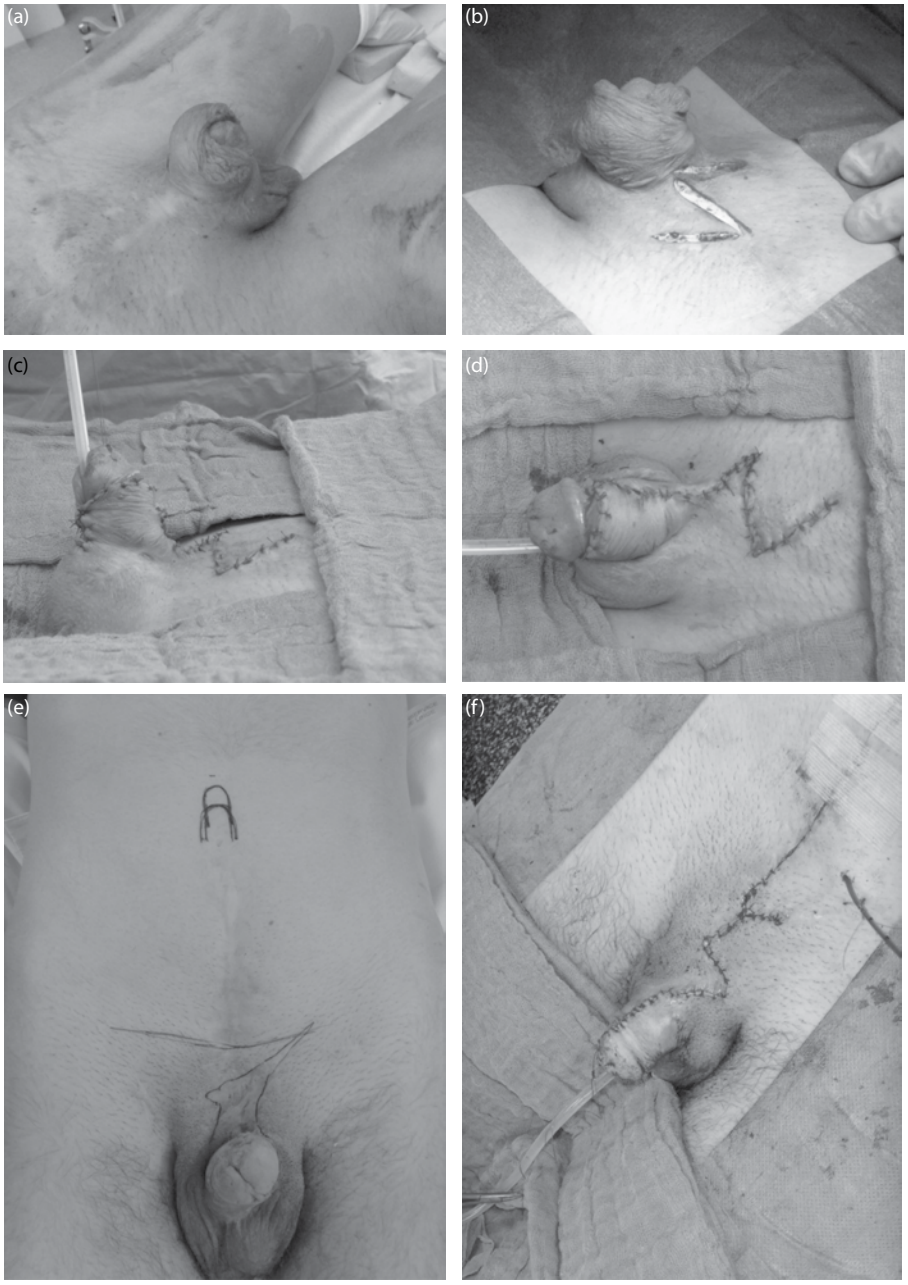

FIGURE 76.3 Examples of Z-plasty on the dorsal aspect of the penis extending into the prepubic area to obtain maximal lengthening (a–f).

reconstruction[17,18] McAninch[19] has described the use of (not too widely) meshed split-thickness skin grafts for scrotal reconstruction. Meshed grafts in this location may produce "good aesthetic results," but they will never measure up to the functional capacity of sheet or 1:1 perforated grafts.

The use of this reversed mesh graft is shown in two cases in Figure 76.5.

Unfortunately, in some boys there just is not enough tissue due to underdevelopment or partial or complete loss of penile tissue after primary closure. These patients might be good candidates to undergo a phallic construction or further penile reconstruction with the use of microsurgical tissue transplantation techniques or local pedicled perforator flaps (Figure 76.6).

Most of these patients have some form of continent urinary diversion, and therefore a nonfunctional urethra. Although the ejaculatory ducts are mostly intact, they are often abnormally positioned as a prepubic fistula. These anatomic facts create unpredictable sperm production. For these reasons, the urethral reconstruction may be a moot point in this group of patients, thus making a phalloplasty in these "boys without a penis" much easier than a penile reconstruction in a patient who wants to void through his new penis. The different options and peculiarities for a phalloplasty in an exstrophy patient will be addressed further in this chapter.

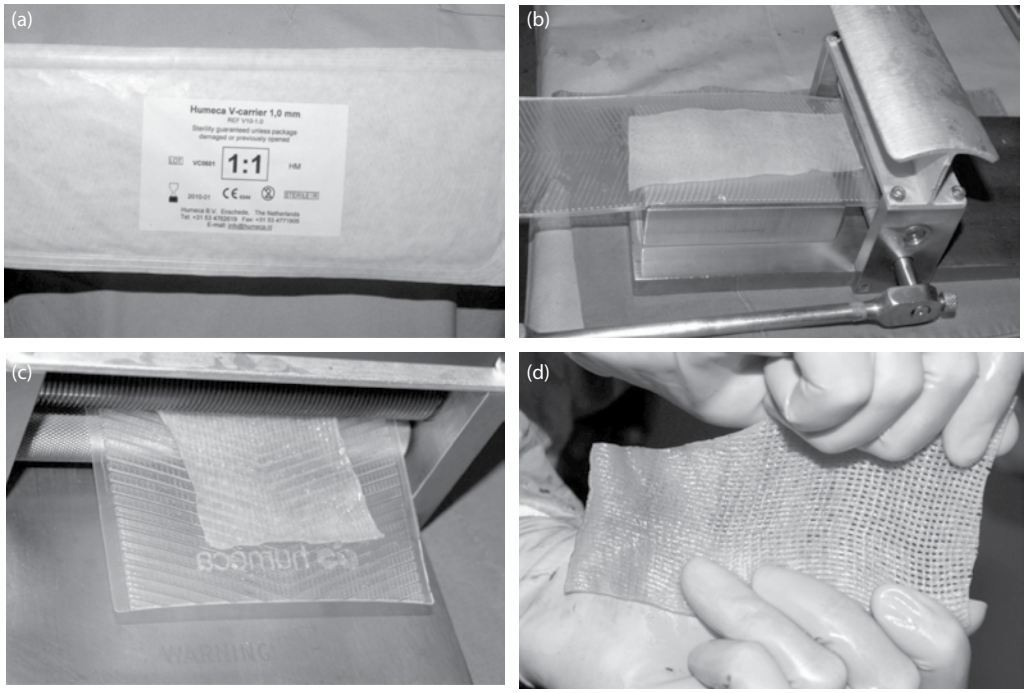

FIGURE 76.4 Reversed mesh graft (a–d).

Penile Trauma

Posttraumatic Genital Reconstruction

Posttraumatic genital repair is an uncommon but special chapter in surgical reconstruction. A reconstructive algorithm based on the etiology, an assessment of the extent of injury, and an anatomic inventory includes several goals and observations. First, the anatomically protected position of the genitalia implies that patients who have genital injuries often have large concomitant injuries as well, and are often

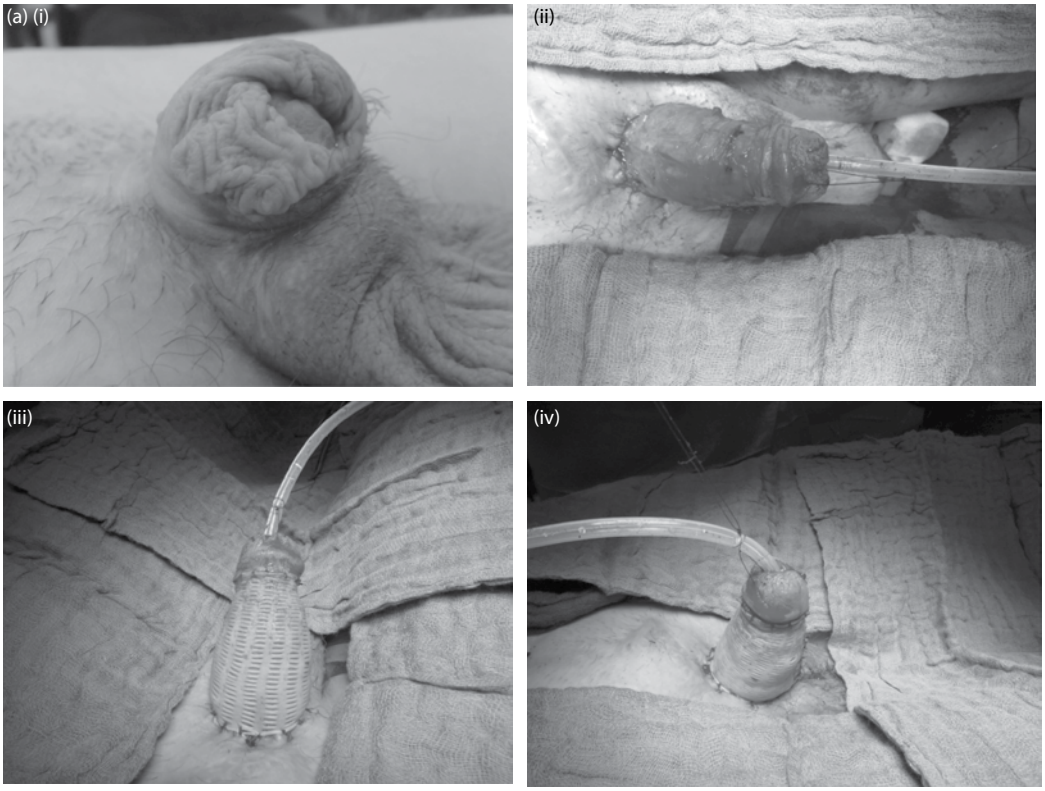

FIGURE 76.5 (a)(i)–(iv) Reversed mesh graft in complex exstrophy. (*Continued*)

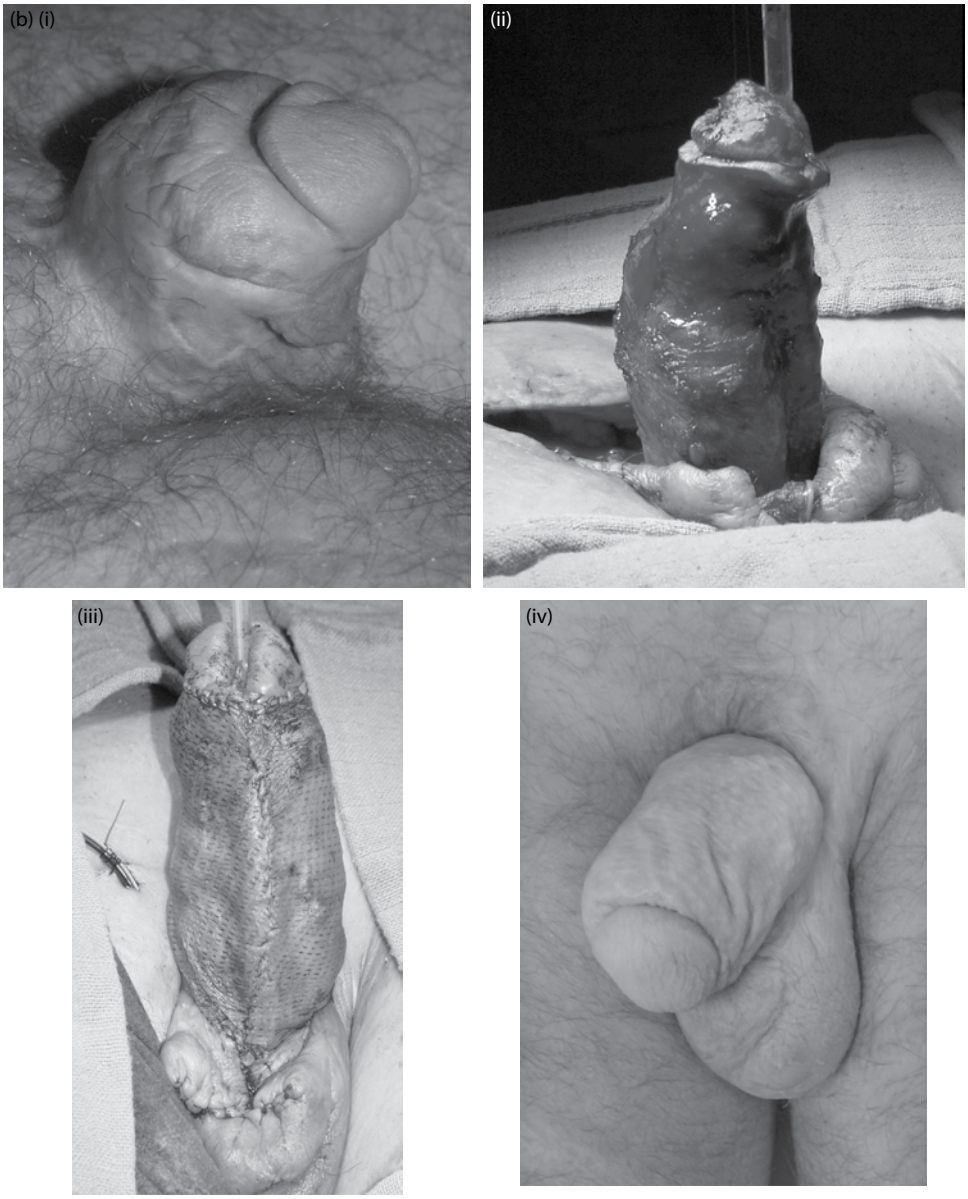

FIGURE 76.5 (Continued) (b)(i)–(iv) Reversed mesh graft in case of complex hypospadias.

critically ill. Resuscitation and life support of the patient take precedence over any reconstruction. However, genital reconstruction is of prime relevance, and only hand, eyelid, and lip reconstruction are considered more important in the reconstructive hierarchy. Second, aesthetics are foremost in genital reconstruction. Although it is not often articulated, the appearance of the genitalia is important to the self-esteem of a patient who is recovering from trauma. What is frivolous to one person may be a lifelong obsession to another, and genital aesthetics are as valued as other cosmetic areas, such as the face, nose, and breasts. Third, the genitalia appear to be a "privileged site," such that the usual postreconstructive sequelae of scarring and contracture are often spared in genital reconstruction. This may be due to the fact that the average adult man has five to eight nocturnal erections every night, thereby inherently stretching scars or skin grafts on the penile shaft. This stretching may combat and overcome the tendency of myofibroblasts to contract a skin graft or scar.

Buccal mucosa grafts are often used in urethral reconstruction. They can also be useful in glans reconstruction. After partial penectomy (traumatically or for cancer treatment), the residual corpora sometimes are still long enough to allow for sexual intercourse. However, the penis is completely covered with skin, which leads to an unnatural look. For these patients, the corpora can be released by transsection of the suspensory ligament and the tip of the corpora can be covered by buccal mucosa-free grafts. They create a mucosa-covered glans-like-looking tip of the penis (Figure 76.7a–c).

Genital Replantation

Microsurgical techniques and free tissue transplantation have become the state-of-the-art treatment for many reconstructive problems. The first uses of the microscope in genital reconstruction for penile reattachment

FIGURE 76.6 Examples of patients who are candidates for undergoing phalloplasty (a–d).

after amputation were reported independently by Cohen et al.[43] and Tamai et al.[44] in 1977. However, the first account of successful reattachment long predated the introduction of microsurgical techniques. In 1929, Ehrich[45] first reported a successful penile attachment by opposing and anatomizing the lacerated corporal bodies and repairing the overlying tunica only. This technique was occasionally successful but usually associated with loss of the overlying skin, glans, sensation, and erectile and voiding function.[46]

Penile replantation often mimics the algorithms of other amputated extremities that are candidates for

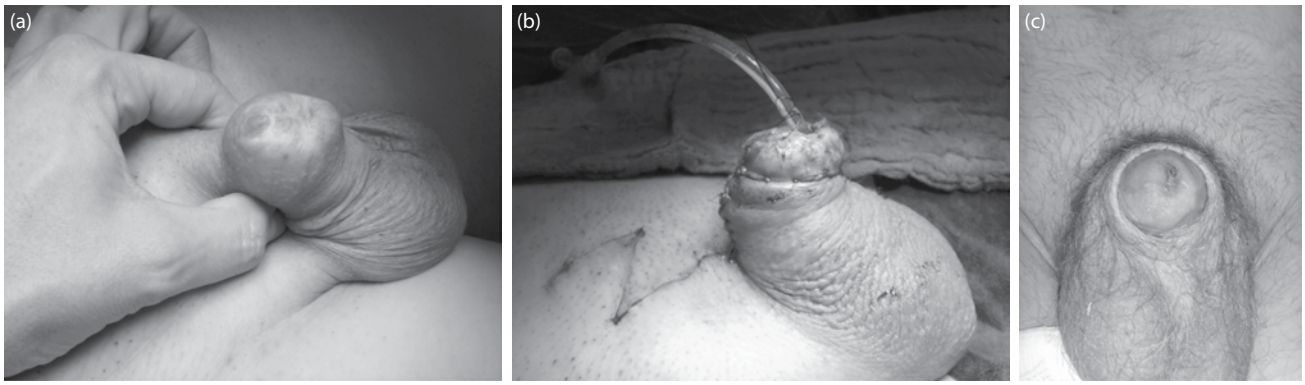

FIGURE 76.7 (a) Penis after partial penectomy for spinocellular epithelioma, showing residual corpora that, after release, could be sufficient for sexual intercourse. (b) After penile elongation with release of the suspensory ligament and coverage of the distal part of the penis with buccal mucosa. (c) Result of glans reconstruction using buccal mucosa.

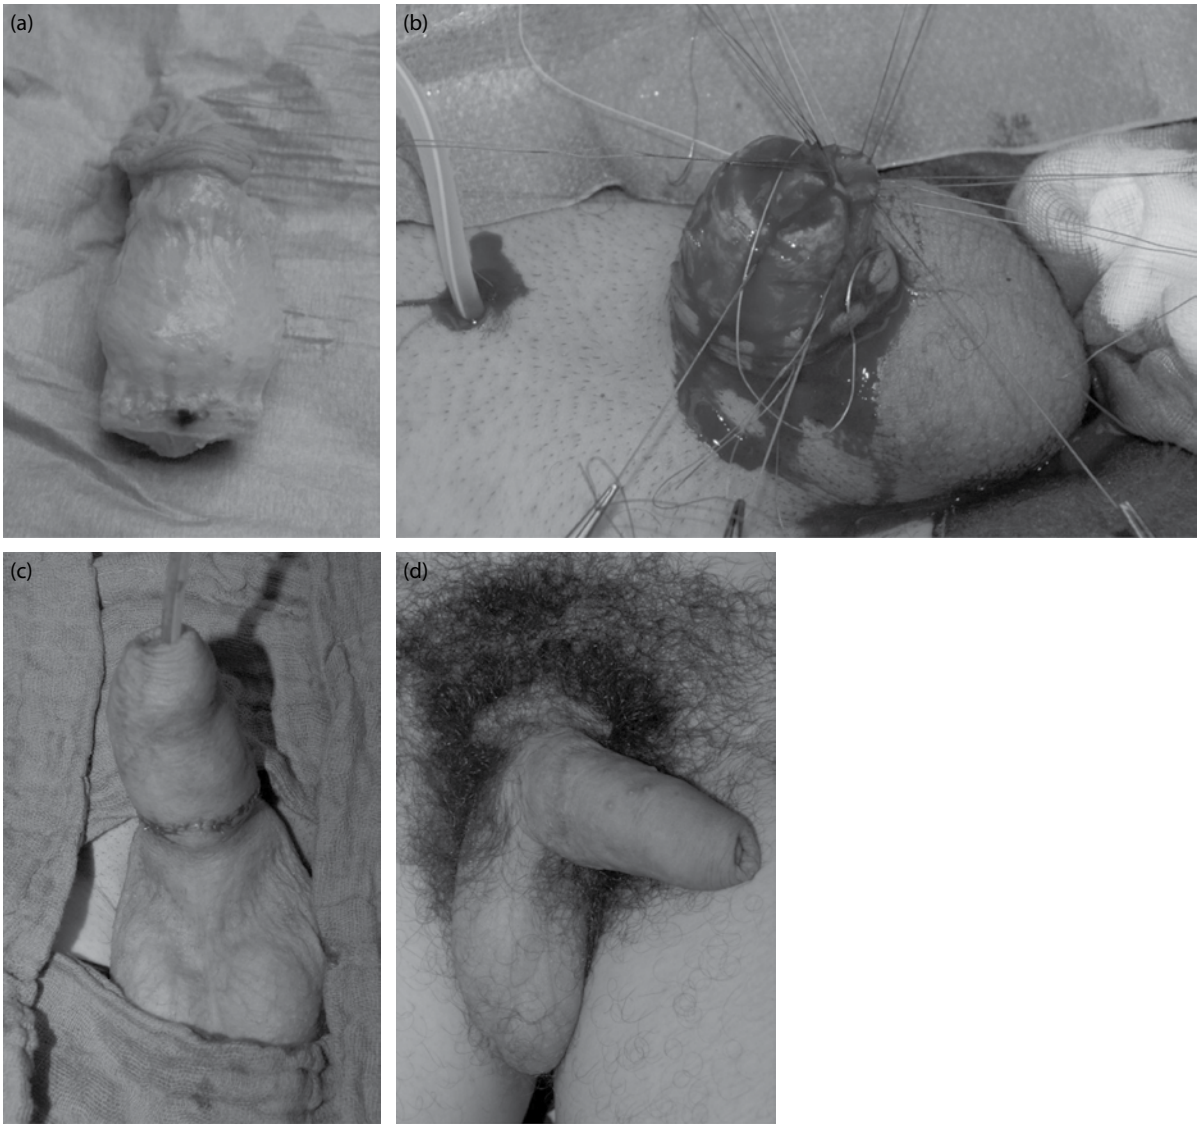

FIGURE 76.8 (a) Self-inflicted penile amputation. (Courtesy of Dr. Nathalie Roche.) (b) Preparation of microsurgical anastomoses. (Courtesy of Dr. Nathalie Roche.) (c) Immediate postoperative result. (d) Late postoperative result.

reattachment. The penis is initially wrapped in saline-soaked gauze and placed into a plastic bag, which in turn is placed in a bag or cooler of ice with water (the so-called "bag-in-a-bag" technique). Because genital amputations are often self-inflicted, it is important to involve the psychiatrist even before restorative surgery. After the induction of anesthesia, the proximal and distal ends of the amputated penis are examined microscopically. Minimal debridement is followed by mechanical stabilization of the urethra and reapproximation of the tunica albuginea of the corpora cavernosa.

Revascularization is completed by use of microsurgical magnification, instrumentation, and 9-0 and 10-0 nylon sutures to reanastomose the deep dorsal arteries, the deep dorsal vein, and the superficial dorsal vein. Multiple nerve coaptations are meticulously completed with 10-0 and 11-0 nylon sutures. The dartos fascia and skin are then loosely approximated to complete the reattachment. A suprapubic tube is inserted to divert the urinary flow for 2–3 weeks, and the patient is prescribed bed rest in a warm room.

The ideal candidate for genital replantation is a patient with a clean, sharp cut in which the amputated part has been cooled (Figure 76.8a–d).

RECONSTRUCTION OF MALE GENITALIA IN SEVERE PENILE INSUFFICIENCY

There is still a lot of controversy regarding whether to perform a phalloplasty in children. Penile construction in children is similar to that in adults with one added requirement—growth through puberty to adulthood. Because the phallus is constructed of somatic tissues (showing linear

growth) but replaces a penis that is formed by genital tissues (demonstrating a more exponential growth), the growth rates are temporally and quantitatively different during puberty.[14] Care must be taken to accurately predict the anticipated growth rate and to design a phallic model that is larger and longer than the normal genital size for that age group.[15]

Furthermore, the body proportions between prepubertal boys and postpubertal boys are different. The extremities are proportionally bigger in infants than the rest of the body. Using flaps from extremities will result in a disproportionate penis. An alternative proposed by Roberto De Castro consists of the creation of a phallus based on an abdominal flap.[95] Despite the surgical feasibility of this technique, the advantage should be weighed against the possible disadvantage. The advantage is the fact that the patient, as a child, will identify more easily as being a boy and should experience less stress, but this does not outweigh the disadvantage that the abdominal phallus will remain small after puberty, while the lower abdominal scar can interfere with the outcome of future state-of-the-art phalloplasty.

Another issue that we are just now beginning to address is the "correct" age at which to proceed with the insertion of penile prostheses. Once these boys have reached 18 years and the age for majority, they must be physically and psychologically prepared to manage a phallus that has previously been erectionless.

There is another nagging problem with operating on children—the lack of informed consent. Although the child's best interest and surgery's best intentions are usually served by early reconstruction, there are no long-term studies that have evaluated the results of this surgery over a lifetime or even a generation.

Finally, it comes as no surprise that the large majority of these genitally compromised boys require prolonged psychological therapy to deal with genital loss, surgical trauma, inadequacy, and scarring. These psychological issues are often closely commingled with the need for secondary surgery to complete reconstruction.

Complete Phallic Reconstruction

The term *phalloplasty* was first used in 1858 by Sprengler to indicate the reconstruction of the integument after decollement (separation of the superficial tissue layers) of the penis.[56] Bogoras, the first to report on the reconstruction of the entire penis, labeled his procedure "penis plastica totalis."[57] He was also the first to use a single abdominal tube, a technique later applied by others. Subsequently, *phalloplasty* was used to describe penile reconstruction.

Following World War II, some leading plastic surgeons showed an interest in the penile reconstructive procedure. In 1948, McIndoe[58] improved the abdominal tubed flap by constructing a neourethra while raising the pedicle tube employing an inlay skin graft. Maltz[59] and Gillies[60] popularized the technique when they added a costal cartilage graft as a rigidity prosthesis. Gillies was the first to report the use of this technique in a transsexual patient. The Stanford team[55,61] refined the procedure, tubing an infraumbilical abdominal flap outside in, in order to create a skin-lined tunnel as a future urethral conduit. This method reduced the number of stages previously necessary for phalloplasty.

Snyder described a phalloplasty technique incorporating a preconstructed superficial skin-lined conduit for intersex patients employing a single pedicled infraumbilical skin flap.[62,63] Hester et al. performed a penile reconstruction in one stage using a vertical, superficial inferior epigastric artery flap with a subcutaneous pedicle, in a male born with ambiguous genitalia.[64] However, after McGregor and Jackson introduced the groin flap in 1972,[25] Hoopes[65] commented that "the groin flap may prove the method of choice for phallus reconstruction." Orticochea[66] used a gracilis myocutaneous flap in a five-stage phalloplasty procedure, and claimed it produced cosmetically and functionally superior results. The Norfolk team also used a unilateral gracilis myocutaneous flap for phalloplasty.[40] Sometimes, a combination of flaps was used. Exner[67] implanted a ridigity prosthesis in a rectus abdominis muscular flap and used bilateral groin flaps to cover the neophallus.

Once microsurgery established a foothold in genital construction, plastic surgeons began to explore and map out the genital neurovascular supply and to consider expanding the applications of microsurgery to elective reconstruction of the genitalia. Chang and Hwang[68] described an ingenious adaptation of the tube-in-tube concept into a free tissue transfer with the radial forearm flap originally described by Song et al.[69]

Since the early reports, a wide variety of other free flaps have also been described for phalloplasty, including the dorsalis pedis flap,[70] the deltoid flap,[71] the lateral arm flap,[72] the fibular flap,[73] the tensor fasciae latae flap,[41] the anterolateral thigh (ALT),[74] and the deep inferior epigastric artery perforator (DIEAP) flap.[75] The fact that so many techniques for penile reconstruction exist is evidence that none are considered ideal. Still, most of these articles are only case reports or small series, and even nowadays the "old" Chinese flap or radial forearm flap is by far (>90%) the most frequently used free flap in the literature,[75] and is therefore often considered the gold standard for penile reconstruction. Monstrey et al. recently published the only large (287 patients) and well-documented (long) term follow-up study on the use of the radial forearm phalloplasty.[75] They describe the technique they used in almost 300 consecutive cases and evaluated to what degree this supposed gold standard technique has been able to meet the ideal goals in phallic reconstruction. This group also reported the first large series of penile replacement surgery for severe penile insufficiency.[96] In their first report, they report on seven radial forearm flaps and four ALT flaps. Both techniques are described with their advantages and disadvantages.

Radial Forearm Flap: Technique and Long-Term Results

The creation of a phallus with a tube-in-a-tube technique is performed with the flap still attached to the forearm by its vascular pedicle. A small skin flap and a skin graft are used to create a corona and simulate the glans of the penis (Figure 76.9a–f).

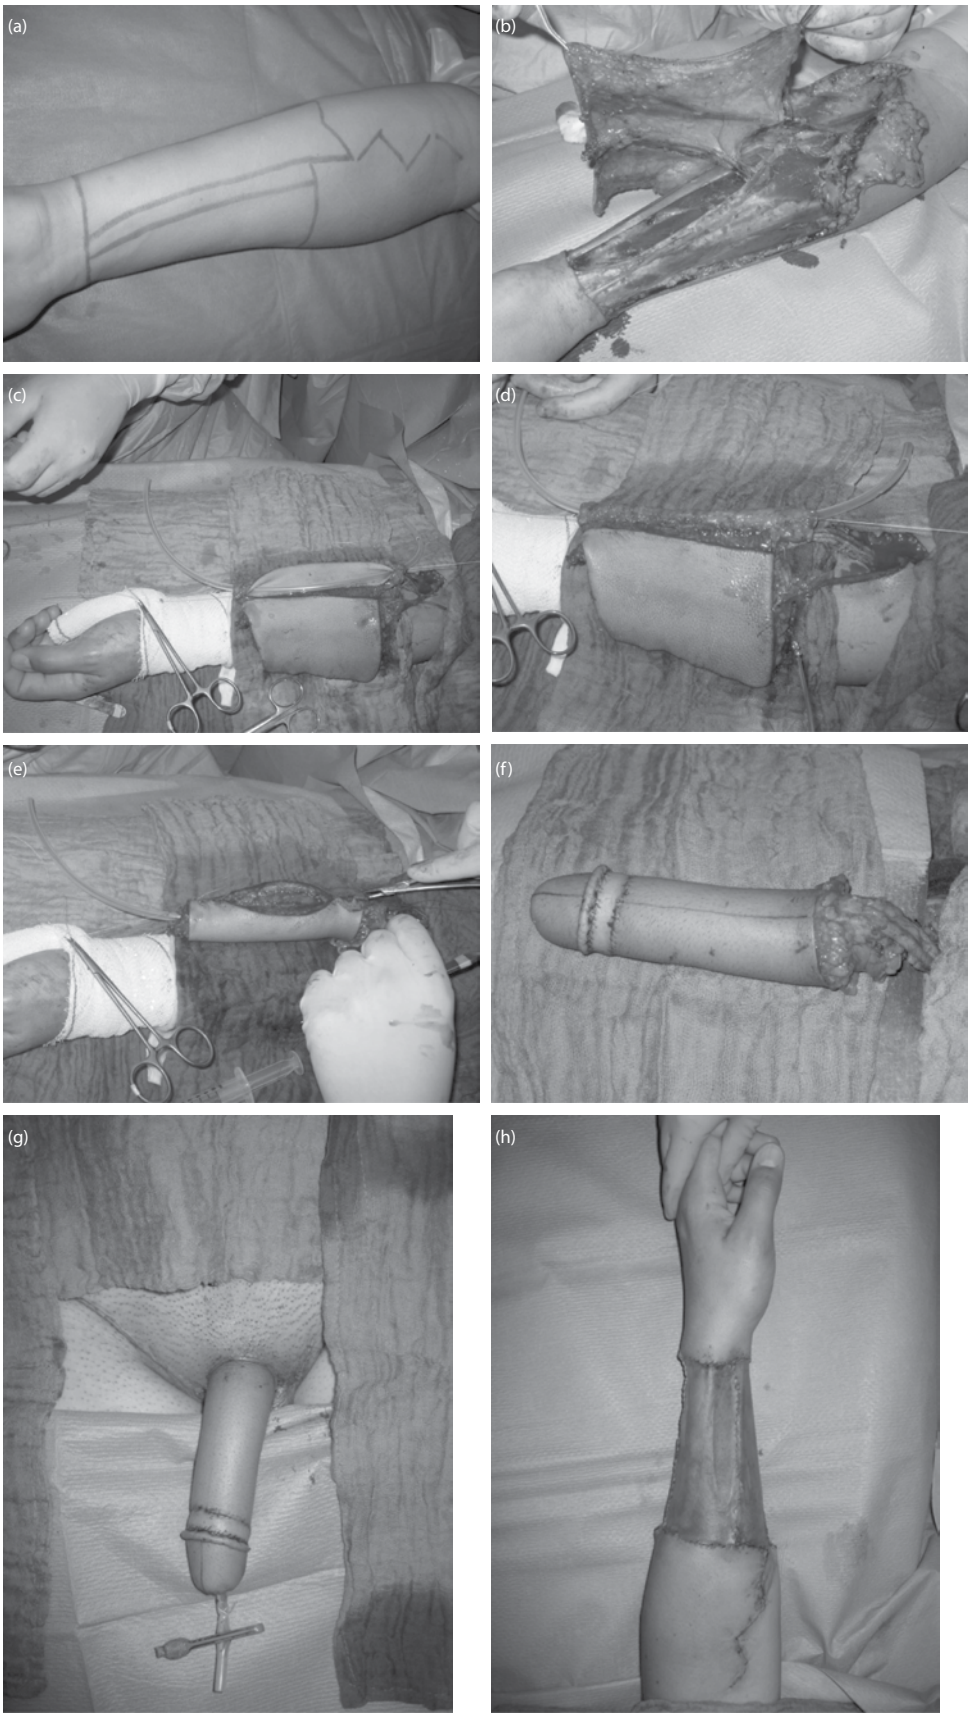

FIGURE 76.9 Standard radial forearm technique: (a) Design and (b) dissection of the flap. (c and d) Tubing (inner tube) of the urethra. (e) Outer tube of the penis itself. (f) Creation of the glans of the penis (with penis still attached to the forearm, just prior to transfer to the pubic area. Immediate postoperative result of (g) the penis and (h) the donor site on the arm.

When a urethral reconstruction is needed, the urologist prepares the native urethra for connection. After former reconstructions of the urethra, most scar tissue is removed and healthy mucosa is exposed to anastomose to the flap urethra. The free flap can be transferred to the pubic area after the urethral anastomosis (Figure 76.9g and h): the radial artery is microsurgically connected to the common femoral urethra in an end-to-side fashion, and the venous anastomosis is performed between the cephalic vein and the greater saphenous vein. One forearm nerve is connected to the ilioinguinal nerve for protective sensation, and the other nerve of the arm is anastomosed to one of the dorsal penile nerves for erogenous sensation.

The average hospital stay for the phalloplasty procedure is 2½ weeks.

Tattooing of the glans can be performed after a 2- to 3-month period, before sensation returns to the penis.

Phallic construction had become predictable enough to refine its aesthetic goals, which include the use of a technique that can be replicated with minimal complications. In this respect, the radial forearm flap has several advantages: the flap is thin and pliable, allowing the construction of a normal-sized, tube-within-a-tube penis; the flap is easy to dissect and is predictably well vascularized, making it safe to perform an (aesthetic) glans-plasty at the distal end of the flap. The final cosmetic outcome of a radial forearm phalloplasty is a subjective determination, but the ability of most patients to shower with other men or to go to the sauna is the usual cosmetic barometer (Figure 76.10).

The potential aesthetic drawbacks of the radial forearm flap are the need for a rigidity prosthesis and possibly some volume loss over time.

Of the various flaps used for penile reconstruction, the radial forearm flap has the greatest sensivity.[78] Monstrey et al. always connect one antebrachial nerve to the ilioinguinal nerve for protective sensation, and the other forearm nerve with one genital nerve (clitoral nerve in transsexual patients and dorsal penile nerve in males).

After 1 year, all patients had regained tactile sensitivity in their penis, which is an absolute requirement for safe insertion of an erection prosthesis.[78]

In a long-term follow-up study on postoperative sexual and physical health, more than 80% of the patients reported improvement in sexual satisfaction and greater ease in reaching orgasm (100% in practicing postoperative female-to-male [FTM] transsexuals).[79]

For biological males as well as FTM transsexuals undergoing a phalloplasty, the ability to void while standing is a high priority.[80] Unfortunately, the reported incidences of urological complications, such as urethrocutaneous fistulas, stenoses, strictures, and hairy urethras, are extremely high in all series of phalloplasties, even up to 80%.[35] For this reason, certain (well-intentioned) surgeons have stopped reconstructing a complete neourethra.[74,82]

In their series of radial forearm phalloplasties, Monstrey et al.[75] still reported a urological complication rate of 41% (119/287), but the majority of these early fistulas closed spontaneously, and ultimately *all* patients were able to void through the newly reconstructed penis.[83]

The major drawback of the radial forearm flap has always been the unattractive donor site scar on the forearm (Figure 76.11a and b). Selvaggi et al. conducted a long-term follow-up study[84] of 125 radial forearm phalloplasties to assess the degree of functional loss and aesthetic impairment after harvesting such a large forearm flap. An increased donor site morbidity was expected, but the early and late complications did not differ from the rates reported in the literature for the smaller flaps, as used in head and neck reconstruction.[84] No major or long-term problems (such as functional limitation, nerve injury, chronic pain or edema, or cold intolerance) were identified. Finally, with regard to the aesthetic outcome of the donor site, they found that the patients were very accepting of the donor site scar, viewing it as a worthwhile trade-off for the creation of a phallus.[84] Suprafascial flap dissection, full-thickness skin grafts, and the use of dermal substitutes may contribute to a better forearm scar.

Anterolateral Thigh Flap

The development of perforator flaps has given rise to some new reconstructive options in patients with severe (congenital) penile insufficiency. Perforator flaps have the advantage of reducing the donor site morbidity, increasing the range of motion, and combining different tissue flaps on one single pedicle. Although, overall, the free vascularized radial forearm flap, the pedicled ALT flap is considered the gold standard phalloplasty alternative specifically in patients with congenital penile insufficiency. This flap is a skin flap based on a perforator from the descending branch of the lateral circumflex femoral artery, which is a branch from the femoral artery (Figure 76.12).

The potential advantages of the ALT flap are

- A pedicled flap reconstruction (the flap has a sufficiently long pedicle) avoids the technically more complex microscopic procedure and might also shorten the operation time.
- A visible donor site scar on the forearm, often considered the signature of FTM transsexualism, is avoided and the donor site on the leg can more easily be concealed.
- Previous reconstructive surgeries at the pelvis, groin area, and lower abdomen (e.g., in case of bladder exstrophy) might have altered the local anatomy and vasculature, making a microsurgical anastomosis more difficult.
- The subcutaneous fat layer is much thinner than in a (biologically female) trans man, facilitating the (urethral) tube-within-a-(penile)-tube reconstruction of the penis; moreover, many exstrophy patients empty their bladder by catheterization through a continent diversion (e.g., appendicovesicostomy) and do not even require a urethral reconstruction in their phalloplasty. An ejaculatory opening can be left at the ventral aspect just above the scrotum.

It is very important to preserve and incorporate any useful glandular, penile, and cavernosal tissue at the base

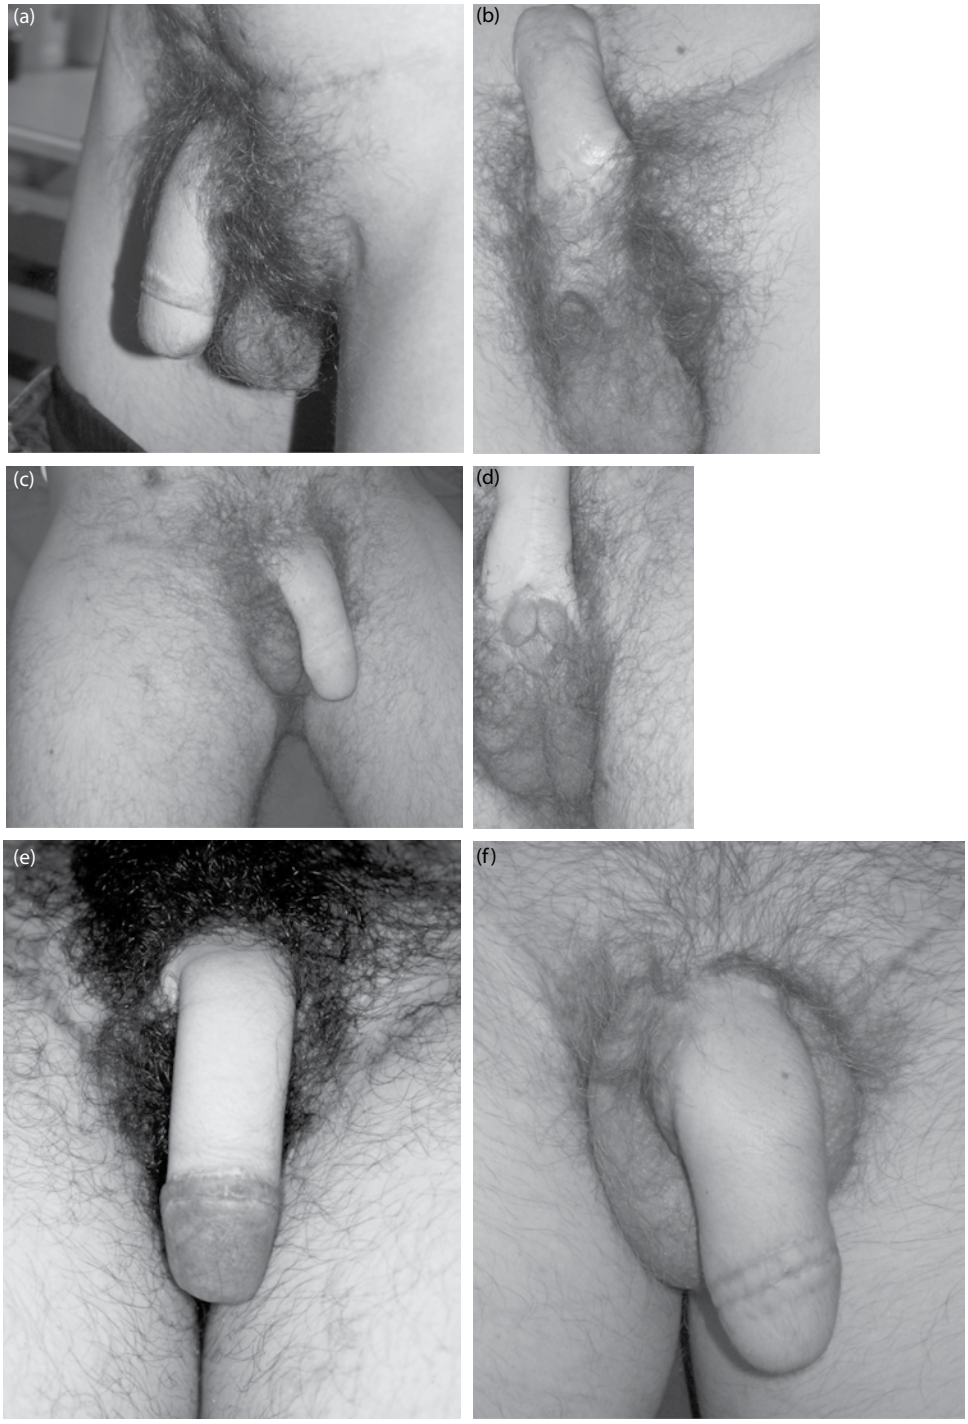

FIGURE 76.10 Late postoperative results of radial forearm phalloplasties.

of the newly reconstructed phallus in order to facilitate sexual stimulation and pleasure (Figure 76.11c). If available, a dorsal penile nerve is identified and connected with a cutaneous nerve of the flap; if not available, the lateral femoral cutaneous nerve is connected to the ilioinguinal nerve.

Usually, it is recommended to perform a three-dimensional angio CT scan preoperatively to provide detailed information on the perforator vessels and the subcutaneous tissue layer.

Unfortunately, similar to the radial forearm flap, the ALT flap also has a rather high urological complication rate, with frequent strictures and/or fistula formation. Secondary procedures might be needed to treat these complications, and especially the treatment of urethral strictures is challenging and difficult.

Especially in exstrophy repair where the closure of the pelvic ring has been unsuccessful and the distance to the femoral vessels is large, this flap is a good option. Some examples are show in Figure 76.13.

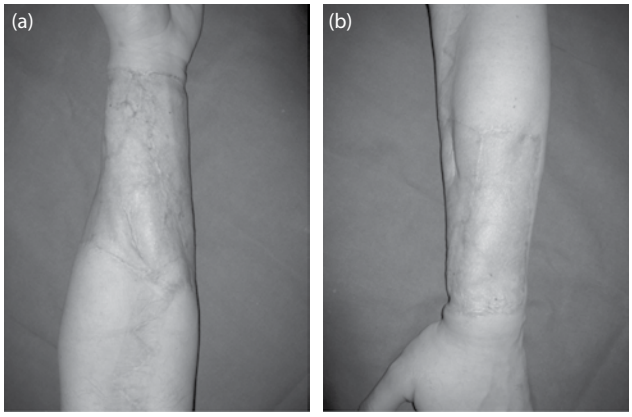

FIGURE 76.11 (a and b) Late result of the donor site at the forearm.

Erection Prosthesis

In phalloplasty, the insertion of an erection prosthesis is required in order to engage in sexual intercourse. In the past, attempts have been made to use bone or cartilage, but no good long-term results are described. The rigid and semirigid prostheses seem to have a high perforation rate and therefore were initially not used in our patients. Hoebeke et al., in the largest series to date on erection prostheses after penile reconstruction, only used the hydraulic systems available for impotent men. A recent long-term follow-up study showed an explantation rate of 44% in 130 patients, mainly due to malpositioning, technical failure, or infection. Still, more than 80% of the patients were able to have normal sexual intercourse with penetration.[83] In another study, it was demonstrated that patients with an erection prosthesis were more able to attain their sexual expectations than those without a prosthesis (Figure 76.14a and b).[79]

A major concern regarding erectile prostheses is long-term follow-up. These devices were developed for impotent (older) men who have a shorter life expectancy and who are sexually less active than the mostly younger patients with penile insufficiency. More specifically, the hydraulic systems tend to be susceptible to leak after 5–10 years. Actually, some newer semirigid devices have become available that hopefully are more durable and will decrease the need for revision surgery.

GENERAL CONCLUSION

In this chapter, an overview of actual reconstructive techniques for severe penile insufficiency was given.

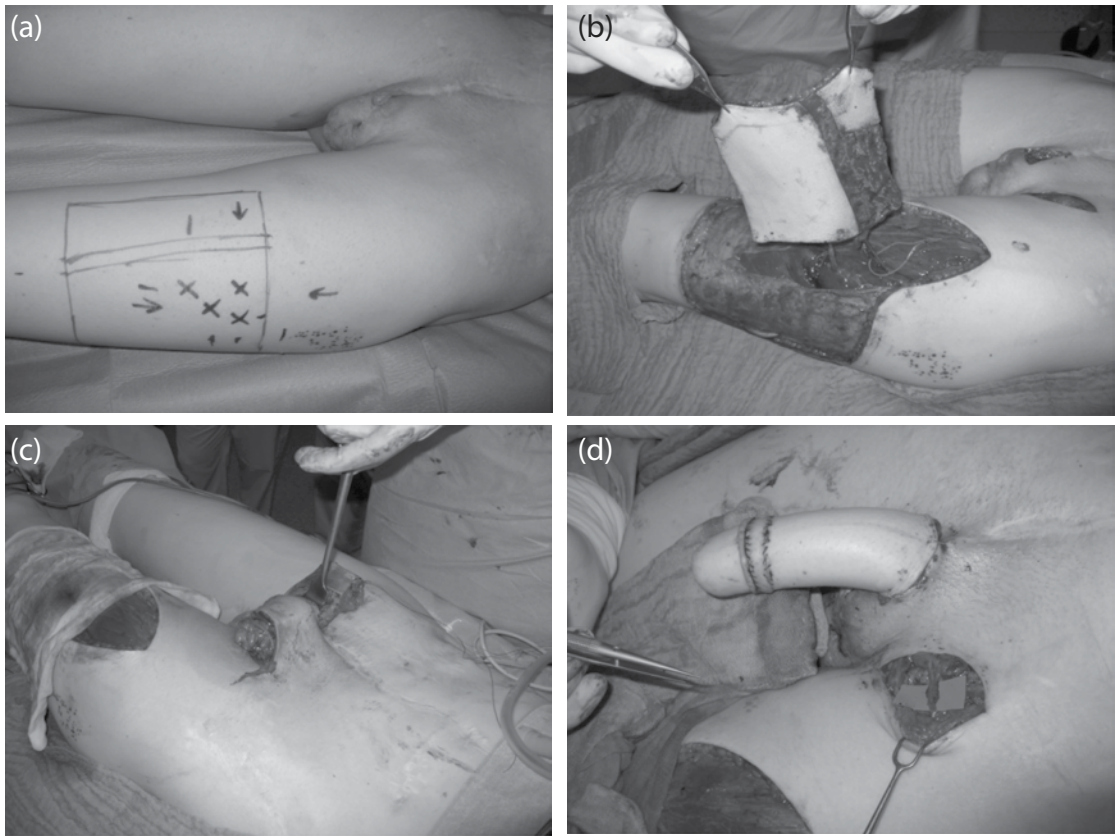

FIGURE 76.12 (a and b) The reconstruction of a penis with a pedicled ALT flap used as a tube-within-a-tube technique (only possible in thin boys without a penis and after defatting). No real urethra was reconstructed here since the patient had a urostomy. (a) Preoperative view. (b) After flap dissection. (c) The flap is tunneled underneath the rectus femoris muscle. (d) Suturing and nerve connection (ilioinguinal nerve to lateral femoral cutaneous nerve).

CHAPTER 77

Hernia, Hydrocele, Testicular Torsion, and Varicocele

Hiep T. Nguyen and Guilherme Rossini

INTRODUCTION

Problems associated with the testis, such as hernia or hydrocele, testicular torsion, and varicocele, are common in infants and children. These conditions range in acuteness and severity, from being one of few pediatric urologic emergencies to a benign process that is likely to resolve and therefore warrant just observation. While their diagnosis can be difficult to make at times, problems associated with the testes mandate accurate and prompt recognition in order to prevent potential testicular damage or loss. Their management options are often diverse and controversial, requiring the clinician to be aware of these issues in counseling the patients or their parents. While these conditions can be correct surgically, they may have long-term consequences, such as testicular atrophy and infertility, requiring further follow-up care after surgical management.

HERNIA AND HYDROCELE

Definition and Incidence

An inguinal hernia is defined as a protrusion of organ or tissue through an abnormal opening in the lower abdominal wall. A direct inguinal hernia results from a weakness in the floor of the inguinal canal, allowing abdominal content and fluid to herniate through the external ring, medial to the epigastric vessels. In contrast, an indirect inguinal hernia results from a patent *processus vaginalis* (PV), allowing abdominal content and fluid to herniate through the internal ring. A direct inguinal hernia is uncommon in children, while an indirect one is more common in this age group. A hydrocele is defined as an accumulation of fluid around the testis. A communicating hydrocele results from a patent PV in which the opening through the internal ring is small, allowing fluid but not bowel to enter the scrotum. A noncommunicating hydrocele results from a patent PV in which the opening through the internal ring is closed, but the PV is not completely obliterated. Since there is no communication with the peritoneum, the fluid in the noncommunicating hydrocele originates from the mesothelial lining of tunica vaginalis as a result of inflammation of the testis or epididymitis. A communicating hydrocele is common in children, while a noncommunicating hydrocele is more common in adolescents.

Hernia and hydrocele occur in approximately 1%–3% of full-term infants, but are three times more common in premature infants.[1,2] With regards to hernia, the male-to-female ratio is 8 to 1. A hernia or hydrocele occurs more often on the right than the left (2:1) and is present bilaterally in 16% of the patients.[1] Ten percent of children with a hernia or hydrocele will have a positive family history. Approximately one-third of the children with a hernia or hydrocele will be diagnosed before 6 months of age. An increased incidence of hernia or hydrocele is seen in patients with cystic fibrosis (15%);[3] connective tissue disease, such as Ehlers–Danlos and Hunter–Hurler syndrome;[4,5] and congenital hip dislocation.[6] Children with a ventriculoperitoneal shunt or on peritoneal dialysis continuous ambulatory peritoneal dialysis (CAPD) are also at higher risk of developing a hernia or hydrocele.[7]

Etiology and Pathophysiology

In the male fetus, the testes develop from the cranial end of the mesonephros. The gubernaculum forms from a band of condescended mesenchyme, connecting to the lower pole of each testis. Around the eighth week of gestation, an outpouching of mesothelial cells from the coelomic cavity grows into the substance of gubernacular mesenchyme, forming the PV. The PV is composed of a lining of simple mesothelium, surrounded by a fibrous layer of variable thickness and fatty connective tissue containing blood vessels, nerve trunks, lymph nodes, and a variable amount of muscle.[8] The skeletal muscles of the PV are derived from the transverse abdominis muscle, and the smooth muscle component is derived from the dartos muscles. Occasionally, the lining of the PV undergoes proliferation due to chronic irritation. It may contain papillary structures or nodules. On histologic examination, fibrin deposition, extensive scarring, and psammoma bodies may be evident. In addition, mesothelial hyperplasia may be present with multinucleated cells, forming tubule-like structures within the fibrous tissue. These structures may appear to invade into the fibrous subserosa of the irritated PV. These features are often confused with those of rhabdomyosarcoma, mesothelioma, and metastatic carcinoma.[9]

By the 28th week of gestation, the testes begin to move from the posterior abdominal wall to the internal ring, as a result of growth of the fetal trunk and pelvis. The PV forms a channel through which the testes descend into the scrotum. It is believed that testicular descent is directed by the gubernaculums[10] and assisted by the PV, which allows transmission of the abdominal pressure to the fetal testes, causing their descent through the inguinal canal.[11] The passage through the inguinal canal takes approximately 3 days and appears to be regulated by the genitofemoral nerve and the release of the calcitonin gene-related peptide (CGRP).[12,13] The testes enter the scrotum between the 32nd and 38th week of gestation; in some patients, this process may be delayed up to the 40th week of gestation.

After the descent of the testes, the entrance to the inguinal canal, the internal ring, closes and the lumen of the PV is obliterated. Progressive fibrous obliteration of the PV occurs in a cephalad direction beginning above the epididymis.[14] Organ culture of the PV from human infants demonstrates the presence of a CGRP receptor on the mesechymal fibroblasts, but not the epithelial cells. Addition of CGRP induces fusion of the PV through its effects on the fibroblasts.[13] In the future, CGRP may be utilized in the clinical management of hernia or hydrocele in children.[15] In addition, it is observed that a patent of the PV is often seen in association with epididymal abnormalities.[16] Since epididymal development is dependent on androgen stimulation, it is speculated that closure of the PV is also regulated by androgen. Another suggested mechanism to account for the persistently patent PV is the failure of smooth muscles in the PV to regress. Normally, these muscles disappear after taking part in the descent of the testis, a process that appears to be regulated by the autonomic system. In patients with a hernia, the muscles fail to undergo apoptosis and maintain the patency of the PV.[17–20]

In the female fetus, the ovaries descend in a similar manner, except that the process is halted in the pelvis. The cranial portion of the gubernaculum forms the ovarian ligament, and the caudal portion forms the round ligament, which runs from the uterus to the labia majora. It appears that the gubernaculum also plays a role in guiding ovarian descent.[21] Only rudimentary development of the PV occurs, forming the canal of Nuck.

Presentation and Diagnosis

Children with a hernia or hydrocele often present with a history of a painless lump or bulge in the groin, scrotum, or labium (Figure 77.1). In younger children, this bulge may be more obvious while the child is crying, straining, or doing maneuvers that increase abdominal pressure. In older children, the hernia or hydrocele often gets larger during the day and smaller at night or during time of recumbency. Occasionally, a child may present with symptoms similar to those of acute testicular torsion, resulting from torsion of the hernia sac.[22,23] Approximately 10% of patients with an inguinal hernia present to medical attention with symptoms of bowel obstruction, such as nausea, vomiting, abdominal distension, and localized or generalized abdominal tenderness.

On physical examination, bowel can be palpated or heard during manipulation of the inguinal or scrotal bulge in patients with a hernia. Occasionally, a silk glove sign can be detected on exam, as the layers of PV can be felt around the spermatic cord, feeling like silk rubbing on silk. It has been suggested that the silk glove sign is not due to an empty hernia sac but the hypertrophied cremasteric muscle fibers.[24] Unfortunately, this physical finding is very inaccurate in the absence of finding an obvious hernia or hydrocele.[25] It should be noted that in most patients with a hernia, there are no findings on physical examination, and the diagnosis is dependent on the clinical history alone.

Typically, a nontender bluish discoloration to the scrotum and a soft mass around the testis are noted in patients with a hydrocele. In others, a painless mobile cystic swelling may be found anywhere along the spermatic cord. Termed a cord or encysted hydrocele, it is not reducible and can often be confused with a hernia.[26] Rarely, a child may present with an abdominoscrotal hydrocele in which a scrotal hydrocele has a dumbbell-shaped extension through the internal ring into the abdomen that forms an intra-abdominal cystic mass. In most patients,

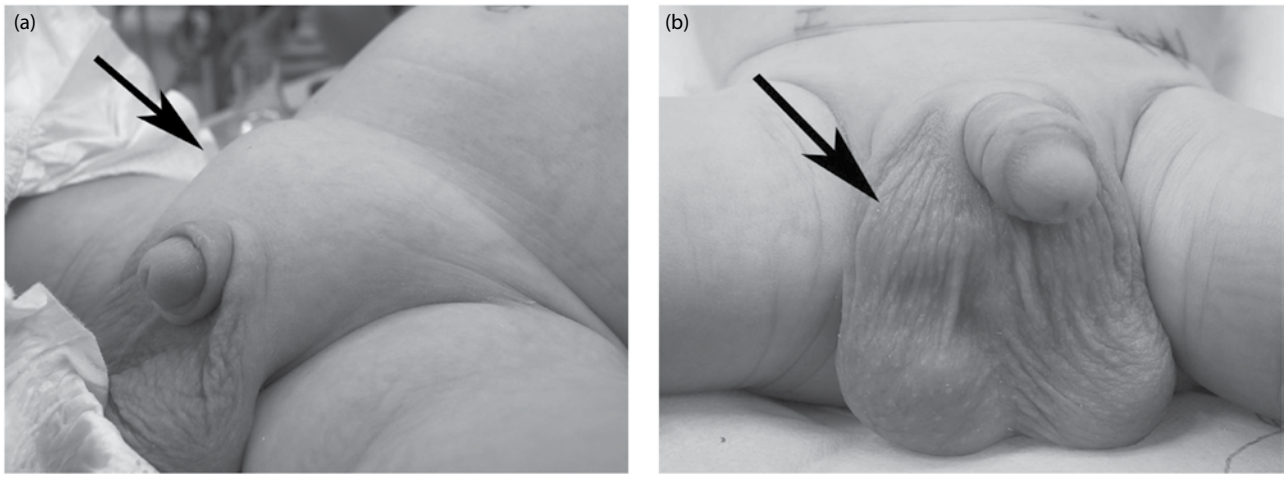

FIGURE 77.1 On physical examination, a bulge can be seen in the groin (a) or in the scrotum (b), distinct from the testis in infants with an inguinal hernia.

the hydrocele contains an exudative fluid. However, other fluid types have also been found in association with a hydrocele. A meconium hydrocele results from an in utero perforation of bowel and subsequent inflammation and calcification of the meconium.[27] A pyocele can develop in association with acute appendicitis,[28,29] infection of the epididymis or testis, tuberculosis peritonitis,[30,31] or primary bacterial infection.[32] A pneumocele may develop as a consequence of necrotizing enterocolitis or other causes of bowel perforation.[33] A hematocele can form as a result of blunt abdominal trauma with associated splenic injury or scrotal injury.[34] A hydrocele may also contain ascites fluid, such as bile, chyle, urine, cerebrospinal fluid in patients with a ventriculoperitoneal shunt, or dialysate fluid in patients on peritoneal dialysis. Hydrocele may also occur in girls, arising from the canal of Nuck.[35]

Being able to distinguish a hernia from a hydrocele on physical exam is often difficult. It has been suggested that transillumination may be used to identify a hydrocele (Figure 77.2). However, it should be noted that since bowel fluid and air will transmit light in a manner similar to that of hydrocele fluid, this finding is not reliable. When a scrotal mass is easily reducible, this suggests that there is a large patent PV representing either a hernia or a large communicating hydrocele. In contrast, when the mass is not reducible, it is likely to represent either a noncommunicating hydrocele, one with a small patent internal ring, or an incarnated hernia.

In most patients with a hernia or hydrocele, the diagnosis can be made by clinical history and physical examination. In those few patients in whom the diagnosis cannot be well established, further radiological examination may be helpful in establishing the diagnosis. In addition, when the testis cannot be palpated on physical examination, further radiological imaging is required to rule out potentially serious pathologies, such as undescended testis, infection, or testicular cancer. Ultrasonography (US) is widely utilized in evaluating inguinal and scrotal pathology. In patients with a hernia, fluid or air-filled loops of bowel may be identified in the inguinal canal or scrotum. When there is omental herniation, hyperechoic masses can be seen. However, it should be noted that US often fails to detect herniated bowel loops since the herniation is often periodic. In the absence of finding bowel or fluid in the inguinal canal, an increased groin width, as measured by US (7.2 ± 2.0 mm compared with 3.6 ± 0.8 mm in normal inguinal canal), has been used as diagnostic criteria for a hernia.[36] In contrast, a hydrocele on US can be identified by identifying fluid in between tunical layers and the normal testis or epididymis. The hydrocele may contain loculations. Fine-particulate matters seen on US may represent pus or blood, while calcification (seen as hyperechoic masses) suggests the presence of meconium.

Aside from US, other imaging techniques are seldom helpful in the diagnosis of a hernia or hydrocele. A kidney, ureter, and bladder (KUB) may demonstrate air or calcification in the scrotum, suggesting the presence of a pneumocele or meconium hydrocele, respectively. Herniography has been utilized in the diagnosis of a hernia.[37] Iothalamate solution (60%) is injected into the peritoneum. The patient is placed in an upright position for 10 minutes; a KUB or a computed tomogram (CT) is obtained to identify contrast lining the patent PV or hernia sac.[38,39] Because of potentially serious complications, such as bowel injury, contrast reaction, and peritoneal irritation, its use is limited to special circumstances, such as evaluating chronic groin pain.[40,41]

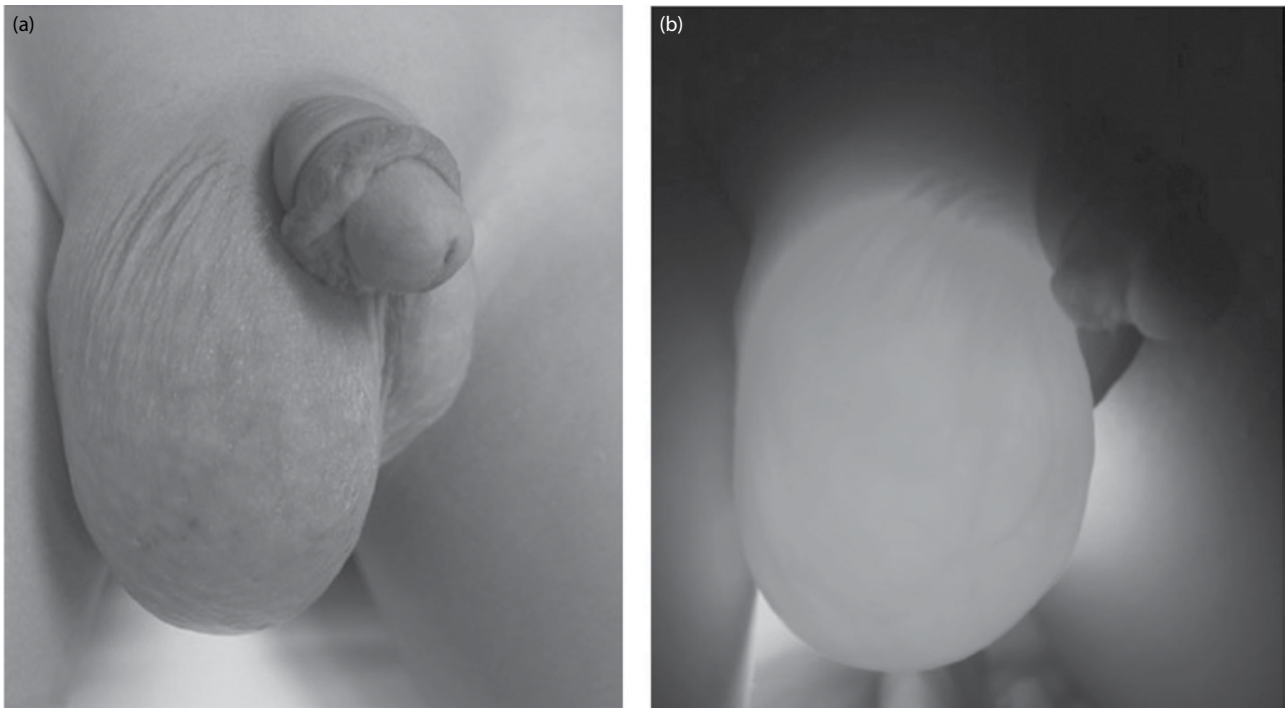

FIGURE 77.2 On physical examination of a boy with a hydrocele, scrotal swelling can be seen involving the testis (a), and it does transilluminate (b).

Management and Techniques

Hernia Repair

Currently, there is no effective medical management of a hernia; the use of a truss is primarily of historical interest. Since inguinal hernia is likely to persist indefinitely, it is recommended that children who are diagnosed with an inguinal hernia undergo surgical repair to prevent bowel incarceration and potential testicular atrophy. This is of particular importance in premature infants and neonates, who are at higher risk of developing bowel incarceration while waiting for surgery.[42] In extremely premature infants, hernia repair can be safely deferred until the child is ready to be discharged from the neonatal unit.[43] It is reported that the success rate for hernia repair approaches 99%.

For the parents, one potential concern in the surgical management of hernia or hydrocele is the possible harmful effects of general anesthetics on the brain development of the infants. Animal studies suggest that early exposure to anesthesia may impair normal neuronal development. However, epidemiological studies in children exposed to surgery with anesthesia early in life are contradictory and can neither rule out nor confirm anesthetic-related neurotoxicity.[44] Currently, most experts believe that general anesthesia within the first 1–2 months should be reserved for emergencies, while elective surgery after 3–6 months is safe. The type of surgical repair is dependent on the type of inguinal hernia. The direct inguinal hernia requires reconstruction of the floor of the inguinal canal with or without the use of prosthetic materials, such as polypropylene, Dacron, or polytetrafluoroethylene (PTFE). Since it is an uncommon type of hernia in children, a review of all types of direct inguinal hernia repair is beyond the scope of this chapter but is provided by Read.[45] Repair of the indirect hernia can be approached with either an open or a laparoscopic technique. Czerny and Banks was credited with introducing the concept of high ligation of the hernia sac in 1877. In brief, an inguinal incision, which is preferably hidden in a skin crease, is made approximately one-third the distance from the pubic tubercle to the anterior iliac spine. Scarpa's fascia is next incised, and the external oblique fascia is exposed. The shelving edge of the fascia is then defined with blunt dissection; this will allow for easier closure of the external oblique fascia later. To expose the inguinal canal, the fascia is incised along the direction of the fibers, parallel to the shelving edge over the external ring. After identifying the spermatic cord, the cremasteric muscles are separated to expose the hernia sac, which is located superior medial to the vas and testicular vessels. The hernia sac is carefully dissected from adjacent structures and divided between hemostats (Figure 77.3). The hernia sac is next freed proximally to the internal ring, where it is ligated with absorbable sutures. The distal portion of the hernia sac is opened down to the testis to prevent hydrocele formation. A similar technique is done for the repair of inguinal hernia in girls (Figure 77.4). It is important in these patients to open the hernia sac to ensure that there are no herniated

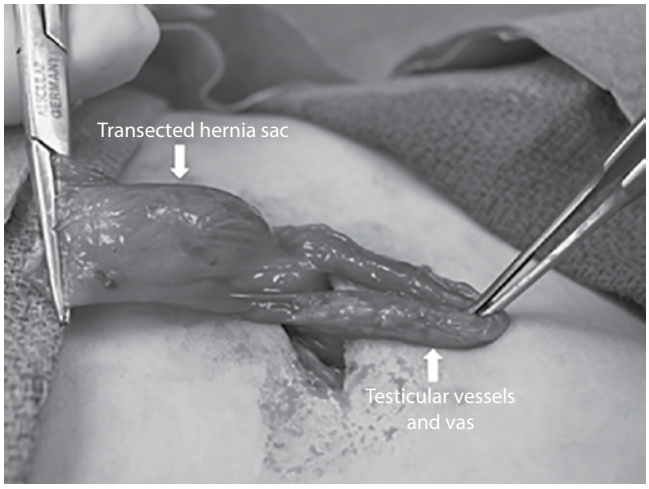

FIGURE 77.3 During the repair of an inguinal hernia, the hernia sac, which is located anterior medial to the spermatic cord, is carefully dissected away from the cord, ligated, and divided.

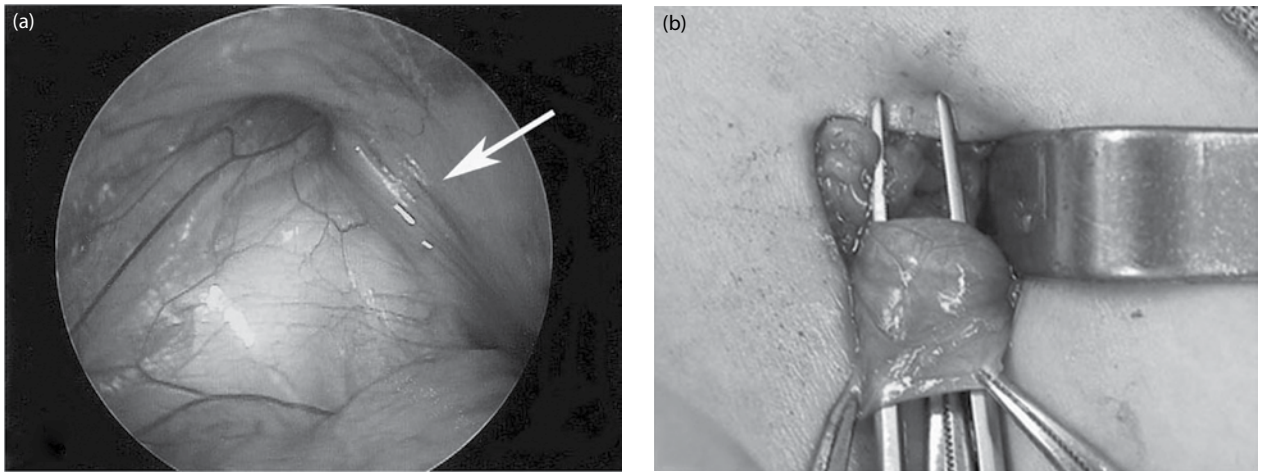

FIGURE 77.4 Inguinal hernia can also develop in girls. (a) On laparoscopy, an opened internal ring can be seen with the ovarian ligament (arrow) entering it. (b) On inguinal exploration, a hernia sac is identified. The hernia sac should be carefully examined to make sure that there are no structures herniating through the sac.

structures, such as gonads or fallopian tubes. Variations of this technique include approaching the hernia sac through a scrotal[46] or a low inguinal groove incision.[47] However, it should be noted that these approaches might limit surgical exposure to allow high ligation of the hernia sac near the internal ring.

The repair of the indirect hernia may also be performed by laparoscopy. The internal ring can be approached either transperitoneally or preperitoneally,[48] and the opening closed with a metal clip or sutures.[49] The surgical success rate using this technique is approximately 97%.[50,51] The laparoscopic approach is especially useful in patients with recurrent hernia. It allows for identification of the etiology of the recurrence, such as incomplete ligation of the hernia sac, the de novo development of a direct hernia, and the presence of other types of hernias, such a femoral hernia.[52,53] More recently, the use of needlescopic hernia repair has been advocated. In brief, a 1.7 mm needle laparoscope is introduced through the umbilicus to visualize the opened internal ring. Through a second port placed laterally, a grasper may be placed in the abdomen to help in the traction of the spermatic cord. A 2–3 mm incision is then made in the skin directly over the internal ring, and a suture is passed percutaneously anterolateral to the internal ring to perform an extraperitoneal high ligation of the hernia sac.[54] Long-term results and complication rates using this technique are not yet known.

Hydrocele Repair

Unlike hernias, hydroceles may resolve spontaneously during the first year of life. Thus, in the absence of a hernia, surgical treatment for hydroceles can be deferred and observation is warranted. In older children who acutely present with a hydrocele, the underlying etiology, such as epididymitis or orchitis, should be treated. If the hydrocele persists several months after treatment, surgical repair may be considered. In young children, the hydrocele repair is performed in a manner similar to that described for repair of the indirect hernia, since these patients are likely to have a patent PV. Particular attention should be paid to opening up the PV distally to testis to prevent recurrence of the hydrocele. In older children, the hydrocele repair can be performed through a midline or transverse scrotal incision since there is a low likelihood of a patent PV. The tunica vaginalis can be excised, everted (the bottle procedure), or imbricated (the Lord procedure). Sclerotherapy has been used in the treatment of hydroceles. The hydrocele is injected with a sclerosant such as tetracycline or polidocanol.[55] Complications include pain, long-term hazards of the sclerosant, and leakage of the sclerosant through a patent PV. In addition, recurrence following treatment is common. Consequently, sclerotheraphy is not recommended for children.

Potential Structures Encountered in the Hernia Sac during Surgery

Numerous structures can be potentially encountered in the hernia sac; therefore, great care should be taken when dividing the sac. Typically, the hernia sac may contain intestine (small bowel, large bowel, appendix, and Meckel diverticulum) or omentum. Occasionally, the bladder or intra-abdominal catheters, such as a CAPD catheter or a ventriculoperitoneal (VP) shunt, may herniate through the sac.[56] Less frequently, ectopic tissue such as that from the adrenal cortex,[57] spleen,[58] liver,[59] kidney,[60] and brain[61] can be found in the hernia sac. In a few rare cases (<0.1% of hernia repairs in adults and even less in children[62]), an unexpected discovery of a neoplasm is made during a hernia repair. Types of neoplasm found in the hernia sac include primary mesothelioma and liposarcomas,[57] extrarenal Wilms' tumor,[63] and metastatic cancer from the gastrointestinal tract, the ovaries, and the prostate.[8]

More frequently, the gonads and their associated structures may be encountered in the hernia sac. Despite having a palpable testis in the ipsilateral hemiscrotum, an additional testicle may be found at the time of hernia repair in boys with supernumerary testis[64] or cross-testicular ectopia. In approximately 2%–3% of phenotypic girls undergoing hernia repair, a testis may be found in the sac, suggesting the diagnosis of testicular feminization syndrome.[65,66] In these patients, the testis can be removed either after puberty to reduce the risk of germ cell malignancy (such as gonadoblastoma) or at the time of hernia repair to reduce the risk of virilization when the androgen insensitivity is not complete. An ovary can also be found in the hernia sac in 4% of girls undergoing surgery. Approximately 25% of these patients will have evidence of torsion effects or infarction in the herniated ovary.[67] Less often, genital duct structures are identified at the time of surgery or during pathological evaluation. Functional Wolffian duct derivatives, such an accessory vas or epididymis, may be seen separate from the spermatic cord. In patients with hernia uterine inguinale who have an anti–Mullerian inhibiting factor or its receptor defect, persistent Mullerian structures, such as a uterus, may be found in the hernia sac.[67–69] Due to the close relationship with Wolffian duct structures, great care has to be taken in excising the persistent Mullerian structures. In 2%–6% of the cases, nonfunctional Mullerian or Wolffian remnant structures can be identified in the hernia sac.[70,71] These structures are characterized by ciliated low columnar cells with occasional interspersed pale round cells, occurring singly, in small groups or in large clusters.[72] They are smaller than functional duct derivatives and lack significant muscular coats. Given the potential for finding various structures in the sac, some clinicians have recommended sending the hernia sac routinely for pathological examination. However, Miller et al.[73] observed that in their series of 456 patients, only 4 cases (0.88%) had unexpected findings on pathological evaluation of the hernia sac. None of these cases were of clinical significance (i.e., changed the patient management). The authors concluded that the routine histologic evaluation of inguinal hernia sacs in children is an unnecessary expense and should be reserved for select cases at the discretion of the surgeon.

Management of the Contralateral Patent Processus Vaginalis

In children who present with a unilateral hernia, much controversy exists as to the management of the contralateral side. Some surgeons recommend routinely exploring the opposite side for a patent PV, while others are more selective based on clinical criteria, such as age or sex.[74,75]

Some utilize further radiological imaging, such as US,[76] or perform diagnostic pneumoperitoneum[77] or laparoscopy through the umbilicus[78,79] or hernia sac[80,81] to diagnose a patent PV. Others recommend just observation for the development of a contralateral hernia. From autopsy studies, it is observed that the incidence of a patent PV is 90% in preterm infants, 80% in newborns, 60% in children less than 1 year of age, and 15%–30% in adults.[82,83] From studies in which the patency of the contralateral PV was assessed in children with a unilateral hernia, it is observed that the incidence of a patent PV is also age dependent. Approximately 60% of children less than 2 months of age who had a unilateral hernia had a patent contralateral PV. This incidence declines during the first 2 years of life and stabilizes at 40% in children from 2 to 16 years of age.[75,84]

Several studies have also observed that the incidence of a contralateral hernia developing following unilateral hernia repair ranges from 3.6% to 10% (an average of approximately 7%),[85–89] far exceeding the rate of a patent PV. Chertin et al. similarly found that the incidence of developing a contralateral hernia in 300 girls who presented with a unilateral hernia and underwent a unilateral repair was 8%.[90] Using a univariate analysis with the Cox regression models, Ikeda et al. observed that a left-sided hernia and a positive family history were significantly associated with the metachronous development of a contralateral hernia.[91] However, the incidence was at most 10%. Miltenburg et al. performed a meta-analysis of the risk of metachronous hernia in infants and children and found that there was a 7% risk of developing a contralateral hernia following unilateral repair.[92] Gender and age were not risk factors. Similar to the findings by Ikeda et al.,[91] there was an 11% risk of metachronous hernia if the original hernia was on the left side, a risk that was 50% greater than if the original hernia was on the right. Of patients who developed a metachronous hernia, 90% did so within 5 years, with a complication rate of 0.5%.[78] Based on these findings, it can be concluded that patients with a patent PV do not necessarily progress to develop a clinically apparent inguinal hernia. Concurrent management of a contralateral PV is of probable benefit in premature and young infants, where the risk of a second anesthesia is high, and in children with risk factors for hernia recurrence, such as cystic fibrosis or connective tissue disease. Interestingly, it was observed that in a study in which the parents were presented with the above issues and asked to choose between unilateral hernia repair only or with concomitant evaluation and repair of a contralateral patent PV for their child, 85% of the parents chose the latter.[93] Approximately 80% of those who chose the latter surgical option indicated that convenience was the primary motive in their choice, and only 19% had concerns about their child undergoing a second anesthesia if a contralateral hernia later developed.

Complications of Hernia or Hydrocele Repair

In general, the complication rate is higher in patients undergoing hernia repair than in those undergoing hydrocele repairs and in emergent compared with elective repair. The primary concern is associated with the anesthetic risk;[94] this is of particular significance in premature infants and those less than 3 months of age. Improvement in pediatric anesthesia techniques, such as the use of laryngeal mask[95] with caudal[96] or local anesthesia and the use of regional anesthesia in premature infants,[97] has greatly decreased the risk of potential anesthetic complications. Early complications associated with a hernia or hydrocele repair include local edema, hematoma, and wound infection. Early recurrence of inguinal or scrotal swelling may be due to a missed hernia or refilling of the potential space with fluid. Late complications include iatrogenic, upward displacement of the testis (incidence of 1% in children undergoing hernia repair);[98] paravesical abscess;[99] damage to spermatic cord; and recurrence. The incidence of spermatic cord injury during uncomplicated inguinal hernia surgery is approximately 1%, and less during hydrocele repair.[100] However, if the hernia is incarcerated, the risk of spermatic cord injury increases significantly to 6%–10%, with a subsequent testicular atrophy rate of 4%.[101] It is suggested that due to pressure, the bowel incarceration induces ischemia on the spermatic cord. The rate of recurrence following open hernia or hydrocele repair is approximately 1%–3%; however, it may be as high as 20% in premature infants undergoing repair.[45] Recurrence may be due to failure to dissect a complete sac, tearing of the sac, or slippage of sutures in ligating the sac. Moreover, in patients with recurrent hernia, other pathologies, such as connective tissue diseases, should be considered. Hydrocele formation following hernia repair with either an open or laparoscopic approach occurs in less than 1% of the patients.[50,51]

TESTICULAR AND APPENDICAL TORSION

Definition and Incidence

Normally, the tunica vaginalis covers the anterior surface of the testis, epididymis, and various distances over the spermatic cord. Attachment with the gubernaculum and scrotal wall posteriorly allows the testis to be fixed, preventing its twisting around the vascular mesentery. However, when these attachments are not secure, torsion of the testis may occur, leading to vascular compromise. Although testicular torsion can occur at any age, there is a bimodal distribution in the age of presentation, during puberty and during the neonatal period. More commonly in adolescents, testicular torsion involves torsion of the spermatic cord within the tunica vaginalis, an intravaginal torsion. Due to abnormal fixation of the testis and epididymis, the testis is allowed to freely hang within the tunical cavity. This "bell clapper" deformity allows the testis to adopt a horizontal position in the scrotum (Figure 77.5a). It is found in 12% of testes at postmortem, and frequently occurs bilaterally.[102] It is the most common etiology of torsion in adolescents, in whom rapidly increasing testicular mass associated with puberty increases the chance of the testis rotating. Intravaginal testicular torsion can also occur intermittently, spontaneously twisting and untwisting (Figure 77.5b). Torsion of an undescended testicle is an uncommon condition in adolescence and adulthood;

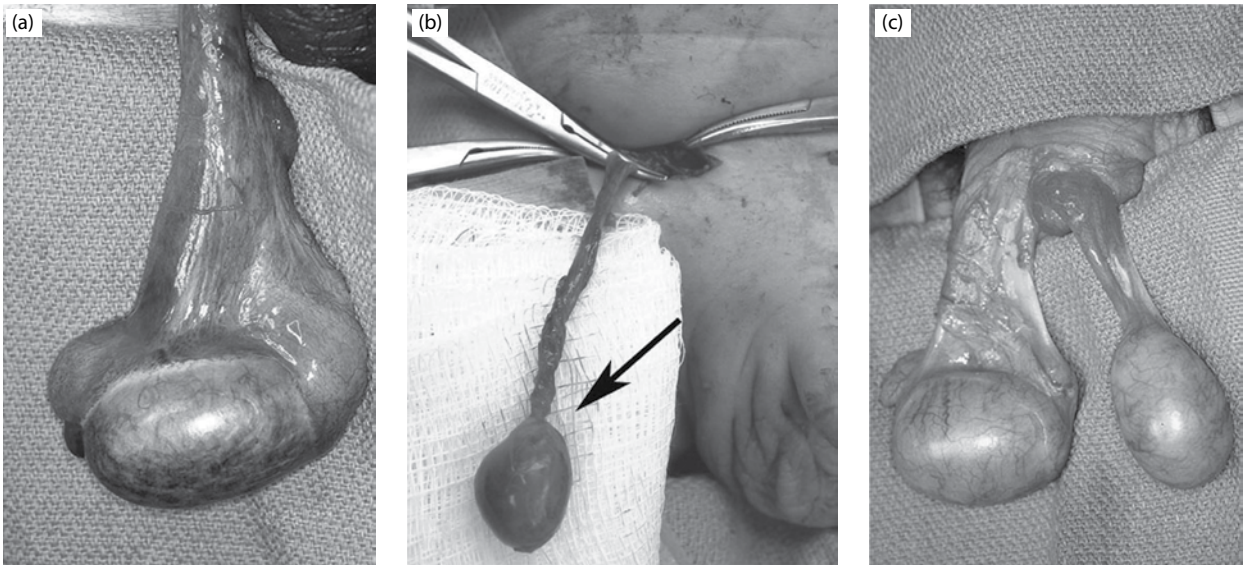

FIGURE 77.5 (a) In adolescents, testicular torsion occurs intravaginally, commonly due to the bell clapper deformity. (b) In neonates, testicular torsion occurs extravaginally, in which the entire cord is twisted about its axis (arrow). (c) In children with intermittent torsion, such as the one shown here, who presented with intermittent left testicular pain, a bell clapper deformity (left testis) is often seen on the affected side.

however, it is reported to occur more frequently than torsion of a normally descended testis. In a patient with pain and uncorrected cryptorchidism, a testicular tumor must also be considered in the differential diagnosis.[103]

Approximately 10% of all testicular torsions occur in newborns. In 70% of these patients, torsion occurs prenatally and is diagnosed at the time of birth. In the other 30% of patients, torsion occurs in previously normal testes.[104] Testicular torsion in newborns occurs primarily extravaginally. In the neonatal period, the descending or recently descended testis and its coverings are very mobile within the scrotum, creating a risk for the spermatic cord to twist en masse (Figure 77.5c). Multiparity, excessive uterine pressure, and a strong cremasteric contraction have been suggested as etiologic factors for extravaginal torsion.[105]

Torsion of the testicular appendages may also occur. The appendix testis is a vestigial remnant of the Mullerian system located on the upper pole of the testis. It is found in 90% of males and bilaterally in 60% (Figure 77.6a). Appendages may also be found on the epididymis (Figure 77.6b), epididymotesticular grove, or the cord itself. These appendages are remnants of the Wolffian system. Approximately 95% of the appendical torsions involve the appendix testis. The peak age of presentation is around 10 years.[106] It has been suggested that hormonal stimulation during pubertal development increases the size of the testicular appendages, making them more susceptible to twisting around their small blood supply. In a review of 100 boys less than 15 years of age who presented with acute scrotal pain, Melekos et al.[106] observed that 42% had testicular torsion and 32% had appendical torsion.

Presentation and Diagnosis

Children and adolescents who present with an acute painful scrotum require prompt evaluation. Timely and accurate diagnosis is required to prevent testicular loss. While the differential diagnosis is extensive (Table 77.1), the diagnosis can be determined based on history, physical examination, and limited laboratory and radiological evaluation. Typically, adolescents with intravaginal testicular torsion will present with acute onset of severe scrotal pain. In a series of 670 patients with acute testicular torsion, 89% of the patients presented with a complaint of acute-onset ipsilateral testicular pain.[107] The remaining patients presented only with pain referred to the ipsilateral lower abdomen, groin, or thigh. The majority of these patients were later found to have torsion in the undescended testis. Associated trauma and recent exercise were seen in 4% and 10% of the patients, respectively. About 11% of the

TABLE 77.1 Differential diagnosis for acute or subacute scrotum

Testicular neoplasms
Spermatocele
Varicocele
Dermatologic lesions
Inflammatory vasculitis (Henoch–Schonlein purpura)
Idiopathic scrotal edema
Referred pain

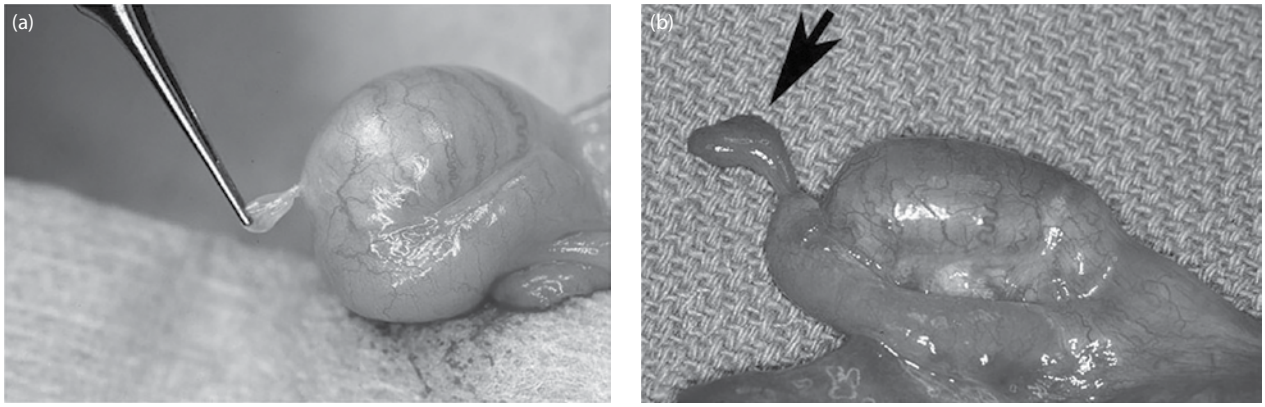

FIGURE 77.6 Acute testicular pain can also be due to torsion of the testicular appendages, such as the appendix testis (a) and appendix epididymis (b).

patients were woken from sleep with the pain. Nausea and vomiting were associated with testicular torsion in 39% of the patients, while urinary symptoms, such as dysuria and urgency, were usually absent (less than 5%). Interestingly, 36% of the patients had a previous history of testicular pain or swelling. A prior history of ipsilateral orchidopexy does not exclude the diagnosis of testicular torsion. Inadequate fixation and the development of single adhesions forming an axis for the testis to twist have been observed in patients with a prior history of orchidopexy but presenting with a recurrent testicular torsion.[108] Physical examination of the torsed testis is often very difficult due to the severity of the pain. Important signs of testicular torsion include a firm testicle high riding in the scrotum, an abnormally transverse orientation of the testis, and the absence of a cremasteric reflex.[109] In many cases, acute hydrocele or marked scrotal edema develops when several hours have passed since the onset of the scrotal pain. Fever and an elevated white blood cell count are seldom associated with testicular torsion. Intermittent testicular torsion has a presentation similar to that of intravaginal torsion, except that the episode is self-limited, with resolution of symptoms after the cord spontaneously untwists. Many who present with acute testicular torsion have a history of prior episodes consistent with intermittent testicular torsion. Those with intermittent torsion are likely to have normal physical exam at time of evaluation, when the pain has resolved. In contrast to those with intravaginal torsion, patients with extravaginal neonatal torsion typically present with painless swelling and scrotal discoloration. A firm testis with an associated hydrocele is often noted incidentally on newborn examination or during diaper change. Interestingly, associated scrotal erythema is not often present, but the overlying skin is discolored by the underlying hemorrhagic necrosis.

Patients with appendical torsion can also present with pain similar to that in those with intravaginal testicular torsion. However, the presentation for appendical torsion can be quite variable, from an insidious onset of scrotal discomfort to acute severe scrotal pain. Consequently, it is often difficult to differentiate appendical torsion from other causes of acute scrotum. At the earlier stages, the pain may be localized to the upper pole of the testis or epididymis, and a firm nodule can sometimes be palpated in this region of the scrotum. The pain is often more of a gradual onset rather than developing acutely, and associated symptoms such as nausea, vomiting, and abdominal pain are very infrequently associated with the testicular pain. On physical examination, the infarcted appendage can be seen through the scrotal skin as a blue dot; this is considered pathognomic for appendical torsion. However, the "blue dot" sign is only seen in approximately 20% of patients with an appendeal torsion.[106] In the latter stages, scrotal wall edema and erythema can develop, distorting the physical examination. The cremasteric reflex is usually preserved and the testis remains mobile.

In those who are suspected of having testicular torsion on a clinical basis, prompt surgical exploration is mandatory. Adjunctive radiological tests should only be obtained when their purpose is to confirm the absence of testicular torsion so that surgical exploration can be avoided. These tests are also of use in patients in whom the duration of symptoms suggests a nonsalvageable, dead testis if torsion is the cause. In these limited cases, color or power Doppler US or ^{99m}Tc-radioisotope scintigraphy may be obtained to evaluate testicular blood flow. Both of these tests are dependent on the availability of the equipment and personnel. False negatives can occur with any of the above modalities. The choice of which modality to utilize varies depending on the institutions, local experience, and availability and reliability of the tests. Color Doppler US studies can assess the anatomy of the scrotum and its content, while determining the presence or absence of testicular blood flow (as measured by velocity). The sensitivity of color Doppler US is reported to be as high as 90%, with a specificity of 99%.[110] However, caution must be used in the interpretation of these studies; almost 40% of patients, especially those younger than 8 years of age, may fail to demonstrate flow on the asymptomatic side.[111,112] Power Doppler US measures blood flow by detecting the number of red blood cells, as opposed to the velocity of flow. Although blood flow is more consistently detected in younger children with power Doppler,[111] evidence from animal studies suggests that power Doppler and color Doppler are equally efficacious in the detection of torsion.[113] Radionuclide imaging was originally the study of

choice for ruling out testicular torsion.[114] However, it only allows for the assessment of blood flow. Its positive predictive value has been reported to be around 75%, with a sensitivity of 90% and a specificity of 89%.[111] Hyperemia of the scrotal wall can give false impressions of testicular blood flow. In addition, it is difficult to image children with small scrotal sacs or testis using this study.

Effects of Unilateral Torsion on Testicular Function

Ischemia damage from torsion is related to the duration of the torsion and number of turns on the spermatic cord. Studies in dogs have demonstrated that all spermatogenic and Sertoli cells are not viable after 6 hours of testicular ischemia, and all Leydig cells are lost after 10 hours of ischemia.[115] However, in humans, severe testicular atrophy can be seen as early as 4 hours, when the degree of torsion is greater than 360°.[116] It is likely that when the cord is torsed greater than 360°, the artery becomes completely occluded. In contrast, when the torsion is less than 360°, arteriolar stasis develops secondary to venous occlusion and edema. In general, testicular atrophy is rare before 8 hours of torsion but is common after this time period.[117] The mechanism of testicular damage appears to be related to a combination of ischemia and reperfusion injury, resulting from activation of the xanthine oxidase system in parenchymal cells or from leukocytes adherent to the reperfused venule walls.

The effects of ischemia do not seem to be limited to the torsed testis. In patients who had treatment of testicular torsion within 4 hours of the onset of symptoms, half of the patients had abnormal semen analysis in follow-up, suggesting injury to both testes.[117] Studies in rats have confirmed that unilateral torsion can induce bilateral testicular damage and reduced fertility.[118,119] Several mechanisms have been suggested to explain these observations, including an immunological cause, congenital dysplasia, and damage of the normal testis by reflex vasoconstriction. It is suggested that torsion disrupts the normal blood–testis barrier, allowing the release of sperm antigens from the damaged testis. The antigens induce formation of autoantibodies, which then can attack the unaffected testis. In rats, it has been demonstrated that orchidectomy of the torsed testis, treatment with perioperative antilymphocyte globulin and splenectomy,[120] or administration of immunosuppressants such as steroids and cyclosporine[121] can prevent contralateral testicular damage. Similarly, in humans, patients with torsion for greater than 24 hours who had undergone an orchidectomy are more likely to have normal semen analysis than those in whom the torsed testis was left in place.[117] While there is ample evidence in animal studies that damage of the contralateral testis is mediated by an immune response, direct evidence in human studies is lacking. Anti-testis antibodies have been found only in approximately 10%–20% of patients who had a testicular torsion.[122,123] However, their presence does not correlate with infertility or with any testicular exocrine or endocrine dysfunction. An alternative explanation for the observed abnormal semen parameters in patients with unilateral torsion is the presence of underlying congenital dysplasia in the unaffected testis. Biopsies from the contralateral testis at the time of treatment for unilateral torsion demonstrate abnormalities such as desquamation of the germinative epithelium, atrophy of the Leydig cells, and malformation of spermatoblasts in 88% of the cases.[124] The presence of these abnormalities so soon after the onset of torsion suggests that there may be preexisting underlying pathology in contralateral testis. However, this explanation does not explain the consistent correlation between the duration of torsion and total sperm count, unless the damage is compounded by another mechanism.[125] The most recent explanation of the observed damage in the nontorsed testis is that it is caused by ischemia induced by reflex vasoconstriction. In animal studies,[126–128] unilateral testicular torsion induces an immediate and progressive decrease in blood flow to the contralateral testis and a gradual increase after detorsion. Like the affected side, the contralateral testis can be damaged by a combination of ischemia and reperfusion injury. The effect of torsion on contralateral testicular blood flow appears to be mediated by sympathetic nerve discharges from the genitofemoral nerve.[129]

Several studies have suggested that testicular damage after torsion could be limited by cooling of the testes, suppressing immune-mediated damage, and chemical sympathectomy to prevent reflex vasoconstriction. In animal studies, external cooling of the testis can delay the effects of ischemia for a few hours.[130] In addition, verapamil, surfactant, allopurinol, platelet-activating factor inhibitors, and hyperbaric oxygen have been used in an attempt to decrease reperfusion injury.[121,131,132] Similarly, immunosuppression with steroids, cyclosporine, and azathioprine has also been used in reducing testicular damage induced by an immune response.[133] Drugs such as capsaicin, 6-hydroxy dopamine hydrobromide, guanethidine monosulfate, and nitric oxide have been shown in animal studies to reduce testicular damage by preventing vasospasm and hypoxia in the contralateral testis.[134,135] Apart from hypothermia, the other methods of limiting testicular damage following unilateral torsion have been used in humans.[136]

Treatment

When suspected with testicular torsion, the patient should be taken to surgery without delay. Manual detorsion may be tried if surgical intervention cannot be done for a period of time. The testis should be turned caudal to cranial, and medical to lateral.[137] If the first attempt is unsuccessful, the testis should be turned in the opposite direction. If the detorsion is successful, the pain should resolve immediately. However, this process is often very painful, and manual detorsion may not completely correct the obstructed blood flow. Consequently, surgical intervention is still required following manual detorsion.

Fixation can be accomplished by securing the testis to the septum or placement into a dartos pouch. For transseptal fixation, the scrotum is opened through an incision in the median raphe. For the pouch fixation, the incision is made transversely following the skin creases of the scrotum. When using the latter method, the dartos pouch is made after the skin is incised. The tunica vaginalis is then

entered, and the testis is examined. The spermatic cord should be detorsed to restore blood flow. The affected testis should be placed in a warm sponge and observed for several minutes to determine viability. If it is nonviable, then the necrotic testis should be removed. Exploration of the contralateral testis should also be performed, and in all cases, the contralateral testis must be fixed. The testicles can be fixed to the median septum with 3–4 fine, nonreactive, and nonabsorbable sutures. These sutures can be brought through the septum, enabling the contralateral side to be fixed concurrently. Alternatively, a dartos pouch is created and fixation relies on scarification of the testis. The tunica vaginalis is everted and the testicle placed into the dartos pouch. A nonabsorbable suture is then used to secure the dartos tissue around the cord. This technique is advantageous in that complications such as abscess formation and tubular atrophy are uncommon. In addition, there have been no reported cases of recurrent torsion with this technique. Intermittent torsion is corrected using either of the above techniques on a semiemergent basis. Due to the effects of torsion on the function of the affected and unaffected testis, these patients will require further follow-up care to evaluate for infertility.

The treatment of neonatal torsion is controversial. Some suggest that surgical exploration is unnecessary, while others advocate immediate surgical exploration and fixation of the contralateral side. It is rare to salvage the affected testis in a patient with unilateral neonatal torsion; out of more than 30 cases of bilateral neonatal torsion reported in the literature, only two testicles have been successfully salvaged.[138] Important reasons for exploration are to exclude tumor and prevent possible unilateral torsion from becoming bilateral anorchia.[104] In the rare case of bilateral neonatal torsion, a more conservative approach can be taken. The newborn's general condition and anesthetic considerations should be evaluated to determine whether to proceed with surgical intervention.

The treatment of twisted testicular appendages is nonsurgical, if the diagnosis is certain. Conservative therapy with limitation of activity, scrotal elevation, and administration of nonsteroidal analgesics is highly effective. Most of the symptoms will dissipate once the acute changes of acute necrosis resolve. In rare instances, surgical exploration may be undertaken if conservative management fails. Simple excision of the torsed appendage is curative. Although an asymptomatic appendage is likely to be present on the contralateral side, exploration of the unaffected testis is not indicated. Some have advocated surgical treatment for the management of appendical torsion for these patients, as they seem to recover more rapidly and return to normal activity quicker than those treated conservatively.[139]

VARICOCELE

Definition and Incidence

A varicocele is caused by abnormal dilation of the internal spermatic vein and the pampiniform plexus of the testis. There are three primary vascular supplies to the testis: the internal spermatic, the vassal, and the cremasteric artery and vein. At testicular levels, there is free communication between the arteries. The pampiniform plexus is formed from veins providing the drainage from the testis and epididymis. As this plexus courses toward its drainage into the renal vein on the left and the inferior vena cava on the right, it becomes the internal spermatic vein. Like the arteries, there is free communication between the pampiniform plexus and the vassal vein, which drains via the inferior vesical vein into the hypogastric vein, and the cremasteric vein, which drains via the inferior epigastric vein into the external iliac vein. In addition, the distal portion of the pampiniform plexus is also drained via the anterior scrotal vein into the femoral vein.

A varicocele is rarely seen in boys less than 10 years of age.[140] Its incidence rapidly increases between 10 and 15 years of age, and it is seen in approximately 15% of male adults.[141] There appears to be a causal relationship between the pubertal development and varicocele formation. Varicocele may be classified by size during examination with the patient standing: Grade I varicocele is not visible but becomes palpable during the Valsalva maneuver, Grade II varicocele is easily palpable on exam without the need for the Valsalva maneuver, and Grade III varicocele is clearly visible on exam. Grade I varicocele is seen in approximately 9% of adolescent males, while Grade II is seen in 4% and Grade III in 2%.[142] The true incidence of varicocele may be underestimated since many adolescent males do not routinely undergo proper testicular examination in the upright position. Approximately 90% of varicoceles detected are found on the left side, while bilateral varicoceles occur in 2%–10% of the cases. An isolated, right-sided varicocele is uncommon, and its presence should raise the suspicion of a pelvic mass, compressing venous return.

Etiology and Pathophysiology

There are many theories as to the etiology of a varicocele. It is speculated that there are incompetent or absent valves in the left spermatic vein, which allows retrograde blood flow into the pampiniform plexus.[143] It also has been hypothesized that the anatomic differences between the left and right spermatic veins (with the left being longer and having a right-angle insertion into the left renal vein) allow for preferential transmission of higher hydrostatic pressures to the left pampiniform plexus. Alternatively, it has been suggested that a varicocele develops as a consequence of the left renal vein being compressed as it passes between the aorta and the superior mesenteric artery. However, this "nutcracker effect" has not been seen clinically.[144] Finally, it is hypothesized that a varicocele develops from abnormal embryonic transformation of the primary venous system into a secondary system. The inferior vena cava is formed as the subcardinal, the posterior cardinal, and the supracardinal veins involute. Disordered involution may cause a persistence of intercardinal anastomoses that could lead to the formation of the varicocele.[144]

While the etiology of a varicocele remains unclear, its effect on the testis is well documented. Biopsies from the testes of men with unilateral varicocele demonstrate incomplete maturation arrest at the spermatid and spermatocyte levels.[145,146] In addition, there is decreased

spermatogenesis and seminiferous tubular thickening with decreased tubular diameter. Interestingly, these changes are seen in both testes but are more severe on the varicocele side.[145] It has also been observed that there are changes in the other components of the testis. Leydig cell hyperplasia is seen in association with varicocele. Its presence can be used for prognosis, since the pregnancy rate was observed to be decreased from 40% to 5% in men with a varicocele who have Leydig cell hyperplasia on testicular biopsy.[147] Sertoli cell abnormalities have also been reported in men with varicocele. On light and electron microscopy, spermatids are seen to be maloriented relative to Sertoli cells, and Sertoli–germ cell junctional complexes appear to be structurally abnormal.[148] Finally, the testicular microvasculature is also affected in adolescents and men with varicocele, in which proliferative endothelial lesions in the capillaries are seen. These vascular lesions precede the testicular changes and are reversible with surgical correction.[149]

Varicocele is also associated with specific biochemical changes. It has been observed that there is decreased intratesticular testosterone concentration in some adult men with varicocele.[150] It is not surprising that this decrease correlates with impaired spermatogenesis and Leydig cell changes in men with varicocele.[150,151] Similarly, a decrease in serum testosterone has been noted in some men with bilateral Grade III varicoceles.[152] However, this observation is not seen in patients with other grades of varicocele.[153] Inhibin B is a glycoprotein produced by Sertoli cells and can potentially serve as a marker of Sertoli cell function in patients with varicocele. It is observed that serum inhibin B levels tend to be positively correlated with sperm concentration in some patients.[153,154] In comparison, it is more consistently observed that men[155,156] and adolescents[157] with varicocele have elevated gonadotropic hormones such as follicle-stimulating hormone (FSH). In addition, an excessive gonadotropin (in particular FSH) response to gonadotropin-releasing hormone (GnRH) is seen in some adolescents with varicocele. In one study,[158] it was observed that 31% of adolescents with a unilateral varicocele had an abnormal response to GnRH stimulation, and 75% of those with testicular hypotrophy of greater than 3 mL differential had an abnormal response. However, it should be noted that 54% of those who did not have elevated FSH and luteinizing hormone (LH) in response to GnRH stimulation also had hypotrophy. Aragona et al.[159] observed a correlation between abnormal testis histology and an exaggerated response to GnRH. This abnormal GnRH response appears to be limited to those with Tanner stage V. Approximately 40% of the Tanner stage V had an exaggerated response to GnRH, while those with Tanner stage III and IV had no difference in LH or FSH response to GnRH.[160] Unfortunately, the use of GnRH as a predictor for the need for surgery is limited since it does not correlate with the grade of the varicocele, testicular hypotrophy, or fertility.[160,161]

Since 98% of the testicular mass is comprised of seminiferous tubules and germinal cells, it is not surprising that the histologic, deleterious effects of varicocele may be seen grossly by changes in testicular volume. The average size of the testis in an adult male is 24 ± 3 mL. Normally, there is no more than 2 mL difference. It has long been noted that the ipsilateral testis of patients with a unilateral varicocele can be significantly smaller than the contralateral side.[162] It should be noted, however, that in adult men, although a varicocele can cause significant ipsilateral testicular atrophy or hypotrophy, there does not seem to be a correlation between loss of testicular volume and fertility status in men with a left varicocele.[163] In adolescents, absolute changes in testicular volume cannot be used since the testis is growing during puberty. Consequently, the percent volume loss compared with the right side is utilized. Like adult men, adolescents with a unilateral varicocele may have a significant amount of testicular volume loss. It remains a topic of debate as to what percentage of volume loss is considered significant (10% vs. 25%).[164,165] Nevertheless, it has been observed that volume loss is seen in 34% of adolescents with Grade II varicocele and 81% with Grade III.[141] Several prospective studies[159,164,166] have demonstrated that in adolescents, the testicular volume either fails to increase or even decreases in the presence of the varicocele.

The effects of the varicocele can also be seen in the semen quality. A "stress pattern" can be observed in the semen of adults with a varicocele in approximately 90% of cases.[167] These characteristic changes consist of subnormal motility, an increase in immature forms, a shift from oval to tapered, and amorphous sperm forms.[168] These changes may worsen over time.[169] In adolescents, varicocele is associated with impairment in sperm motility and morphology with no significant difference in sperm counts.[170] Surgical correction of the varicocele in adulthood[171–173] or in adolescence[164,174–176] results in improved semen parameters. In the only prospective study,[177] the only improvement in sperm concentration was noted in adolescents with a unilateral varicocele who underwent surgical correction.

Several theories have been suggested to speculate on the etiology of how a varicocele induces these damaging changes to the testis. It is speculated that these changes may be mediated by increased venous pressure or retrograde flow of toxic metabolites from the adrenal gland. Currently, the most plausible theory is that a varicocele induces thermal damage to the testis. Intratesticular temperature is normally maintained at around 33°C–34°C. A countercurrent heat exchange between the blood coming down and the blood leaving the testis allows the testis to be maintained at a lower temperature. It is suggested that a varicocele disrupts this countercurrent heat exchange and induces testicular hyperthermia, which interferes with normal spermatogenesis.[178] This theory has been demonstrated in animal models of varicocele (reviewed by Turner[179]). In primates,[180] dogs,[181] and rats,[182] partial ligation of the left renal vein results in varicosity of the left spermatic vein and the pampiniform plexus. The surgically created varicocele induces bilateral increases in testicular blood flow and temperature, resulting in decreases in intratesticular testosterone and sperm output.[179] These effects do not appear to be immunologically or neurologically mediated[183] and are reversed with varicocelectomy.[184,185] The pathophysiology of varicocele is multifactorial, and none can independently explain the mechanisms of impaired spermatogenesis. It is likely that a combination of several factors affects spermatogenesis

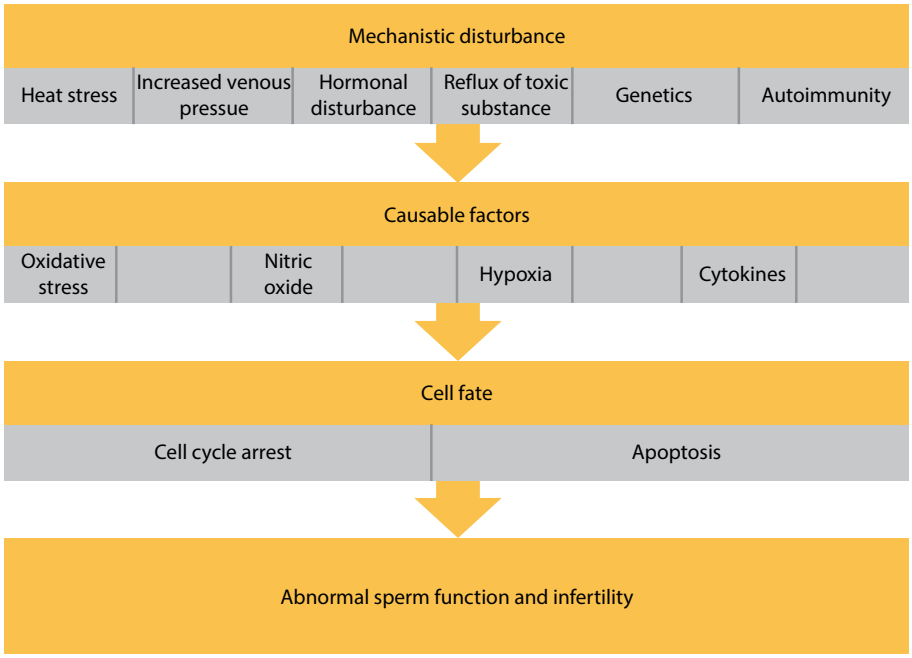

FIGURE 77.7 Summary of the potential etiology of abnormal sperm function and infertility in patients with varicocele.

and sperm function, and the relative involvement of these factors is different in each patient (Figure 77.7).[186]

Presentation and Diagnosis

The majority of the adolescents who present with a unilateral varicocele are asymptomatic; pain or a dull nagging ache is the presenting symptom in only approximately 3% of the patients.[187] The varicocele is usually detected on physical exam as scrotal swelling or mass. In evaluating for the presence of a varicocele, it is essential to examine the patient standing up and then perform the Valsalva maneuver. In addition, the testes should be carefully evaluated for their size and consistency. Several methods of testicular measurements, including rulers and calipers, orchidometers, and US, have been employed. Measurement using orchidometers such as the Prader, Rochester, and Takihara is readily available and inexpensive to perform; however, the accuracy of the measurement is highly dependent on the experience of the examiner. In comparison, measurement using testicular US is better correlated with actual testicular volume[188,189] but is more costly. Another advantage of using US in evaluating varicocele is its ability to pick up unexpected pathology, such as a retroperitoneal mass, intratesticular varicocele, or testicular mass. Intratesticular varicocele is seen on scrotal Doppler US as an intratesticular anechoic lesion with active Doppler flow. It is found in association with traditionally large extratesticular varicoceles and has been shown to resolve following spermatic vein ligation.[190]

When possible, a semen analysis should be obtained. Semen quality is a good indicator of testicular function in adults with varicocele. However, it should be noted that its use in adolescents with a varicocele has some potential limitation. Often, it is very difficult to obtain semen analysis in adolescents due to ethical concerns. In addition, normal semen parameters have not been well defined prior to sexual maturity; between 12 and 19 years of age, spermatozoa are absent, and semen parameters reach adult values 29–33 months after the onset of puberty.[191] Consequently, the interpretation of semen parameters is problematic in adolescents who are undergoing pubertal changes.

Serum measurement of FSH with or without GnRH stimulation may be potentially helpful in identifying those with testicular dysfunction induced by varicocele. However, as indicated previously, elevation in FSH levels and abnormal GnRH responses do not always correlate with abnormal semen parameters or fertility. In addition, not all patients with testicular dysfunction have elevated FSH or abnormal response to GnRH. Consequently, their routine use in evaluating adolescents with varicocele is limited.

In a very selected group of patients, further radiologic imaging may be utilized in the evaluation of a varicocele. Internal spermatic vein venography can delineate the anatomy of the varicocele; however, it is costly and invasive. Its use tends to be limited to selected patients with recurrent varicocele[192] or during intraoperative evaluation.[193] Another method in the evaluation of a varicocele is scrotal thermography to measure the scrotal temperature.[194,195] It is suggested that an observed increase in testicular temperature might identify those patients at risk for varicocele-induced testicular damage. Due to the lack of correlation with outcome, it is not commonly used in the US currently. Color Doppler US may also be used in evaluating for the presence of a varicocele (Figure 77.8). It is able to define the number of dilated veins, as well as the severity of dilation. However, with these various

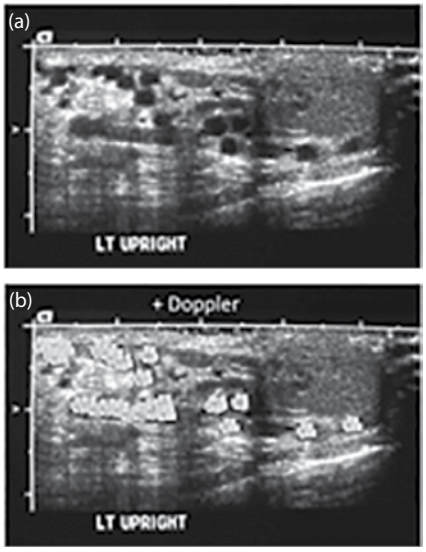

FIGURE 77.8 (a) On US, a varicocele can be identified by its "Swiss cheese" appearance. (b) Doppler US can demonstrate retrograde flow in the varicocele.

radiologic methods, many subclinical varicoceles can be identified (i.e., those that are not palpable on physical exam but are visualized with radiologic imaging). Using contact thermography and venography, approximately 7% of those with left-sided and 86% of those with right-sided varicocele are identified in the absence of findings on physical examination in adolescents who present for evaluation of a varicocele.[196] Because subclinical varicoceles are seen in approximately 60% of men attending fertility clinics, but also in 40% of fertile men,[197,198] the clinical relevance and thus importance of diagnosing subclinical varicocele are highly debated.

Treatment

Since 15% of adult men have a varicocele but only 20% of them have infertility, observation is a valid option in the management of patients with a varicocele. The risk in observing these patients is that some of them may demonstrate deterioration in the semen parameters and may progress to infertility. While surgical correction reverses these changes in at least 50% of adult men, in others it does not, suggesting a potential for developing irreversible damage. Consequently, early surgical correction of adolescent varicocele has been advocated. This recommendation is based on the assumption that adolescent varicocele is a progressive disease. In the only prospective longitudinal study in adults,[199] semen quality in men with untreated varicocele did not decline with time. However, most had semen quality at baseline that was worse than that of controls. In two studies of adolescent varicocele,[176,177] the authors observed lower semen quality in those who underwent varicocele than in those who were not treated. However, it should be noted that in the first study there was no sequential semen analysis, and in the second, the untreated group had similar semen parameters compared with the controls. In another study,[200] a group of adolescents with a unilateral varicocele was followed with serial exams, with a mean follow-up between the first and second exam of 16 months. There was neither an increase in varicocele grade nor a change in testicular volume differential over time, suggesting that perhaps adolescent varicocele is not a progressive disease. However, the limitations of this study are the length of the follow-up time and correlation with other parameters, such as semen analysis. Currently, there are no convincing data supporting or refuting the premise that adolescent varicocele is a progressive disease.

Consequently, with the goal of preserving fertility, it is important to identify those adolescents with varicocele who would benefit from early intervention. It is generally agreed on that an indication for surgical intervention is for symptoms such as pain. Although an uncommon complaint, 80%–90% of those who undergo varicocele repair will have resolution of their symptoms.[187] In addition, those adolescents with bilateral varicoceles may benefit from surgery since it is difficult to follow their testicular growth since both sides are affected. Similarly, in older patients with abnormal semen parameters on serial evaluation, surgical intervention would be indicated, allowing for potential improvement in semen parameters[175,176] and fertility.[201] In the era of assisted reproductive technology, studies[202,203] showed that the repair of varicocele often improves fertility success.

Other indications for varicocele repair in adolescents are more controversial. When semen analysis is not available, marked testicular volume differential is used as an indication for surgery. In adult men with a unilateral varicocele, testicular hypotrophy is associated with decreased total motile sperm counts.[204] However, there does not appear to be a correlation between the loss of testis volume and fertility status.[163] Nevertheless, surgical intervention does reverse the growth loss in adolescents with a unilateral varicocele.[170,175–177] Although it remains unclear whether varicocele repair solely for the purpose of reversing testicular hypotrophy improves future fertility potential, most would agree on this as an indication for intervention, in the absence of semen analysis. Size (i.e., grade) of the varicocele has also been suggested as a potential indication for surgical intervention. It is observed that in infertile men with Grade III varicocele, there was a greater improvement in sperm concentration and motility than in those with Grade I or II varicocele.[205] However, there was no difference in fertility rates in those with large or small varicocele who underwent repair.[205,206] Consequently, the grade of the varicocele in itself is not predictive of the need for surgical intervention. Similarly, the finding of a "soft" testis in association with the varicocele is not a strong indication for surgery. This finding is quite subjective and difficult to quantify, and consequently, there is a lack of data proving its value in predicting the need for early intervention. Finally, parental and adolescent preference often plays a role in determining the treatment of varicocele. They may feel that surgery may be of some psychological benefits, restoring normal scrotal appearance and allowing them not to worry about potential future complications.

Techniques of Varicocele Repair

There are several techniques that can be employed in the treatment of a varicocele, including percutaneous, open, and laparoscopic approaches. With percutaneous techniques, the dilated veins can be sclerosed with a chemical agent or occluded with coils or balloon. Access can be obtained percutaneously in a retrograde manner via the femoral or jugular vein or in an antegrade manner via the varicocele itself.[207,208] The advantages of the percutaneous techniques include being less costly and having a shorter recovery time than open surgery. In older patients, these techniques can be performed under local anesthesia, alleviating the need and risk of general anesthesia. However, it should be noted that in 15%–27% of the patients undergoing transvenous occlusion, the procedure could not be performed due to difficulties getting to the varicocele.[209] Potential complications include extravasation of contrast material, coil migration, postprocedure hydrocele formation (11%), and recurrence (5%).

Open surgical correction of varicocele has conventionally been the standard treatment of varicocele for many years. This treatment can be performed inguinally, retroperitoneally, or subinguinally. The Ivanissevich repair utilizes an incision in the inguinal region with the patient in reverse Trendelenburg position. The spermatic cord is exposed and mobilized in the inguinal canal. Under loupe magnification, all veins are ligated. The testicular artery, which may be dilated with warm saline or papaverine and identified visually or with Doppler US, can be spared or mass ligated with the veins. The advantage of this procedure is that it is easy to perform due to its anatomic familiarity and easy access to the cord. With this technique, there is a 3%–8.6% incidence of hydrocele postoperatively and a 16% recurrence rate in the treatment of adolescent varicocele. Both the hydrocele rate and recurrence rate can be reduced using microscopic dissection. Sparing the artery decreases the risk of hydrocele formation by sparing the lymphatic vessels surrounding the artery but increases the risk of recurrence due to missed venous connection.

The Palomo technique utilizes a muscle-splitting incision one to two fingerbreadths medial and anterior superior to iliac crest and the same distance above the estimated position of the internal ring, providing access to the retroperitoneum. The vessels are identified on the posterior aspect of the peritoneum; they may be better visualized by providing traction on the testis. As with the inguinal approach, the testicular artery can be ligated with the vein. The advantage of this technique is that above the inguinal canal, there are fewer venous branches requiring ligation, and that the vas and its associated vessels have separated from the rest of the cord, minimizing the risk of their injury. However, this approach often is more anatomically difficult and could miss scrotal or pelvic collaterals feeding into the varicocele. The incidence of hydrocele postoperatively is approximately 7%. Similar to that of the Ivanissevich repair, the rate of recurrence is around 11%–14% with sparing of the artery or 2% with not sparing the artery. Several studies[210] have demonstrated that ligation of the artery during Palomo repair can be safely performed and does not result in testicular atrophy.

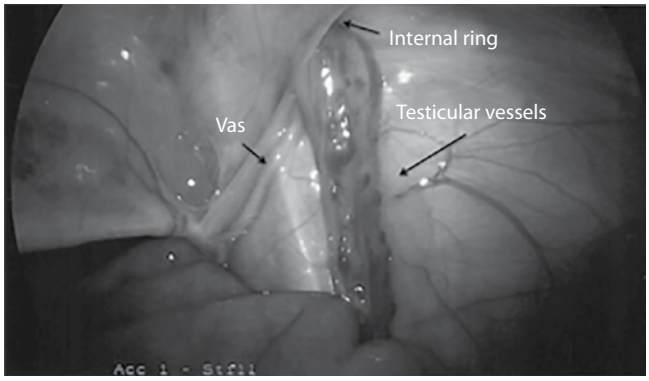

FIGURE 77.9 On laparoscopy, the spermatic veins can be easily identified in the retroperitoneum. Above the level of the internal ring, the vas and its vessels have separated away from the cord, minimizing its injury during the dissection.

The subinguinal technique utilizes a low transverse inguinal incision to expose the cord below the external ring. The external oblique aponeurosis is opened, and the testis is delivered out of the scrotum. Using an operating microscope, the artery and lymphatic vessels are identified and spared, while all the external spermatic veins and scrotal veins are ligated. By being able to identify and preserve the artery and lymphatic vessels, the incidence of postoperative hydrocele is very low (approximately 0.8%), with a 2.1% recurrence rate.[211]

Over the past decade, the laparoscopic approach to varicocele repair has gained much popularity. It can be performed with a transperitoneal or a preperitoneal approach. For the transperitoneal approach, an incision is made in the umbilicus and is extended down to the midline fascia. A pneumoperitoneum is created with a Veress needle or by the open Hassan technique. The abdomen is insufflated to 12–14 cm H_2O. Two additional ports are placed, one in the midline near the pubis and the second in between the other two. The position of the ports should allow the instruments to triangulate the work area. The patient is placed in a steep Trendelenburg position to allow the bowel to move out of the pelvis. Collaterals can be accessed by compressing on the main vein and squeezing the testis (Figure 77.9).[212] The vessels are mobilized from the peritoneum and are ligated. The artery may be identified with a Doppler US and spared.[213] After the completion of the procedure, the abdominal pressure should be reduced and the area carefully inspected for bleeding. The advantages of this technique include a shorter postoperative convalescence due to avoidance of a larger inguinal or abdominal incision, better visualization,[214] and the capacity to treat other associated problems, such as bilateral varicoceles or concurrent inguinal hernia.[215] The laparoscopic Palomo can be safely performed in patients who have undergone prior inguinal surgery without a risk of testicular atrophy.[216] The disadvantages include the requirement for general anesthesia, the cost, and the potential for bowel injury, bleeding, and peritonitis. Using this technique, the incidence of postoperative hydrocele is approximately 7% and the recurrence rate is 15%.[217–219]

Treatment of Postoperative Hydrocele and Recurrence

Esposito et al.[220] observed that the median incidence of postoperative hydrocele after varicocele surgery is about 12%. The incidence is higher after an artery-non-sparing versus -sparing procedure (17.6% compared with 4.3%). Interestingly, no difference in the postoperative hydrocele rate was observed between surgeries performed laparoscopically or those by open techniques. Hydroceles are infrequently detected within 6 months of varicocele repair, generally occurring after 6 months up to 3 years following surgery.[221] Total hydrocele regression occurs in approximately 80% of the patients following clinical observation or treated with simple scrotal puncture.[220] However, some may require open hydrocele repair.

Recurrence following varicocele repair is usually noted several months after surgery.[222] A lower recurrence rate is seen when performing mass ligation compared with artery-sparing surgery.[210,223] It is uncommon that recurrence is due to delayed recannalization.[222] Reoperation is indicated when the indications for the original surgery persist. Intraoperative venography may be helpful in defining collaterals that were missed during the initial surgery. This can be accomplished by placing the patient in a reverse Trendelenburg position and making a small scrotal incision to expose the dilated veins. The vein is cannulated with an angiocatheter, directed away from the testis. The catheter is then injected with 30% contrast at a volume of 1 mL/kg body weight. After an x-ray is obtained, the vein is flushed with normal saline solution. It is generally recommended that the cord should be approached at a higher level, in order to ligate the missed collaterals.

CHAPTER
78

Minimally Invasive Management of Inguinal Hernias

Nicholas G. Cost and Paul H. Noh

INTRODUCTION

The first case of "minimally invasive surgery" in children was reported by Stephen Gans in 1971, in which he successfully verified a contralateral inguinal hernia via an endoscope introduced through the known hernia sac.[1] Therapeutic use of laparoscopy for pediatric inguinal hernia was then first reported by El-Gohary in 1997,[2] when he performed laparoscopic repair in girls by successfully everting the hernia sac into the peritoneal cavity and then using an endoloop to perform a "high ligation" (Video 78.1). Subsequently, Montupet and Esposito reported their experience in the mid-1990s of using laparoscopy to treat pediatric inguinal hernias in boys.[3]

In essence, a minimally invasive inguinal hernia repair in children is an adaptation of conventional herniotomy that fundamentally involves a high ligation of the indirect hernia sac. Broadly, laparoscopic pediatric inguinal hernia repairs can be classified into two approaches: (1) purely intracorporeal ligation and (2) laparoscopic-assisted extracorporeal ligation. In addition to traditional multiport laparoscopy, numerous novel minimally invasive techniques have been developed to approach the same problem in a variety of ways. These include "single-incision laparoscopy," such as laparoendoscopic single-site surgery (LESS) or single-incision laparoscopic surgery (SILS), or a wide array of endoscopically visualized extracorporeal ligations, such as subcutaneous endoscopically assisted ligation (SEAL) or percutaneous internal ring suturing (PIRS).

Regardless of the approach, the theory of minimally invasive approaches to the patent processus vaginalis (PPV) or indirect inguinal hernia in a child is the same, that is, reduction of any intraperitoneal contents and attempting to mechanically close the peritoneal connection. Herein, we aim to describe the various techniques of minimally invasive inguinal hernia repair in children, discuss their success rates, highlight the risk of complications, and lastly, mention special considerations in the management of these patients, such as hernia recurrence or bowel incarceration or strangulation.

TECHNIQUES OF THE VARIOUS MINIMALLY INVASIVE APPROACHES

The minimally invasive approaches to pediatric inguinal hernias can be broken down into two categories: (1) transperitoneal access with intracorporeal manipulation to close the hernia and (2) transperitoneal access for endoscopic visualization of extracorporeal management of the peritoneal communication. The various techniques approach dissecting out or ligating the hernia sac in a number of ways; however, they all share these two basic forms of minimally invasive access. A full discussion of laparoscopic access to the peritoneum is outside the scope of this chapter, but we discuss the details of patient positioning and the operative steps of each technique.

Transperitoneal Access with Intracorporeal Management of the PPV

This is the "traditional" technique of laparoscopic pediatric inguinal hernia repair used via multiport laparoscopy as it was initially described.[2,3] While there have been modifications in the number of ports used, the basic approach is the same, which involves transperitoneal access followed by high ligation of the hernia sac either with or without attempts at "disrupting" the peritoneal continuity with cutting or cautery. Patient positioning is as follows: using a supine position with the legs slightly spread, secure the patient to the table at the chest and legs using straps. During the surgery, it may be helpful to place the patient in a slight Trendelenburg position to allow for gravity retraction of the bowel (Figure 78.1), and it may also help to have the patient rotated slightly with the side of interest up. For this reason, we recommend testing the bed and patient positioning, once secured, prior to prepping and draping. After access is obtained, we prefer to use a 5 mm laparoscopic camera to visualize the inguinal ring of interest, as well as the contralateral inguinal ring, to evaluate for a concomitant bilateral PPV. Of note, any grossly appreciable patency will generally manifest itself with scrotal swelling at this point from transmission of the abdominal insufflation. One caveat is that in the setting of a clinical hernia, with a patency that does not extend into the scrotum, one may not observe scrotal distention with insufflation, but this does not rule out an open canal.

While there are recent descriptions of SILS duplicating a similar herniorraphy technique,[4,5] the traditional approach at this point would be to place additional ports as needed. Additional instruments are placed under direct vision via stab incisions without trocars. We prefer to use

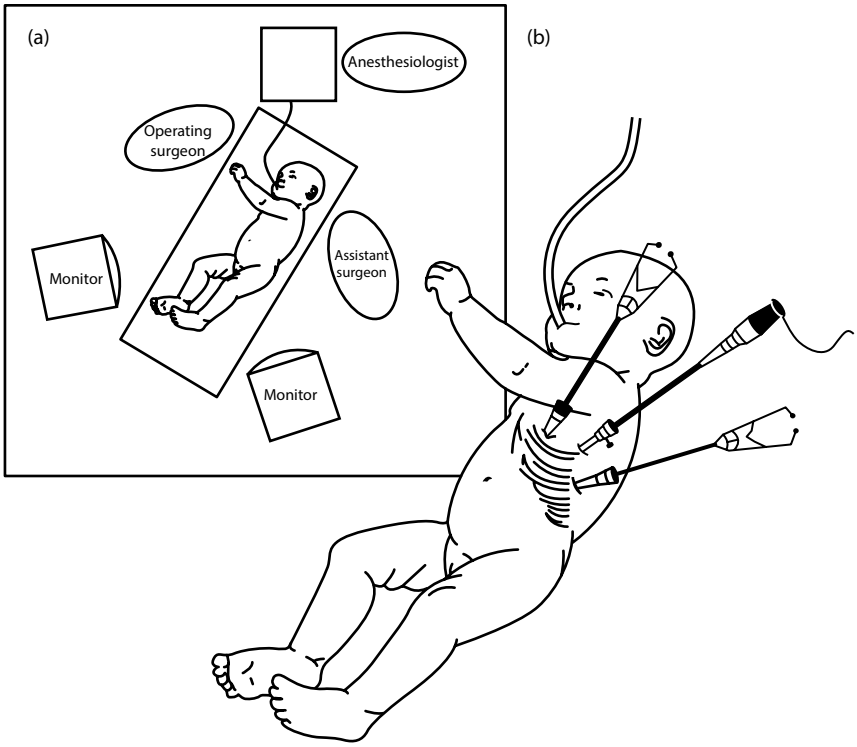

FIGURE 78.1 Drawing of patient positioning: (a) Trendelenburg and (b) side of interest up. You will need to adapt this drawing, but basically it shows patient positioning, with a child secured to the bed with straps across the knees and chest, and an image in the Trendelenburg and bed rotated positions to have the affected side up.

two 3 mm laparoscopic instruments to achieve triangulation on the inguinal ring of interest; however, it is worth mentioning that in the setting of bilateral hernias, the ports may be best placed in both the right and left lower quadrants in the midclavicular line to allow the surgeon to approach both sides (Figure 78.2).

At this point, whether a single-incision laparoscopic platform or a multisite setup is employed, the approach is similar. Any intraperitoneal contents or herniated bowel is reduced, and the patent inguinal ring is evaluated. Various approaches call for some combination of the following: (1) full dissection of the PPV, (2) simple interruption of the continuity of the peritoneum at the level of the inguinal ring, and (3) suturing closed the peritoneal surface of the intra-abdominal inguinal ring. Some surgeons may even include the conjoint tendon in the repair in an attempt to tighten the canal itself. Regardless, it is vital to assess the surrounding anatomy and, in boys, take care to not injure the spermatic vessels and the vas deferens. We prefer to use 3 mm instruments (an atraumatic grasper and scissors) to then interrupt the peritoneum diving into the PPV, which is done using a combination of cold-cutting and electrocautery. We then use a standard laparoscopic needle driver and absorbable suture to close the inguinal ring with interrupted sutures, again taking great care not to injure the vas (Figure 78.3, Video 78.2). While we prefer to interrupt the peritoneum directly by incising it prior to suture closure, some authors simply close the ring with nonabsorbable suture without any associated dissection.

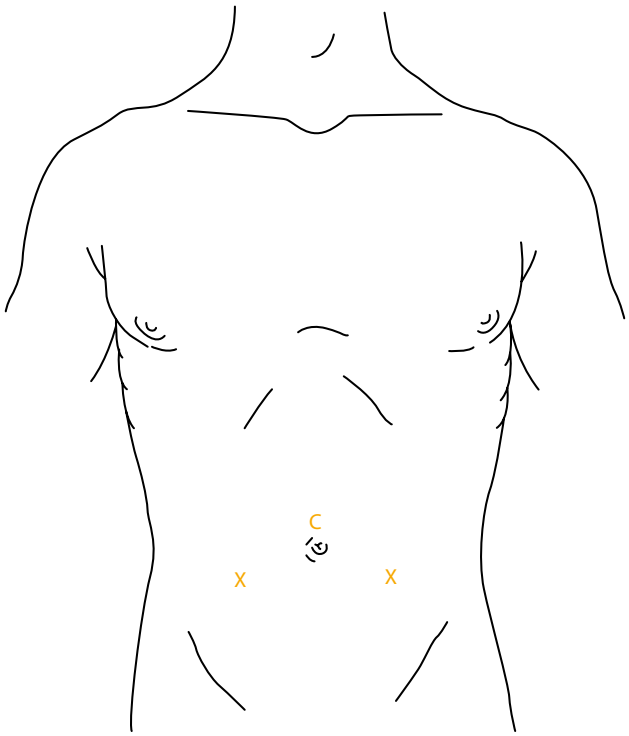

FIGURE 78.2 Schematic of port or instrument placement for standard laparoscopic inguinal hernia repair. C, 5 mm laparoscope; X, stab incisions for 3 mm instruments.

Transperitoneal Access and Endoscopic Visualization for Extracorporeal Management of the Inguinal Hernia

In general, this approach to manage inguinal hernias in children was initially developed in 1995 by Takehara and associates.[6] They termed this repair laparoscopic percutaneous extraperitoneal closure (LPEC). They described placing a laparoscope through an umbilical incision, inserting a 2 mm grasping forceps through a trocar on the left side of the umbilicus, and inserting a specially designed 19-gauge needle with suture material at the midpoint of the affected inguinal line. The opened hernia sac was closed extraperitoneally by circuit suturing around the internal inguinal ring using the LPEC needle.

Two novel variations on this theme described in the mid-2000s include the techniques of one-trocar laparoscopic-assisted extracorporeal closure: SEAL and PIRS (Figures 78.4 and 78.5).[7,8] In general, using intracorporeal laparoscopic visualization, the hernia defect is enclosed by a nonabsorbable suture, which is introduced into the abdomen by a needle on one side of the hernia defect, tracking under the patent processes and above the vessels and vas, and then withdrawn on the opposite side. Extracorporeal knot tying is subsequently performed. As a modification of single-port endoscopic-assisted ligation, in 2008 Bharathi et al. described "preperitoneal hydrodissection," with a small amount of saline injected using a hypodermic or spinal needle in the extraperitoneal space to lift up the peritoneum of the vas and the vessels. The suture could then be advanced to encircle the posterior hemicircumference of the defect.[9]

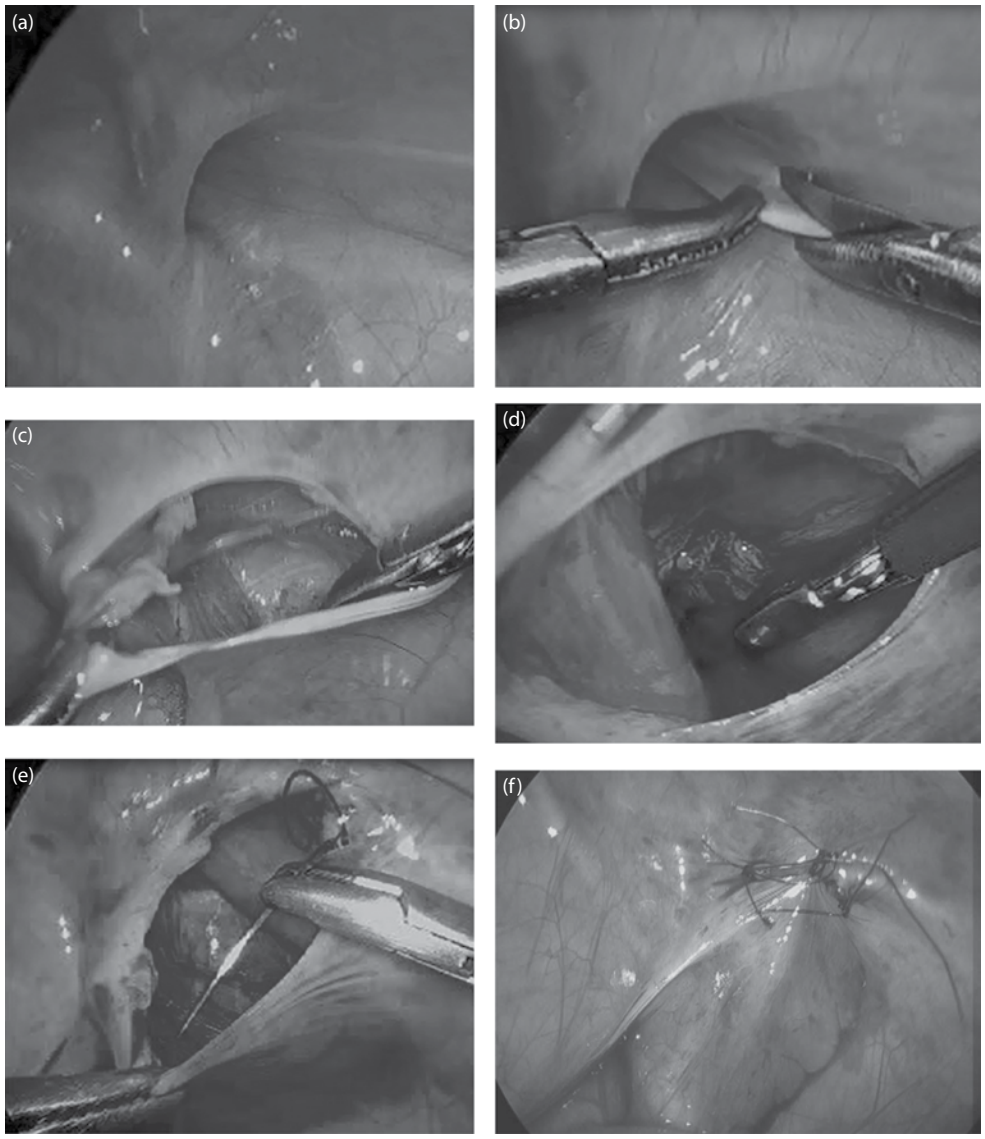

FIGURE 78.3 Standard transperitoneal laparoscopic inguinal hernia repair. Pictures: (a) Open right inguinal ring, (b) incising the peritoneum around the inguinal ring, (c) raising the peritoneum over the vas deferens and gonadal vessels, (d) peritoneal lining disrupted and distal sac retracted, (e) suturing the peritoneum closed, and (f) peritoneum closed with three interrupted, nonabsorbable sutures.

Despite the previously mentioned variations, the basic approach is the same, which involves transperitoneal access, followed by extraperitoneal suture closure of the PPV. Patient positioning is the same as demonstrated in Figure 78.1. After access is obtained, we prefer to use a 5 mm laparoscopic camera to visualize the inguinal ring of interest, as well as the contralateral inguinal ring. Any herniated contents can be reduced under direct inspection and may require placement of an additional instrument if they are incarcerated. Next, we use a hemostat on the skin while directly visualizing the ring intracorporeally to determine the best place to pass the needle from the outside. Preperitoneal hydrodissection can

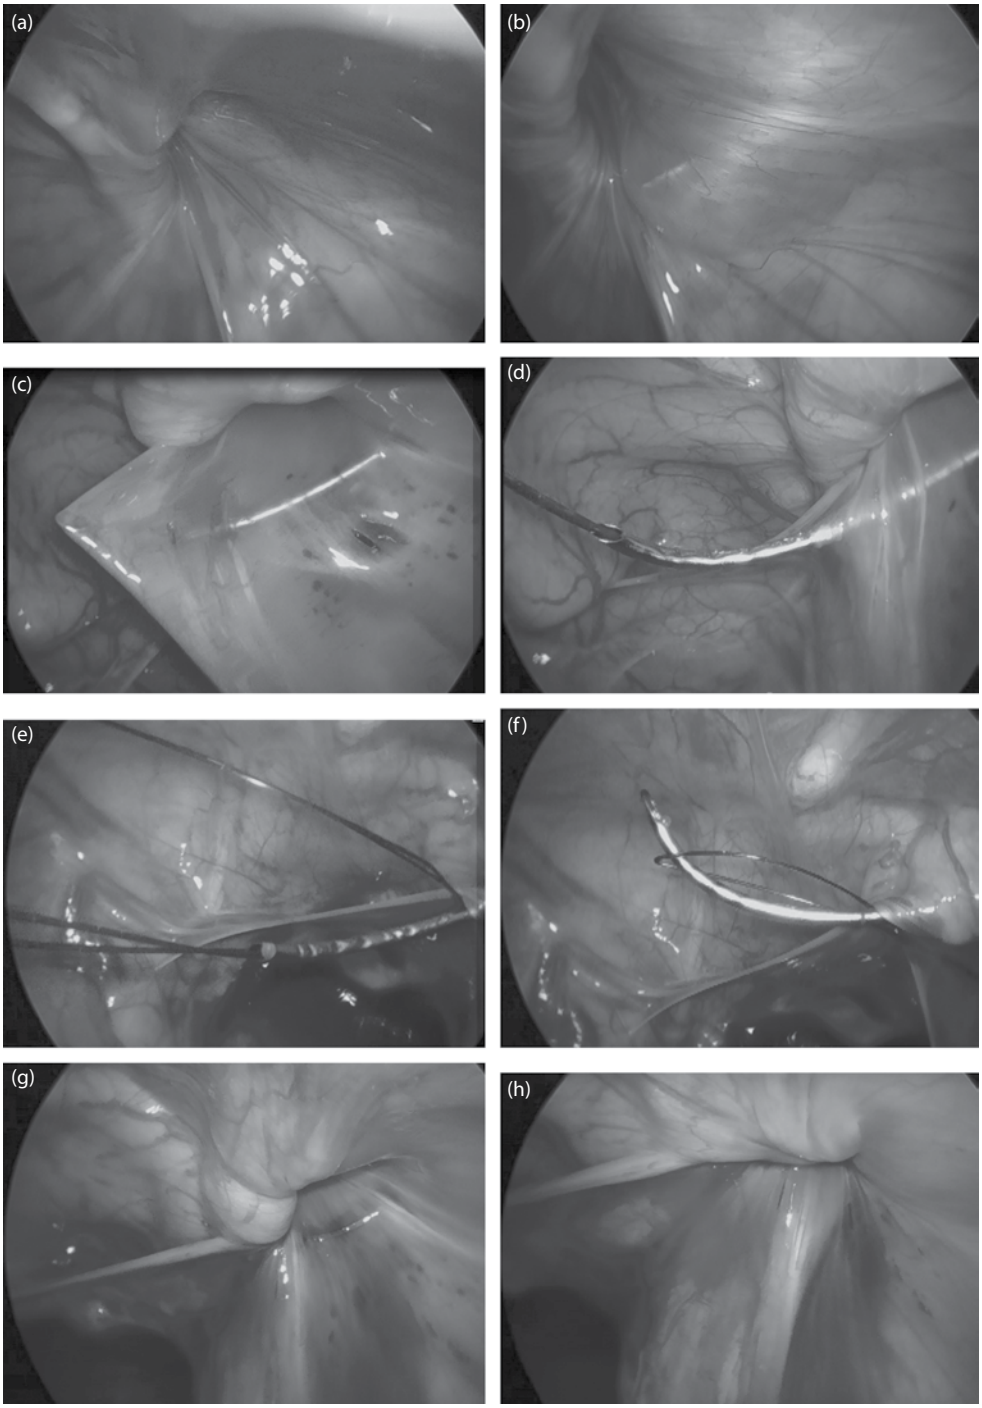

FIGURE 78.4 Pictures and video (Video 78.3) from a one-trocar laparoscopic-assisted extracorporeal hernia closure. Pictures: (a) open right inguinal ring; (b) hydrodissection of peritoneum off the vas and vessels (see needle coming in from laterally); (c) hollow needle being advanced under the ring, below the peritoneum and above the vas and vessels; (d) passing looped permanent suture through the hollow needle; (e) hollow needle advanced over the ring and exiting the peritoneum via the same peritoneal opening made from below—note the second looped permanent suture passed via the hollow needle; (f) loop suture placed around the second suture and pulled back around the bottom of the ring; (g) suture passed completely around the ring; (h) closed ring after suture tied down.

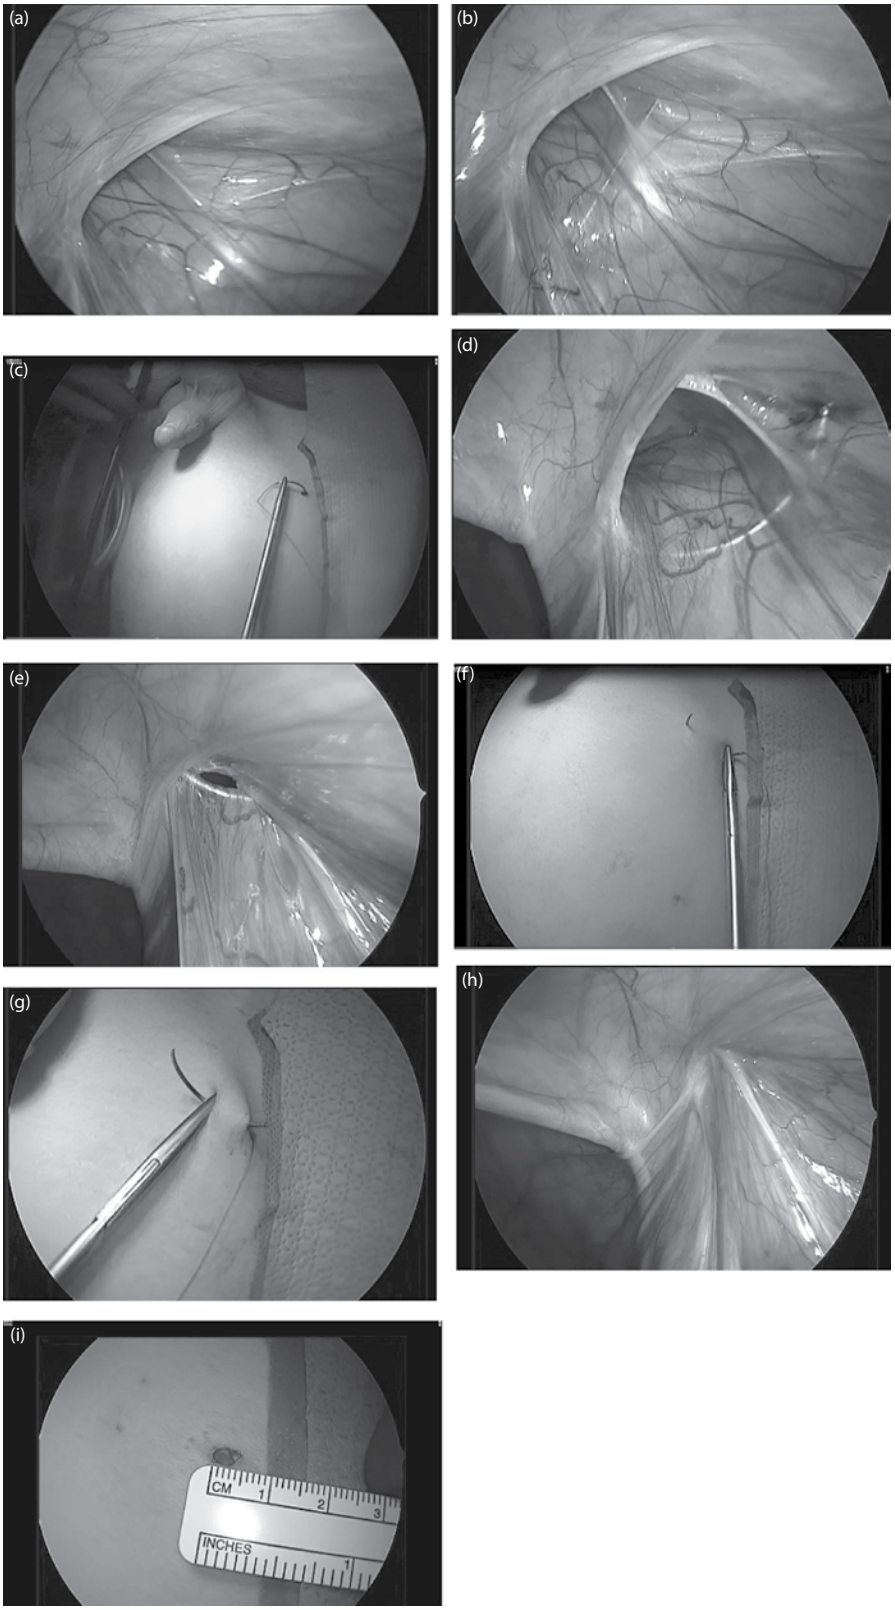

FIGURE 78.5 Pictures and video from an extracorporeal percutaneous minimally invasive inguinal hernia repair. Pictures: (a) Open right inguinal ring; (b) hydrodissection of peritoneum off the vas and vessels (see needle coming in from laterally); (c) CT needle with permanent suture being introduced extracorporeally; (d) CT needle being advanced under the peritoneum through the hydrodissection plane; (e) needle passed above the vas and vessels, under the peritoneum and encircling the PPV; (f) needle exiting extracorporeally; (g) needle being "back-loaded" through the original stab incision; (h) peritoneum closed once knot tied down extracorporeally; and (i) appearance of the stab incision prior to closing. (Pictures and video courtesy of Patrico C. Gargollo, MD, University of Texas Southwestern Medical Center, Dallas.)

be employed at this juncture, prior to passing the suture, to create a "potential space" above the vessels or vas and below the peritoneum. At this point, a small stab incision is made in the skin and subcutaneous tissue. Next, using a nonabsorbable suture on a computed tomography (CT) needle in a standard needle driver, from extracorporeally we gently advance the needle under the peritoneum but over the vessels or vas until the other side of the PPV is reached. The needle is then driven up through the skin until half of the needle is exposed; the back end of the needle can then be driven through the original stab incision. The suture is tied down encircling the PPV, all while visualized from internally to confirm secure closure (Figure 78.5). Of note, based on surgeon's preference, comfort, and the side he or she is operating on, one can start with the stab incision either medially or laterally relative to the affected inguinal ring.

PATIENT SELECTION AND INDICATIONS FOR PEDIATRIC INGUINAL HERNIA REPAIR

Surgery is indicated for all children once an inguinal hernia has been diagnosed. Premature infants or those under 3 months of age with an inguinal hernia are usually scheduled on a semiurgent basis. This is as opposed to the asymptomatic older child, who may be scheduled for surgery in a truly elective manner. In the setting of a communicating hydrocele, most surgeons will observe the majority of children less than 12 months of age,[10] and some children may continue to be observed for longer, as the majority of PPVs will close within the first 12–24 months of life.[10–12]

There is no place in children for conservative management of inguinal hernia. Operative indication is often delayed, although this is usually age dependent.[10,13] Surgery is offered for a communicating hydrocele after the age of 12 months because of persistent enlargement and the potential risk of hernia later in life, and to prevent future symptoms and avoid complicating the diagnosis of an acute scrotum in the future. Surgical treatment is offered for hernia to prevent the risk of incarceration, obstruction, and the necrosis of hernia contents, as well as surrounding cord structures. In females, torsion of the ovary is also possible.[10,14,15] There are no absolute or relative contraindications to inguinal hernia or hydrocele repair; however, surgery is often delayed for other reasons, such as fitness for surgery or issues of abdominal pressure, as occurs in reduction of large abdominal wall defects.

COMPLICATIONS OF MINIMALLY INVASIVE SURGERY FOR PEDIATRIC INGUINAL HERNIA

When discussing the specific complications of laparoscopic pediatric inguinal hernia repair, one must begin with complications secondary to the laparoscopic access in general. Laparoscopy carries its own set of complications, such as air embolism, hypothermia, decreased venous return, hypercapnia, acidosis, needle or trocar injury, and viscous or vessel injury. These are generally seen as a consequence of a lack of surgeon experience. In general, the insufflation pressure should be kept below 15 mmHg, especially in infants, to avoid respiratory compromise or hypercapnia. End-tidal carbon dioxide monitoring and core body temperature should be monitored rigorously in all babies. In addition, laparoscopic surgery carries risks of injury to the iliac vessels, the inferior epigastric vessels, and the gonadal vessels. In gaining laparoscopic access, there is a risk of vascular injury, and thus even these initial steps must not be taken lightly.[16,17] In the case of vascular injury, we stress the importance of adherence to surgical principles, starting with calmly directing the operative and anesthesia teams while gaining proximal and distal control of any bleeding vessel and avoiding reckless movements and potential further damage to surrounding structures.

Other risks of laparoscopic hernia repair are ones shared by open herniorrhaphy as well. Postoperative hydrocele deserves specific mention given the variation in the management of the distal sac in a laparoscopic repair. In some repairs, the distal sac is left intact, and thus raises concern for a higher rate of postoperative hydrocele. However, this has not been borne out when critically appraising the available literature. Similarly, recurrence is of special concern in laparoscopic repairs; the potential for incomplete closure of the ring circumference, the inclusion of tissues other than peritoneum in the ligature, and the failure to detect a direct hernia are some factors suspected as causes for recurrence.[18,19] Some authors have observed that boys have a higher recurrence rate than girls. During relaparoscopy, they found that most recurrences occur medially. Thus, the stitches at the medial aspect of the hernia, close to the vas, seem to be the most crucial ones.[18] This can explain the extreme caution and margin that a surgeon exercises while passing the needle close to the vas or epigastric vessels at the medial side of the internal ring. It seems that even leaving a small medial gap is enough to invite subsequent widening and hernia recurrence. It may be that these are more appropriately termed "incomplete closures" rather than true "recurrences." In girls, the surgeon will have no concerns in placing stitches medially. Therefore, this is probably the reason why girls have fewer recurrences.[18]

The other known complications with open surgery, such as iatrogenic tethering of the testis resulting in a secondary or acquired "undescended testis," chronic inguinal pain, and wound infections, are rare with the laparoscopic approach. Data regarding testicular atrophy and injuries to the vas are not yet available, as long-term results have not been studied. However, it has been proposed that these may be observed much less frequently in minimally invasive approaches, supposedly due to less and more precise dissection enabled by magnification.[16]

OUTCOMES

Laparoscopic repair has been increasingly employed over the last two decades for pediatric inguinal hernias; however, in terms of outcomes, it will always be compared with the long-standing results from open herniorraphy. Proponents of the minimally invasive approach cite the ease of examining the contralateral internal

ring, decreased manipulation of the vas deferens and spermatic vessels, decreased operative time, and an ability to identify unsuspected direct or femoral hernias. The only level 1 evidence in support of a comparison between open and laparoscopic pediatric inguinal hernia repair is a prospective single-center, randomized study of 97 patients from 2005.[20] In their experience, while the operative time for laparoscopic approach took approximately 5 min longer, it was associated with statistically significantly decreased pain, improved parental perception of faster recovery, and a parental perception of better wound cosmesis. The laparoscopic approach also allowed for detection of contralateral hernia at the same time, and this was associated with a statistically significantly lower rate of detecting metachronous contralateral hernias during follow-up. However, various authors have reported varying experiences in terms of success and complications (Table 78.1).

There is clearly an element of experience and the presence of a learning curve that impact the time necessary to complete any operative procedure, as well as the rates of success and complications. In this regard, laparoscopic pediatric inguinal hernia repair is no different, and analyses have shown that increased experience leads to shorter operative time and improved outcomes.[19,25,33,34] One study investigated a learning curve of 75 cases, demonstrating a reduced recurrence rate after that mark.[34] A recent meta-analysis compared series in the literature of open and laparoscopic pediatric hernia repairs with similar findings as the previously mentioned randomized trial.[33] The average reported operative time for a unilateral laparoscopic herniorrhaphy ranges from 10 to 55 min.[16,25,33] This compares to open unilateral herniorrhaphy at 18–52 min, which was not statistically significantly different.[33] However, in the setting of bilateral hernia repair, the laparoscopic approach was statistically significantly shorter, with a range of time reported from 34 to 70 min compared with open repair at 39–95 min.[33] Similarly, the laparoscopic approach showed a statistically significantly reduced rate of metachronous contralateral hernia, with an odds ratio of 0.26. The actual rates of metachronous contralateral hernia varied for open repair from 3% to 11% and for laparoscopic repair from 0% to 6%. Also, in this meta-analysis no significant difference was observed between laparoscopic and open repair in duration of hospital stay, time to resume full activity, recurrence, and complications.

Specifically on the topic of recurrence and complications, there are a variety of reports in the literature, and as previously mentioned, experience clearly plays a role in these outcomes.[25,33,34] The reported rate of recurrence for open herniorrhaphy is between 0% and 5%, which is similar to that in most reports of laparoscopic pediatric inguinal hernia repair, with the exception of one outlying study reporting a recurrence rate of 27%.[26] Factors thought to portend lower recurrence rates include female sex,[18] young patient age,[34] and surgeon volume and experience.[11,12,14]

As previously mentioned, there are risks from hernia repair, both open and laparoscopic. While some authors

describe a lower complication rate with one or the other approach, most reports find no difference between the two. Reported rates for any complication (including recurrence) vary between 1% and 27% for laparoscopy and between 0% and 16% for open repairs. Specific complications, such as postoperative hydrocele, are a concern because in a laparoscopic herniorrhaphy, the distal portion of the sac is left intact without even being split. However, the rates are surprisingly low (0%–5%), which compare favorably to those of open repairs (0%–3%). Other known complications with open surgery, such as iatrogenic tethering of the testis, inguinodynia, and wound infections, are almost unseen in laparoscopic repairs. Testicular atrophy and injuries to the vas are rare complications even in open herniotomy and seem to be observed even less frequently in laparoscopic repairs.[16]

One additional area of concern is the added cost of laparoscopy in this setting. While a full cost-effectiveness analysis has yet to be done, a recent limited analysis indicated that open repair after reduction of an incarcerated hernia was more cost-effective than laparoscopy.[27] This is despite findings similar to those above with decreased hospital stay for laparoscopic repair. The increased cost was mostly carried by the fixed cost of the instrumentation and equipment, in addition to increased operative time. However, this was a limited analysis, only factoring in the cost of surgery and hospitalization; it did not account for other factors, such the need for a later contralateral repair, the cost of repeat visits and hospitalization for recurrence, and the societal cost of missed parental work related to longer hospital stay. It is worth noting that diagnostic laparoscopy alone, when looking for a contralateral inguinal hernia at the time of open hernia repair, has been demonstrated as cost-effective.[35]

Given the relatively new development of the various novel laparoscopic techniques (i.e., LPEC, SEAL, and PIRS), there are a lack of long-term data to allow proper comparison to traditional laparoscopic or open pediatric inguinal hernia repair. However, the results to date for recurrence and/or complications appear to reflect the overall experience with traditional laparoscopic repair.[16,36,37] While these various numbers may provide a broad overview of the general experience with laparoscopic inguinal hernia repair in children, the guiding mantra for a surgeon should be to perform the procedure that in your hands provides the best and safest outcomes and use your personal data for patient counseling.

SPECIAL CONSIDERATIONS

Management of the Contralateral Inguinal Ring

There could easily be textbook chapters written solely on the topic of managing a contralateral PPV when detected laparoscopically. This is because of the known risk of metachronous contralateral inguinal hernia when performing a unilateral hernia repair. Obviously, detection of this contralateral PPV laparoscopically would allow for simultaneous closure; however, there is debate about the natural history of such a PPV. Data from a series of laparoscopic exploration demonstrate a rate of contralateral patency between 10% and 40%.[16] However, a recent, large retrospective review on the issue found that when not addressing an asymptomatic contralateral PPV, the rate of metachronous hernia is approximately 2%. This compares with a recurrence rate of 0.2% if the contralateral PPV is repaired at the same time.[38]

While such limited data would support the routine inspection and repair of contralateral patency, the debate is far from settled. The questions surrounding the issue are as follows: (1) What percentage of these contralateral PPVs truly become symptomatic? (2) Does detection of all contralateral PPVs lead to overtreatment? (3) Is it effective to detect and treat all contralateral PPVs in order to avoid a second anesthetic in the group that eventually develop a true inguinal hernia? (4) Are there ways to determine which patients should have inspection for and/or treatment of a contralateral PPV?

Management of Bilateral Inguinal Hernias

As mentioned earlier in the text, the current data would seem to support the role of minimally invasive approaches to bilateral hernias and communicating hydroceles. There are multiple reports on the fact that with one approach, it is possible to repair both sides, and typically this can be done more quickly than with bilateral open inguinal approaches.[33] Clearly, there are the same risks that exist when approaching a single inguinal ring, such as potential injuries from obtaining peritoneal access, potential vasal or vessel injuries, and risks of recurrence. However, given the defined decrease in operative time, minimally invasive approaches are a reasonable alternative in the setting of bilateral pediatric inguinal hernias.[33]

Management of Recurrent Inguinal Hernias

For recurrent hernias after previous open hernia repair, reoperation with an inguinal incision requires going through the old operation site, which in boys almost always has the vas deferens and testicular vessels embedded in dense fibrous tissue. The operation is tedious and risks damaging these important structures. In such a scenario, laparoscopy allows approaching the pathology from the virgin area and helps avoid the previous operation site. So in effect, technically it may be as simple as a fresh laparoscopic hernia repair. Also, laparoscopy accurately identifies the nature of the defect in children with recurrent groin hernias, detecting unsuspected contralateral indirect, direct, or femoral hernias in a large number of those undergoing laparoscopy.[39]

Management of Incarcerated Inguinal Hernia

The issue of manual reduction of the bowel while the patient is under anesthesia is still controversial; however, using the laparoscopic approach solves this controversy, for the bowel is examined in the peritoneal cavity without the need to manipulate outside through the internal ring,

as happens with the open technique. It is reported that creation of the pneumoperitoneum itself dilates the ring sufficiently, aiding in the reduction of the incarcerated contents. In addition, external compression, forbidden in conventional surgery, is found to be safe and useful because the contents can be observed from inside. Even gentle traction with endoscopic instruments is safe under vision and can facilitate reduction of hernia contents immensely.[40] Laparoscopy also aids in allowing for intracorporeal assessment of the viability of the incarcerated intestine, and if the contents prove unviable, as a result of strangulation, they can be excised totally laparoscopically[41,42] or be laparoscopically guided by a mini-laparotomy on top of the area where the nonviable contents have been laparoscopically placed.[43] One advantage of laparoscopy for incarcerated hernias is that laparoscopic herniorrhaphy is usually done from within the abdomen and bypasses the edematous surrounding tissue and spermatic cord structures, and thus the repair is performed in nonedematous tissue at the internal ring.[44]

Management of Female Inguinal Hernias and Potential for Abnormalities of Mullerian Structures

A minimally invasive approach to female patients with presumed inguinal hernias is ideal because it allows for the assessment of Mullerian structures at the same time as the inspection of the peritoneal cavity to assess the affected inguinal ring. In the setting of open inguinal hernia repair for female patients, the surgeon must confirm the presence of Mullerian structures either via inspection of the peritoneal cavity by pulling on the round ligament to observe a fallopian tube or by concurrent assessment of vaginal length or vaginoscopy.[45,46] However, in utilizing laparoscopic visualization, the surgeon can assess for the presence of Mullerian structures and investigate the potential for complete androgen insensitivity syndrome (CAIS). While only a small minority of prepubertal females with an inguinal hernia will have CAIS (1%–2%), up to 75% of patients with CAIS will present in this manner.[47,48] Thus, it is a diagnosis that must be excluded, and the use of laparoscopic access can prevent the need for ancillary procedures. An additional benefit is the ability to assess the gonads in the setting of CAIS. While it is not determined what the role is for gonadectomy at the time of diagnosis, as opposed to postpubertally, the laparoscopic access does allow for gonadectomy at the same setting, depending on the wishes of the family, as well as the team of surgeons, endocrinologists, geneticists, pediatricians, and psychologists.[46]

Similarly, the entity of hernia uterae inguinale is uncommonly encountered in phenotypically normal boys in the setting of a Mullerian inhibiting substance (MIS) deficiency and persistent Mullerian duct syndrome. While the discovery of Mullerian structures during an inguinal hernia repair can be confusing to the surgeon, as well as the family, a minimally invasive approach offers many advantages, as outlined by a recently published algorithm in managing these patients.[49] In addition to allowing for repair of the hernia, laparoscopy allows for both visualization and biopsy of the gonads and potentially even intra-abdominal reconstruction and orchiopexy or gonadectomy.[50]

CONCLUSIONS

Pediatric inguinal hernias can be safely and reliably managed by a minimally invasive approach, in both males and females, in a wide range of clinical scenarios, from a communicating hydrocele, to a true hernia, to a contralateral PPV, and even for an incarcerated hernia. There are many techniques and variations on the minimally invasive approach to pediatric inguinal hernia repair, and at this point, all seem to have similar efficacy and safety profiles. The most important factor for outcome appears to be surgeon experience. However, while we lack level 1 data demonstrating superiority or equivalence to traditional open inguinal herniorrhaphy, the current data indicate that it is a reasonable and safe alternative to offer patients and their families.

CHAPTER 79

Cryptorchidism

Thomas F. Kolon and Gregory E. Tasian

INTRODUCTION

Cryptorchidism or undescended testes (UDT) are the most common disorder of the male endocrine glands in children. One-third of boys with true cryptorchidism have bilaterally cryptorchid testes, while two-thirds are *unilateral*.[1] The main reasons advocated for treatment of cryptorchidism are impaired fertility, increased risk of testis cancer, increased risk of developing testicular torsion, injury against the pubic bone, and the psychological stigma of an empty scrotum.[2–4] The current standard of therapy in the United States has been the surgical repositioning of the testis within the scrotal sac (orchidopexy), while hormonal manipulation has been more widely used in Europe. However, despite successful relocation of the testis, long-term sequelae of cryptorchidism occur, including infertility, subfertility, and malignancy.

EPIDEMIOLOGY

Cryptorchidism is a common developmental abnormality with a prevalence of 1%–3% in full-term and 15%–30% in premature male infants. In age-corrected full-term boys, spontaneous descent may occur in the first 6 months of life.[5,6] Accordingly, the prevalence decreases to about 0.8% in previously full-term infants at 1 year of age and remains there essentially throughout adulthood. Two-thirds of persistent UDT are unilateral and one-third are bilateral.[1] In boys with unilateral UDT, the right testis is affected twice as often as the left.

In the last decade, the phenomenon of ascending testes (acquired cryptorchidism), which are previously descended testes that ascend out of and cannot be manipulated into the scrotum, has been recognized. An increase in UDT was reported in the United States and South America during the 1970s and 1980s, but since 1985, rates have stabilized or declined in most countries.[7–9] Variability in cryptorchidism rates may be due to observer error with retractile testes, testicular ascent, or previously unrecognized UDT in the high scrotal or superficial inguinal pouch regions.

A number of obstetrical risk factors have been suggested as possible risk factors for UDT, including advanced maternal age, maternal obesity, breech presentation, cesarean section, low parity, consumption of cola-containing drinks during pregnancy, preterm birth, and low birth weight.[6,10–13] Further, hypospadias and a family history of cryptorchidism have also been associated with UDT.[14–16] The incidence of UDT is also directly related to the position of the meatus in boys with hypospadias. Up to 30% of infants with proximal hypospadias will exhibit concomitant cryptorchidism compared with only 2.5%–5% for distal hypospadias. Birth weight has also been closely associated with cryptorchidism: infants of <900 g have approximately 100% incidence of UDT. This incidence steadily decreases as the birth weight of the infant increases (to 3.3% for 2700–3600 g infants).[17,18]

Ascending Testes

Acquired cryptorchidism (or ascending testis) is the ascent of a previously descended testis and subsequent inability to manipulate the testis back into the scrotum. Ascended testes are at risk for developing the same adverse histologic changes seen in primary cryptorchid testes and contribute significantly to the number of orchiopexies performed.[19–26] Acquired cryptorchidism has a reported prevalence of 1%–7% and peaks around 8 years of age.[27–29] Aberrant androgen signaling has been associated with ascending testes. This is supported by the report that boys with a history of proximal hypospadias are at increased risk of developing ascending testes.[30] Given that retractile testes are at risk of becoming true ascended testes, yearly examination of boys with retractile testes or a history of proximal hypospadias is recommended, which could be performed by the pediatrician or pediatric urologist.[31–34]

"Trapped" Testes

In patients who have undergone previous inguinal or scrotal surgery, the testis can become trapped in scar tissue above the dependent scrotum. Identification of the testis can be quite difficult in children who have previously had inguinal or scrotal surgery. Due to the scarring, there is limited mobility of the spermatic cord and, accordingly, increased risk of injury to the testis during operative repair. Various approaches include en bloc mobilization of the spermatic cord and use of a scrotal approach.[35,36]

GONADAL DEVELOPMENT

Proliferation and migration of primordial germ cells from the yolk sac into the mesonephric bodies begins in the

fourth gestational week. By the sixth week, the primordial cell migration from the wall of the embryonic yolk sac along the dorsal mesentery of the hindgut to the genital ridge is completed.[37] These processes accelerate during weeks 5–6, forming the bipotential gonad that replaces the regressing mesonephric body by the end of the sixth week. Differentiation of the bipotential gonad into the testis occurs under control of the SRY (sex-related gene on Y chromosome) gene. Development of testicular histology and endocrine function begins during the seventh gestational week and continues into adulthood. Testis maturation is characterized by four steps (two prenatal and two postnatal) prior to the final maturational changes at puberty.

First, primordial germ cells enter the emerging testicular cords and differentiate into gonocytes. These gonocytes constitute the fetal stem cell pool of the germ cell line and lie in the center of the testicular cords. Human chorionic gonadotropin (hCG) stimulates fetal Leydig cell development, proliferation, and testosterone secretion. Gonocyte proliferation expands the fetal stem cell pool, while fetal Sertoli cells simultaneously differentiate and begin to secrete Müllerian inhibiting substance (MIS). Masculinization of the mesonephric (Wolffian) duct, paramesonephric (Müllerian) duct, and external genitalia begins. MIS causes regression of Müllerian structures, and testosterone causes development of the Wolffian duct, to form the epididymis and vas deferens.[38,39]

In the second step in maturation, gonocytes begin to migrate to the basement membranes of the seminiferous tubules and differentiate into fetal spermatogonia. In this phase, the level of hCG, number of fetal Leydig cells, and level of testosterone reach their peaks during the 13th week of gestation. Masculinization of the external genitalia and resorption of the paramesonephric ducts is completed. Masculinization of the mesonephric duct into the epididymis continues, and the swelling of the gubernaculums begins. Differentiation of fetal spermatogonia continues throughout fetal life. Canalization of the rete testis and mesonephric tubules begins in week 12 and is completed by puberty. Testicular descent occurs in the seventh month of gestation and depends on the multiple factors discussed earlier.

The third step occurs postnatally during the second month after birth (Figure 79.1). By now, the seminiferous tubules contain numerous germ cells. Approximately half are gonocytes, and the rest are fetal spermatogonia. A surge in luteinizing hormone (LH) and follicle-stimulating hormone (FSH) levels stimulates proliferation of fetal Leydig cells, in turn causing a surge in testosterone. A minority of gonocytes attach to the tubule basement membrane and differentiate into adult dark (Ad) spermatogonia, while the majority undergo apoptosis, thus lowering the total germ cell number. Consequently, the gonocyte fetal stem cell pool is replaced by Ad spermatogonia, which ultimately comprise the stem cell pool in adults. The transformation and disappearance of gonocytes is normally completed by 6 months of age. The levels of gonadotropins and testosterone fall as fetal Leydig cells become juvenile Leydig cells, which are quiescent. Some Ad spermatogonia mature into adult pale (Ap) spermatogonia. Fetal Sertoli cells mature into Sa Sertoli cells.

At approximately 5 years of age, the fourth important maturational step commences with the onset of meiosis. Simultaneous transient peaks of LH, number and size of juvenile Leydig cells, and testosterone occur. The increased testosterone stimulates an increase in Ad spermatogonia and the total germ cells. It also triggers the maturation of the mitotic Ad spermatogonia into primary spermatocytes, which are germ cells in the prophase of the first meiotic division. Sa Sertoli cells mature into Sb Sertoli cells.

Final germ cell maturation at puberty depends on adequate completion of the two prepubertal developmental milestones. The pubertal surge in LH and FSH stimulates the inactive juvenile Leydig cells to multiply and mature into adult Leydig cells. These adult Leydig cells produce the high pubertal surge in testosterone, which triggers the final maturation to secondary spermatocytes, early and late spermatids, and sperm. Sertoli cells undergo their final maturation into Sc Sertoli cells. Complete spermatogenesis is usually accomplished by 13–15 years of age.

In the cryptorchid testis, the number of Leydig cells is decreased and they appear atrophic (Figure 79.2). In the first 6 months of life, the total number of germ cells is within the normal range in cryptorchid testes; however, the number of spermatogonia remains low and does not

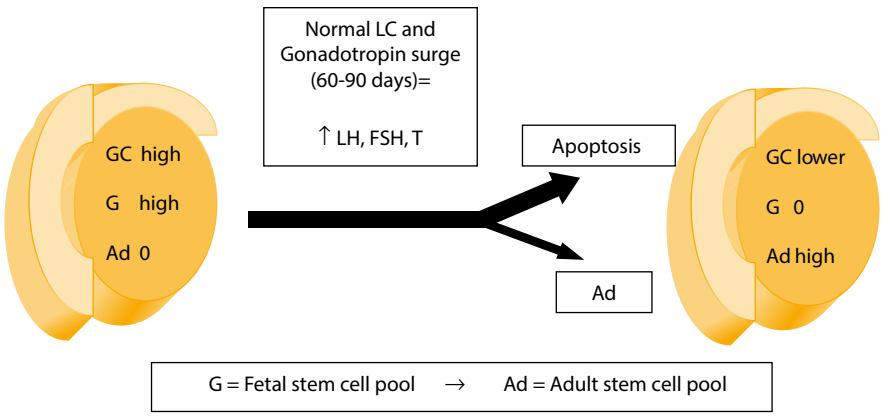

FIGURE 79.1 Third step in maturation: Differentiation of fetal gonocytes into Ad spermatogonia. GC = total germ cell count, G = gonocyte, Ad = adult dark spermatogonia, LC = Leydig cell, T = testosterone.

increase with age. Histologic examination of cryptorchid testes has shown that testes that remain undescended are associated with progressive loss of germ and Leydig cells.[22] There are reports that gonocytes fail to transform into Ad spermatogonia in the cryptorchid testis.[40] The normal postnatal development of Leydig cells and germ cell transformation parallels the normal gonadotropin and resultant testosterone surge around 60–90 days of life.[41,42]

ETIOLOGY

Despite the relatively frequent incidence of cryptorchidism, the etiology and molecular markers of future fertility or malignancy remain obscure. Cryptorchidism is a well-known manifestation of chromosomal abnormalities and a common component of more than 50 syndromes of multiple congenital anomalies. Cryptorchidism, when associated with other congenital anomalies, like hypospadias, has a higher incidence of chromosomal anomalies (12%–25%) than when it occurs as an isolated defect (3%–4%).[43–45] However, at present, there is no consistent chromosomal disorder associated with isolated cryptorchidism.

Cryptorchidism can be viewed as an endocrinopathy. Cryptorchidism accompanies defects in every intrinsic step of the hypothalamic–pituitary–testicular–end organ axis, as well as defects in extrinsic pathways that affect the axis, such as extratesticular cholesterol synthesis, adrenal steroidogenesis, placental "insufficiency," and maternal or environmental endocrine disruptors. Huff clarified the central role of cryptorchidism in the endocrinopathy of hypogonadism. In his analysis of cryptorchid boys, more than 70% of those examined had one or more of these late defects of masculinization associated with the endocrinopathy of hypogonadism. He classified the multiple conditions upstream from cryptorchidism into errors of blastogenesis, organogenesis, sexual differentiation, and late masculinization; while the cascade of events downstream from cryptorchidism are testicular atrophy, microlithiasis, intrauterine torsion, Sertoli cell nodules, and most importantly, germ cell maldevelopment. The abnormal proliferation and maturation of germ cells in cryptorchidism leads to an overall decrease in total germ cell counts and loss of the adult stem cell population. These alterations in germ cell maturation and proliferation produce the most important tertiary abnormalities of the sequence: subfertility and testicular neoplasia.[46]

Several case series of the familial occurrence of cryptorchidism have demonstrated that a heritable component exists.[47,48] Furthermore, large epidemiologic studies have shown a consistent pattern of inheritance for isolated cryptorchidism. Of boys with UDT, 4.0% of their fathers and 6.2%–9.8% of their brothers also had UDT.[6] Elert et al. conducted a study to examine the frequency of a positive family history and to calculate the risk for the newborn male boys to have a UDT. They reported that boys born to parents with a family history of cryptorchidism have a 3.6 times higher odds of having cryptorchidism.[49] These inheritance patterns are consistent with a multifactorial etiology of cryptorchidism. Based on murine gene knockout models, some of the candidate genes involved in cryptorchidism are homeobox (*HOX*), calcitonin gene-related peptide (*CGRP*), insulin-like hormone (*INSL3*), G-protein-coupled receptor affecting testis descent (*LGR8* or *GREAT*), androgen receptor (*AR*), and the estrogen receptor 1 (*ESR1*) genes. In a large, well-designed, cohort study, 3.3% of boys with UDT that did not spontaneously descend had identifiable genetic alterations in the karyotype INSL3, AR, or relaxin family peptide 2 gene (RXFP2). This represented a 10 times greater odds of having a mutation in these genes than controls. The likelihood of having a genetic alteration was higher in those boys with bilateral cryptorchidism (OR 27.1).[50]

Androgen Influence

Hutson has proposed that testicular descent occurs in two phases. The initial transabdominal aspect may be controlled by MIS.[51] The inguinoscrotal descent appears to be androgen dependent and is mediated indirectly through the release of CGRP. Androgens act on the genitofemoral

nerve (GFN), which is sexually dimorphic and releases CGRP upon stimulation, producing rhythmic contractions of the murine gubernaculum. Hutson et al. found two rodent models of cryptorchidism to have deficiencies of CGRP in the GFN (the Tfm mouse and the rat prenatally exposed to antiandrogen).[52,53] Alternatively, Huff has proposed that there is only a transinguinal phase of testis descent based on a pathologic examination of human fetal specimens at Carnegie Human Embryos.[54] According to this theory, after gonadal formation, the formerly suggested "transabdominal migration" is actually a single position where the abdominal testis "appears to descend" due to the unfolding of the human embryo around 8–9 weeks of gestation, as it moves from the embryonic to the fetal stage of development.

Inguinoscrotal descent is blocked in mice with complete androgen resistance (testicular feminization) where the *AR* gene has been knocked out.[51,55] Deletions and mutations may cause structural changes in the AR, altering its function.[56] Up to 50%–70% of male pseudohermaphroditism, which includes hypospadias and cryptorchidism, is due to *AR* gene disorders (androgen insensitivity syndrome [AIS]), suggesting a role for androgens in this developmental process.[57,58] Other studies have shown that prenatal androgen disruption and androgen receptor polymorphisms are associated with hypospadias and primary cryptorchidism, which further supports the central role of androgens in testicular and penile development.[59–63] The majority of *AR* gene mutations identified are in the DNA-binding (exons 2–3) and ligand-binding (exons 5–8) domains. However, the same mutation can result in a different or even a normal phenotype in members of the same family.[64,65] It appears that phenotypic variations in families affected by partial AIS are modulated by factors other than or in addition to point mutations of the *AR* gene. Furthermore, the role of the *AR* gene mutations in isolated forms of hypospadias or cryptorchidism is an active area of investigation. It is a definite yet uncommon cause of hypospadias.[66–68] Since the last edition of this chapter, mutations in the androgen receptor have been identified in boys with isolated cryptorchidism.[50]

Exon 1 of the *AR* gene contains the transactivation domain and encodes polymorphic glutamine (cytosine–adenosine–guanine [CAG]) repetitive sequences. The CAG repeat length ranges from about 15 to 30 units in controls, exhibiting ethnic variability.[69] Within this spectrum, the CAG length influences androgen receptor function, providing enhanced androgen action with a shorter repeat length and decreased function with a longer length.[70] Mutations in a series of CAG trinucleotide repeat sequences located at a polymorphic region in exon 1 of the *AR* gene have been linked to an X-linked neuromuscular disease termed spinal bulbar muscular atrophy or Kennedy's disease.[71] These affected men display subtle signs of androgen resistance, such as gynecomastia, testicular atrophy, and reduced fertility. Increased AR CAG length has also been related to male infertility through defective spermatogenesis, although others have found conflicting results.[72–74] Within the normal polymorphic range, an expansion of the CAG tract decreases the androgen receptor activity and may be associated with cryptorchidism, infertility, and recently, testis cancer.[75–77] The association of CAG repeat lengths with these three conditions suggests that CAG length may have a central role in testiscular dysgenesis syndrome, which is composed of cryptorchidism, poor semen quality, hypospadias, and testicular cancer. Casella et al. have seen an increased CAG length when both cryptorchidism and hypospadias are present.[78] Ogata et al. reported an abnormally expanded CAG length in a boy with undermasculinized genitalia, but later concluded that CAG expansion is not likely a major cause of cryptorchidism.[79,80] Ferlin et al. analyzed CAG and GGC exon 1 repeat lengths in 105 formerly cryptorchid men compared with 115 fertile noncryptorchid men.[81] No difference was found when considered separately, but some combinations of repeat lengths are significantly more frequent in men with bilateral UDT, in a manner similar to that in findings in idiopathic infertile males.

Although historic studies have shown that androgen levels in adult men with a history of hypospadias do not differ from those of controls,[82] more recent studies have indicated that prenatal androgen disruption and androgen receptor polymorphisms are associated with hypospadias and primary cryptorchidism.[59–63] The theory is supported by the findings of Acerini et al., who reported that boys who developed acquired cryptorchidism had shorter penile lengths at 2 years than normal boys and boys with primary cryptorchidism, a difference that did not exist at birth.[29]

Estrogen Influence

The *ESR1* gene is a potentially important candidate gene for UDT. In a Japanese population, Yoshida et al. performed *ESR1* analysis in 63 cryptorchid boys and 47 controls by screening 30 single-nucleotide polymorphisms (SNPs) in the gene.[83] They found a significantly higher polymorphism frequency of an AGATA haplotype (SNP12) within the intron in cases than in controls (34% vs. 21%), and the association of the haplotype with UDT was significant in a recessive mode. The investigators speculate that this SNP enhances *ESR1* signaling. However, when these same SNPs were analyzed in a multiracial population, SNP12 was not associated with the occurrence of cryptorchidism, but was associated with the severity of cryptorchidism.[84] These results suggest that excessive estrogenic effects may decrease expression of INSL3 in Leydig cells, affecting the development of the gubernaculum, and so testicular descent. Further, excessive estrogenic signaling may suppress gonadotropin production and the steroidogenic capacity of Leydig cells, resulting in androgen deficiency.

Similar alterations in sex hormones have been hypothesized to increase the risk of hypospadias.[85,86] Although historic studies have shown that androgen levels in adult men with a history of hypospadias do not differ from those in controls,[82] more recent studies have indicated that prenatal androgen disruption and androgen receptor polymorphisms are associated with hypospadias and primary cryptorchidism.[59–63]

INSL3/RXFP2 Genes

Several investigators have examined the role of Leydig insulin-like hormone as a putative trophic hormone of

the first part of testicular descent. It is a member of the insulin hormone superfamily and is expressed in the developing testis. Mice mutant for *Insl3* are viable but exhibit bilateral cryptorchidism.[87–89] These mice have developmental abnormalities of the gubernaculum and abnormal spermatogenesis and infertility. However, in a manner similar to that of the *AR* gene, mutations of the *INSL3* gene in humans are infrequent.[90–92] RXFP2 (also known as GREAT and LGR8), which is the receptor for INSL3, is also highly expressed in the gubernaculum.[93–95] Mutations in this gene have been associated with cryptorchidism in the mouse and rarely in the human.[96–98] Screening of approximately 700 patients with UDT for allelic variants in INSL3 yielded several mutations, only one of which (P49S) reduced INSL3 binding to RXFP2.[99] Mutation analysis of the *RXFP2* gene revealed a single mutant T222P allele found in 3% of patients and no controls. The mutant allele produces a nonfunctional receptor unable to respond to ligand stimulation in vitro.[97] Thus, in some patients it appears that an abnormal gubernaculum plays a role in the testicular maldescent. These genes may work in concert to help control testis development and migration, but mutations involving these two genes do not represent a frequent cause of UDT in humans.

Homeobox Genes

HOX genes play a key role in the morphogenesis of segmental structures along the anterior posterior body axis.[100] These genes act as master regulatory switches or transcription factors that specify axial identity and control the growth and differentiation of cells related by position. Murine *hoxa10* knockout male mice exhibited bilateral cryptorchidism with developmental abnormalities of the gubernaculum and resultant abnormal spermatogenesis and infertility.[101,102] Similarly, mice homozygous for *hoxa11* deletions are also infertile and cryptorchid.[103] Hormonal disruption was likely not the cause of UDT in these knockout mice, as they appeared normally masculinized. In situ hybridization for *hoxa10* transcripts in wild-type mice indicate that this gene is expressed in the gubernacular cord and bulb, but not in other tissue of the male reproductive tract.[101] Branford et al. found that the reproductive tracts of *Hoxa10* or *Hoxa11* single heterozygous mutants were normal, but male transheterozygotes (*Hoxa10*± and *Hoxa11*±) displayed UDT and tortuous ductus deferens, similar to what is seen with the knockouts of these genes.[102] *Hoxa10* and *hoxa11* appear to be functionally redundant in the development of the male reproductive tract, such that a quantitative loss of any two *hoxa10/hoxa11* alleles results in similar testicular anomalies. It is likely that *hox11* is important for gubernaculum function, as mice with *hox11* mutations exhibited abnormal gubernacula that failed to migrate.[104]

Several human studies have been conducted to evaluate the association between allelic variants in *HOX* genes and UDT. Allelic variants in *hox13* have been shown to be increased in subjects with cryptorchidism compared with controls.[105] Similarly, Kolon et al. found that out of 45 boys, five missense mutations and one large deletion were found in exon 1 of *HOXA10*, which represented a statistically significant elevation in allelic variants in the UDT group compared with controls.[47] However, in a smaller study, Bertini et al. examined exons 1 and 2 of *HOXA10* for allelic variants in 18 patients with UDT and 28 healthy controls. The same allelic variant was detected at similar levels in cases and controls.[48] Further evaluation should be carried out to fully characterize the role of these posterior *HOX* genes in abnormal testicular descent. Many other gene products have been targeted as being expressed in testicular differentiation (i.e., *PAX5*, *SRY*, *SOX9*, *DAX1*, and *MIS*) but not specifically in cryptorchidism (for review, see Hughes[106] and Nudell and Turek[107]).

Hormonal Factors

It has been theorized that this spontaneous descent in infancy may occur due to the normal gonadotropin surge that occurs around 60–90 days of life.[41,108–110] Job et al. and Gendrel et al. reported that this surge is blunted in boys with UDT that remain undescended in the first year of life.[108,109] They demonstrated a significant difference in the polynomial regression curves, comparing the testosterone levels of persistently cryptorchid testes with those having delayed spontaneous descent. However, the positive predictive value that bilateral UDT will have abnormally low testosterone levels is only about 23%. Recently, Iwatsuki et al. reported that peripubertal boys with hypospadias and cryptorchidism had higher levels of FSH than controls.[111] In contrast, Barthold et al. examined gonadotropin and testosterone, estradiol, inhibin B, leptin, and sex hormone–binding globulin in a cohort of cryptorchid boys. They failed to identify any significant differences in hormonal levels in their cohort compared with controls.[112]

An endocrine disruptor is an environmental chemical that interferes with the production, transport, and metabolism of hormones in the body. Some of these agents have estrogenic activity, while others act as agonists and antagonists of androgens. Endocrine disruptors have been hypothesized to play a role in cryptorchidism, as androgens contribute significantly in the physiology of germ cell development and testicular descent. Several environmental chemicals have antiandrogenic effects in rodent models. Although these agents act by many different mechanisms, they all produce similar effects on the developing male reproductive tract. At high *in utero* doses, antiandrogens are associated with UDT and agenesis of the epididymis, while at lower doses, hypospadias and decreased anogenital distances are seen. Boys exposed to the antiandrogenic effects of diethylstilbestrol *in utero* have an increased number of genital abnormalities, including cryptorchidism.[113]

Phthalate esters inhibit testosterone synthesis during fetal life and produce dose-related abnormalities of the male reproductive tract, such as focal hyperplasia of fetal Leydig cells that persists postnatally, as well as agenesis of the gubernaculum.[114–117] Findings with the phthalates are of particular concern because exposure is ubiquitous and phthalates are widely used in many consumer products. The phthalate monoester metabolites

have been found in urine samples of >75% of approximately 2550 participants in the 1999–2000 National Health Nutrition and Examination Survey.[118] In animal models, phthalates reduce cholesterol transport across the mitochondrial membrane, decrease testosterone biosynthesis, and reduce expression of the *insl3* gene.[119–121] Animal research findings demonstrate a coordinated, dose-dependent reduction in the expression of key genes involved in cholesterol transport and steroidogenesis, and a corresponding reduction in testosterone in fetal testes at low dibutyl phthalate (DBP) doses, which do not produce male reproductive tract anomalies.[114] Similar studies have been carried out in adult rats to determine the pattern of gene expression in the proximal Wolffian duct, which gives rise to the epididymis, following prenatal exposure to DBP. Changes in mRNA expression were observed in genes involved in testosterone biosynthesis and testicular descent, including the insulin-like growth factor pathway and the androgen receptor.[122] These alterations in expression of genes at phthalate doses that do not produce isolated UDT suggest that gene–environment interactions could occur in human populations. It has been hypothesized that fetuses with susceptible genotypes exposed *in utero* to environmentally relevant doses of phthalates may be at the greatest risk for developing UDT. Familial clustering of hypospadias and UDT among first-degree relatives has been suggested as evidence for a genetic component for these anomalies. However, another etiologic possibility is the role of exposure to environmental contaminants in familial clusters because of the high probability of shared exposures among first-degree relatives.[123]

These animal findings further advocate a multifactorial and complex etiology of cryptorchidism. UDT is a variable and multifactorial phenotypic trait that likely involves several candidate genes and hormonal and environmental risk factors, rather than a causative single gene mutation. It is likely that a perturbation in the dynamic equilibrium of these factors is involved in the pathogenesis of cryptorchidism.

DIAGNOSIS

History and Physical Exam

A thorough history should include prematurity (the incidence of UDT in premature boys is as high as 30%), maternal use or exposure to exogenous hormones (estrogens), lesions of the central nervous system (myelomeningocele), and previous inguinal surgery. Document a family history of cryptorchidism and other congenital anomalies, neonatal deaths, precocious puberty, infertility, and consanguinity. It is also important to know if the testes were ever palpable in the scrotum at the time of birth or within the first year of life. Testicular retraction, due to a strong cremasteric reflex, is most apparent between 4 and 6 years of age and may lead to an inaccurate diagnosis of UDT.

An undescended testis can be classified by its location. It may be located in the abdomen, the inguinal canal, the superficial inguinal pouch, the upper scrotum, or rarely, in an ectopic location (perineum, contralateral scrotum, or femoral). However, for treatment purposes, the main distinction that needs to be made is whether the testis is palpable.

The patient should be examined supine in the frog leg position with both legs free. With warmed hands, check the size, location, and texture of the contralateral descended testis (CDT). Begin examination of the UDT at the anterior superior iliac spine and sweep the groin from lateral to medial with the nondominant hand. Once the testis is palpated, grasp it with the dominant hand and continue to sweep the testis toward the scrotum with the other hand. With a combination of sweeping and pulling, it is sometimes possible to bring the testis to the scrotum. Maintain the position of the testis in the scrotum for a minute, so that the cremaster muscle is fatigued. Release the testis, and if it remains in place, it is a retractile testis. If it immediately pops back to a prescrotal position, it is a UDT.

For the difficult-to-examine patient (chubby 6-month-olds or obese youths), the sitting cross-legged position or the baseball "catcher's position" can also help relax the cremaster muscle. Wetting the fingers of the nondominant hand with lubricating jelly or soap can increase the sensitivity of the fingers in palpating the small, mobile testis.

A retractile testis is often confused with a UDT. The key to distinguishing a retractile testis from a UDT is demonstrating that the testis can be delivered into the scrotum. The retractile testis will stay in the scrotum after the cremaster muscle has been overstretched, while the low UDT will immediately pop back to its undescended position after being released. If there is any question, the child should be seen in follow-up for a repeat exam. Miller et al. have also recommended the use of hCG stimulation to help distinguish between a retractile and an undescended testis in the hard-to-examine child.[124]

In one series, more than 70% of UDT are palpable.[125] That leaves approximately 30% of testes that cannot be localized by physical exam. For testes that are not palpable, approximately 30% will be found in the inguinal-scrotal area, 55% will be intra-abdominal, and 15% will be absent or "vanished."[125–127] An atrophic or vanishing testis can be found anywhere along the normal path to the scrotum. The etiology is thought to be due to neonatal vascular ischemia, possibly due to torsion.[128] The CDT may be hypertrophied in these boys; however, hypertrophy of the contralateral testis is not an unequivocal sign that the nonpalpable testis is vanished or a nonfunctional nubbin.

Initial diagnostic laparoscopy or inguinal exploration will identify a viable testis or confirm an absent testis by revealing blind-ending spermatic vessels or a nonviable nubbin.[129–133] Upon surgical exploration, 60%–80% of nonpalpable testes are present in the inguinal canal or in the intra-abdominal location, while up to 40% are absent or are an inguinoscrotal nubbin of fibrous tissue and hemosiderin. The presence of bilateral UDT should raise suspicion of an endocrine disorder or an intersex state that should be evaluated. Cryptorchidism associated with hypospadias, especially proximal, should also raise the possibility of the intersex state and occurs in 30%–40% of patients, mainly consisting of defects in the testosterone synthesis pathway.[134]

Laboratory Tests

In boys with unilateral or bilateral UDT where one testis is palpable, no further laboratory evaluation is necessary to aid the diagnosis. In boys with bilateral UDT where neither testis is palpable and also in boys with associated hypospadias, chromosomal and endocrinologic evaluation may be carried out but is not always necessary.[44] These levels should be drawn during the maternal newborn gonadotropin surge or at 60–90 days of life. In patients 3 months or younger with bilateral nonpalpable UDT, LH, FSH, and testosterone levels will help determine whether the testes are present. After 3 months of age, an hCG stimulation test will aid in the diagnosis of the absent testes. A weight-based single injection of hCG (100 IU/kg) is usually sufficient to detect a rise in serum testosterone 4–5 days later.[135] A failure to see a measurable increase in testosterone, in combination with elevated LH and FSH, is consistent with the diagnosis of anorchia.[136,137] MIS may be a more sensitive and specific prepubertal marker for detecting the presence of testes. Lee et al. found that serum MIS correlates with testicular tissue. A measurable value is predictive of nonpalpable UDT, while an undetectable value is highly suggestive of anorchia but warrants further investigation, such as hCG stimulation.[138] It should be noted that both MIS and testosterone levels may be misleading in cases of UDT with a disorder of sex development if the testes are severely dysgenetic or there is a mutation of the anti-Müllerian hormone or receptor genes. Thorup and colleagues further refined the serologic evaluation of bilateral nonpalpable testes. There are preliminary data that a single serum sample, without hCG stimulation, which demonstrates low inhibin B and elevated gonadotropins, is indicative of bilaterally absent testes or nonfunctional nubbins.[139]

Imaging

Hrebinko and Bellinger found that the most reliable mode of exam has been the physical exam by a pediatric urologist (84%) compared with a referring physician (53%). The accuracy of the radiological exam was 44%, and the study did not influence the management decision in any of the cases.[140] Despite the primacy of the physical exam, ultrasound is ordered quite frequently in the initial evaluation of the boy with cryptorchidism.[141] However, the routine utilization of ultrasound is unnecessary. Tasian and Copp analyzed the diagnostic performance of ultrasound in the evaluation of nonpalpable UDT. They found that the sensitivity and specificity of ultrasound in correctly identifying a nonpalpable testis were 45% and 78%, respectively. Accordingly, a positive ultrasound increases and a negative ultrasound changes the probability that a nonpalpable testis is located within the abdomen from 55% to 64% and 49%, respectively. These results indicate that preoperative ultrasound does not reliably localize nonpalpable testes and is not useful in determining the surgical management of these patients.[142]

Early studies have shown that computed tomography (CT) can localize UDT; however, many of the testes seen on CT were potentially palpable in the inguinal canal.[143,144] Recent studies have demonstrated the risk of secondary malignancies conferred by ionizing radiation, which is especially pronounced in the pediatric population.[145] While CT has an important role in the staging of testis cancer, for which boys with a history of cryptorchidism are at risk, there is no role for routine CT evaluation of boys with UDT.

MRI has greater diagnostic performance than ultrasound for localizing nonpalpable testes. Yeung et al. employed gadolinium-enhanced magnetic resonance angiography (MRA) to identify 100% of canalicular UDT and 96% of intra-abdominal UDT (one missed vanishing testis).[146] Eggener et al. performed a hypothetical protocol of MRA with observation of testicular nubbins, and nearly one-third of the boys avoided surgery without any increased cost of care.[147] More contemporary studies that have utilized conventional MRI in conjunction with diffusion-weighted MRI to identify nonpalpable testes have demonstrated similar performance characteristics. In this series, conventional MRI had a sensitivity of 85% and a specificity of 87.5%. When combined with diffusion-weighted imaging, the sensitivity increased marginally to 89.5% and the specificity remained the same. However, even for MRI, not identifying a testis does not completely exclude its absence.[148,149] Currently, for nonpalpable testes open inguinal exploration or laparoscopy is necessary to confirm the presence of testes.

TREATMENT

Hormonal Therapy

Primary hormonal therapy with hCG or gonadotropin-releasing hormone (GnRH) (or LH-releasing hormone [LHRH]) has been used for many years, especially in Europe. The action of hCG is virtually identical to that of pituitary LH, although hCG appears to have a small degree of FSH activity as well. It stimulates production of gonadal steroid hormones by stimulating the Leydig cells to produce androgens. The exact mechanism of action of the increased androgens in testicular descent is not known, but it may involve effects on the testicular cord or cremaster muscle. This medication is administered by intramuscular injection. Multiple series have been published, but due to differences in patient age, treatment schedules, and the possible inclusion of retractile testes, very divergent results have been reported.

Many dosage schedules are reported, ranging from 3 to 15 doses.[150–153] However, hCG appears to be as effective in 3 or 4 doses as in 9 or 10 doses. One of the most common schedules is 250 IU/dose in young infants, 500 IU/dose up to 6 years old, and 1000 IU/dose greater than 6 years old given twice a week for 5 weeks (International Health Foundation). Success rates for descent into the scrotum are 25%–55% in uncontrolled studies, but only 6%–21% in randomized, blinded studies. Distal inguinal testes in older boys are more likely to descend in response to hormonal treatment than abdominal testes. Repeated courses have offered little advantage. Side effects of hCG treatment include increased scrotal rugae, pigmentation, pubic hair, and penile growth, which regress after treatment

cessation. A total dose of more than 15,000 IU must be avoided since it may induce epiphyseal plate fusion and retard future somatic growth.

Agonistic analogues of GnRH, such as nafarelin or buserelin, stimulate the release of the pituitary gonadotropins, LH and FSH, resulting in a temporary increase of gonadal steroidogenesis. Repeated dosing abolishes the stimulatory effect on the pituitary gland, and twice daily administration leads to decreased secretion of gonadal steroids by 4 weeks. These hormones are available as a nasal spray but are only approved for the treatment of cryptorchidism in Europe. Interpretation of results is again tainted by multiple treatment strategies. Success rates in uncontrolled studies range from 13% to 78%, while better-controlled investigations resulted in 6%–38%.[153,154] Rajfer et al. conducted a randomized, double-blind study comparing hCG 3300 IU per week for 4 weeks with GnRH spray 200 μg six times a day for 4 weeks. Descent into the scrotum occurred in 6% of the hCG group and 19% of the GnRH group.[152] Several authors have recommended combined GnRH-hCG hormonal treatment. Lala et al. administered LHRH 1.2 mg/day for 4 weeks and nonresponders also received hCG 500 IU three times a week for 3 weeks. After combined treatment, 38% of testes descended.[154] Bica and Hadziselimovic treated patients with a low dose of buserelin 20 μg as a daily spray for 28 days, followed by hCG for failures. Twenty-six percent of the testes descended with the spray alone, while hCG increased the descent to 37%.[155] Hadziselimovic et al. advocated initial treatment with GnRH spray 400 μg tid into each nostril for 4 weeks, followed by salvage treatment for failures with hCG 1500 IU/week for 3 weeks. A success rate of 56% with GnRH was increased to 65% with the addition of hCG.[156]

The recognized side effects of increased androgens, including increased penile or testicular size, scrotal erythema, or erections, seem to be less with GnRH than hCG. Initial treatment with GnRH may deserve some consideration since it is administered as a spray rather than an injection. Even in 20% of patients, it may aid descent in more distal testes, make intra-abdominal testes palpable, or help differentiate retractile from true UDT. Hormonal therapy may also have a beneficial effect on fertility indices.[157] It has been shown that use of LHRH analogue in boys with very severe histological changes in the testis (total germ cell count of less than 0.2 germ cells/tubule in UDT and less than 0.6 germ cells/tubule in CDT) has an advantageous effect on the developing germ cells. In a study by Huff et al., patients who had no germ cell count on the biopsy did not show improvement after hormonal therapy, but those who had some germ cells demonstrated improvement.[158] This improvement in germ cell count and maturation may eventually reflect a better prognosis for fertility. GnRH, LHRH, and hCG administration prior to orchiopexy has been shown to improve the fertility index on histopathologic analysis of biopsies obtained at the time of orchiopexy.[159,160] Although it is unknown if this effect on testis histology persists into adulthood or disappears once the hormonal stimulus is removed, Hadziselimovic and Herzog showed that men who were treated in childhood with hormones had better semen analyses than men who had childhood orchidopexy alone or placebo treatment.[161]

LONG-TERM PROGNOSIS

Patients with cryptorchidism have two major concerns. They have an increased incidence of developing testicular cancer and also a heightened risk of subfertility.

Testicular Malignancy

Men with a history of cryptorchidism have an increased risk of testicular cancer. The increased incidence of malignancy in cryptorchid testes varies from 49/100,000 (0.05%) to 12/1075 (1%).[162] Early reports stated a significantly higher risk of carcinoma in an abdominal testis; however, inclusion of boys with abnormal karyotypes or genitalia may have biased the results.[163] Although one postulate is that the etiology of the testicular cancer is related to the abnormal position of the testis, the mild increase in cancer in the contralateral descended mate argues for an intrinsic testicular abnormality as the cause. The increase in incidence of malignancy in the cryptorchid testis warrants close follow-up, especially after puberty. Every cryptorchid boy should be taught how to perform a monthly testicular self-examination in order to try to enable early detection. Although the historical teaching has been that orchiopexy does not decrease the risk of testicular cancer, more recent studies have demonstrated that orchiopexy performed before puberty decreases the risk of testis cancer compared with in those boys with cryptorchidism who undergo orchiopexy after puberty. However, the risk of testis cancer does not decrease to that of normal controls even when orchiopexy is performed at an early age.[164,165]

Fertility

Formerly bilaterally cryptorchid men have greatly reduced fertility compared with unilateral cryptorchids and the general male population.[3] Lee et al. showed a paternity rate of 62% (38% infertile) in formerly bilaterally cryptorchid men compared with a matched control group of 94% (6% infertile), indicating a six times increased risk.[166] In contrast, unilaterally cryptorchid men had a paternity rate of 89.5%, which is similar to the level of infertility found in other studies of the general population.[167] Examination of subfertility, or time to pregnancy, shows that bilaterally cryptorchid men have greatly increased waiting times to pregnancy (33.9 months compared with 11.1 months for unilaterals and controls). Lee et al. also examined the association of pretreatment testis location with fertility rates and various hormone levels (inhibin B, LH, FSH, and testosterone) in adulthood.[168] They concluded that "preoperative testis location in men with previous unilateral cryptorchidism is not a major determinant of fertility according to paternity, sperm count, or hormone levels." A prepubertal Ad spermatogonia count or other as yet unidentified molecular markers may be more useful indicators of fertility (and paternity) in these patients. Further investigation is needed concerning sperm motility, morphology, and function.

SUMMARY

Research efforts to define the pathophysiology of cryptorchidism and its sequelae have rapidly advanced in the past 10 years. Surgical techniques have been so refined that today 6-month-old cryptorchid boys are safely and successfully repaired. Further studies will be aimed at identifying those boys that are at increased risk for future infertility or malignancy in order to intervene early and change their outcome.

CHAPTER 80

Surgical Treatment

Daniel P. Casella, Steven G. Docimo, and Francis X. Schneck

INTRODUCTION

The goals of all surgical therapy for cryptorchidism are preservation of fertility, repair of patent processus vaginalis, and relocation of a viable testicle to the scrotum in a tension-free manner. The first step of management is performing an exam under anesthesia and confirming whether a testicle is palpable. One study found that up to 18% of boys who were thought to have a non-palpable testis had a palpable gonad when examined under anesthesia,[1] negating the need for intra-abdominal exploration.

SURGICAL MANAGEMENT OF PALPABLE TESTIS

Inguinal Orchiopexy for the Palpable Testis

The key steps of this procedure are (1) complete mobilization of the testis and spermatic cord, (2) repair of the patent processus vaginalis, (3) preservation of vascular integrity while mobilizing the spermatic cord to achieve tension-free placement of the testis within the dependent position of the scrotum, and (4) fixation of the testis in the scrotum.

A transverse inguinal skin incision is made in the midinguinal canal, usually in a skin crease in children younger than 1 year of age (Figure 80.1). The dermis is opened with electrocautery, and subcutaneous tissue and Scarpa's fascia are opened sharply, taking care to avoid the testis, which is found deep in the scarpas and usually superficial to the external oblique fascia in the superficial inguinal pouch. Sharp dissection cleans the surface of the external oblique fascia of prefascial fat, and gentle spreading over Poupart's ligament defines the full lateral extent of the external oblique fascia (Figure 80.2). This maneuver is helpful to maintain anatomic orientation in defining the area directly over the inguinal canal.

If the testis is intracanalicular and not lying in the superficial inguinal pouch, the external oblique fascia is opened with a small superficial incision that is carried through the external ring, with care taken to preserve the ilioinguinal nerve. Once identified, the tunics overlying the testis are grasped, and the distal gubernacular attachments are sharply dissected. Cremasteric muscular fibers and any anomalous fibrous attachments from the superficial peripheral fascia are then dissected sharply away from the testis and spermatic cord (Figure 80.3). Once the spermatic cord is freely mobilized from cremasteric attachments in the inguinal canal, the tunica vaginalis is opened over the testis (Figure 80.4).

Complete mobilization of the spermatic cord is essential to achieve adequate cord length for tension-free placement of the testis into the scrotum. This should not be done at the risk of devitalizing the vascular supply to the testis or damaging paratesticular structures, including the vas deferens. The key steps in this part of the operation include (1) complete transection of the fused fibers between the cremasteric muscle and the internal oblique muscle; (2) dissection of internal spermatic fascia from the cord structures (Figure 80.5); and (3) complete separation of the patent processus vaginalis from the elements of the spermatic cord, with mobilization and ligation of the hernia sac and peritoneum to at least just inside the internal ring (Figure 80.6). In most cases, division of the processus vaginalis and cremasteric muscle attachments, and separation of the vas from the vascular cord elements provide adequate cord length to allow for placement of the testis in the scrotum. Additional cord length may also be obtained by bluntly dissecting the spermatic vessels from the lateral spermatic fascia with the aid of a Ragnell retractor in the internal ring and a Q-Tip or Kittner dissector. While performing the retroperitoneal dissection, the external oblique may be opened above the level of the internal ring, and the internal oblique muscle can be divided 1–2 cm from the superior lateral margin of the internal ring.

Once adequate cord length has been obtained, the testis must be placed into the scrotum in a tension-free manner. Experimental evidence has documented that transparenchymal suture fixation causes testicular damage by inducing an inflammatory reaction regardless of suture size and material. In comparison, dartos-fixed testes demonstrated complete circumferential adherence, with minimal inflammation and preserved spermatogenesis.[2,3] Based on these studies, securing the testis to the scrotum with a suture violating the testis is avoided. When short-term external fixation to a nylon button is required due to tension, or the operator prefers intrascrotal suture fixation, the suture should traverse the fibrous tissue beneath the lower pole of the testis. It is important to be familiar with the intragonadal vascular anatomy, especially when ligation of the spermatic vessels is contemplated. The collateral arterial circulation through the deferential artery, which

FIGURE 80.1 Initial incision in transverse skin crease.

FIGURE 80.2 Exposure of the external oblique fascia.

communicates with the internal spermatic arterial system both in the spermatic cord and at the lower pole of the testis, was found to be compromised in all testes with placement of a transgonadal traction suture.[4]

In order to place a testis in a dartos pouch, a transverse midscrotal superficial skin incision is made within a rugal skinfold (Figure 80.7), and a mosquito hemostat is then used to develop a tissue plane just under the scrotal skin superficial to the dartos layer. The scrotal pocket should be developed from the median raphe and the lateral scrotal margin (Figure 80.8), with creation of the space in the inferior and anterior portion of hemi-scrotum which allows for fixation of the testis in a prominent, dependent position. After the testis and cord are completely mobilized and the tunica vaginalis is opened fully over the testis, a hemostat is passed just over the pubic symphysis

FIGURE 80.3 Creamsteric and fibrous attachments are freed from the spermatic cord.

FIGURE 80.4 The tunica vaginalis is opened, delivering the testis from the hernia sac.

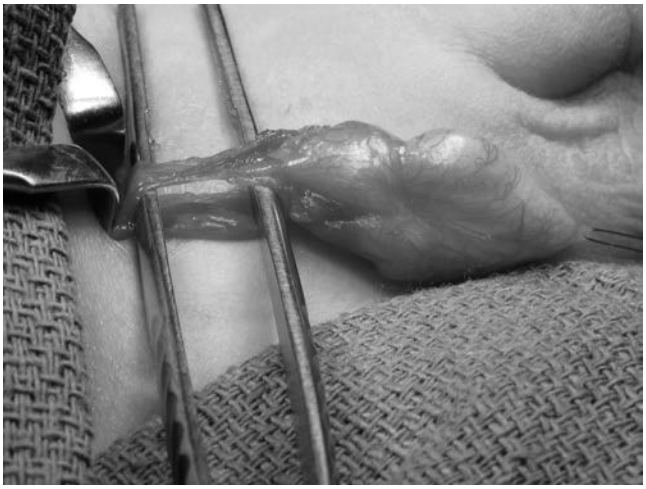

FIGURE 80.5 Hernia sac and lateral spermatic fascia is mobilized from the spermatic cord.

FIGURE 80.6 Ligation of the hernia sac at the level of the internal ring.

FIGURE 80.7 Transverse scrotal skin crease incision.

FIGURE 80.8 Superficial pouch in anterior dependent portion of scrotum.

FIGURE 80.9 Traction suture passed subcutaneously.

from the inguinal incision through the tough dartos fascia into the scrotum. It is important to pass the hemostat into the medial aspect of the scrotum to avoid lateral placement or migration of the testis. The most direct path to the scrotum allows for the most dependent placement of the testis. A second hemostat is back-passed from the scrotum into the inguinal incision; the most dependent tunica vaginalis or remnant of gubernaculum is grasped (Figure 80.9), and the testis is passed into the scrotum (Figure 80.10), with care taken to avoid torsion of the spermatic cord.

The dartos fascial window is closed with a fine absorbable suture, with the option of placing this suture through the redundant tunica vaginalis well above the level of the testis in order to indirectly secure the cord at this position. Closing the dartos layer behind the spermatic cord redefines the floor or inferior aspect of the superficial pouch. The testis is then placed within the dartos pouch, and the scrotal skin closed with fine interrupted absorbable sutures, such as 4-0 chromic vertical mattress sutures. The external oblique fascia is closed with running or interrupted absorbable suture with re-creation of the external ring, taking care to avoid impingement of the spermatic

FIGURE 80.10 Passage of testis into the right hemiscrotum.

FIGURE 80.11 Final postoperative appearance.

cord. For skin closure, we prefer an interrupted subcuticular closure with fine absorbable suture and placement of a flexible liquid dressing, such as Dermabond (Figure 80.11).

Scrotal Orchiopexy for the Palpable Testis

Although inguinal orchiopexy represents the traditional approach to the palpable undescended testicle, many of us now use a single scrotal incision for the vast majority of these cases. The high scrotal orchiopexy was first published in 1989,[5] and in early descriptions involved a high scrotal or inguinal scrotal incision.[6,7] In these early series, it was felt that it was more difficult to dissect the hernia sac from the cord, that high ligation of the hernia was difficult, and the complication rate appeared to be higher than that of traditional approaches. In addition, there was concern about the lack of a retroperitoneal dissection, which had classically been considered a vital part of adequate orchiopexy. In the 1990s, we modified that approach, suggesting that a scrotal incision can be used for palpable ectopic testes and in older children with testicular ascent.[8] In the original description of the "low scrotal" approach, an inguinal incision was used if a patent processus was identified. We found that by using careful patient selection, the likelihood of identifying a hernia was approximately 20%. Over the past decade, this technique has been extended to all but the highest of palpable testes, and hernias identified are corrected through the scrotal incision. There is experience with hundreds of procedures performed through a single scrotal incision, with no evidence of increased risk of hernia recurrence and with excellent outcomes.[9]

The technique of scrotal orchiopexy is reasonably straightforward. First, the testis does not need to reach the scrotum in order to use this approach; the scrotum must be able to reach the level of the testis. An anterior horizontal scrotal incision is made with scalpel or electrocautery. Blunt dissection is used to expose the anterior processus. The testis within its coverings is brought out through the incision, and separated from attachments up to the external ring. The anterior processus is then opened, and patency assessed. Whether or not there is a patent processus, the posterior wall is separated from the vessels and vas deferens in order to release the intrinsic cord length. If there is a hernia, it is separated from the cord well into the external ring, and then suture ligated. At this point, any ectopic attachments that can be isolated from the vessels and vas deferens are divided, and after this maneuver, there is almost always enough length to reach the dependent scrotum. The testis is fixed in the scrotum by whatever method is preferred by the operator.

OPEN APPROACHES TO HIGH OR INTRAPERITONEAL TESTES

Jones Approach for the High Undescended Testis

A high inguinal approach or Jones incision is an open surgical alternative for the high canulicular or intra-abdominal testis.[10] This procedure shares similar indications and surgical principles with laparoscopic orchidopexy, and was the popular surgical approach prior to the advent of laparoscopic management of the intra-abdominal testis; now it is used by some practitioners to manage high palpable testes. Principles include preservation of the spermatic vessels, high retroperitoneal mobilization of the spermatic vessels, and passage of the testis directly through the abdominal wall at the pubic tubercle (Prentiss maneuver). The procedure may also be performed in combination with laparoscopy to help locate the testis and aid in dissection. A transverse incision is made medial to the anterior superior iliac spine and is carried down to the external oblique fascia just superior to the internal ring. Once the fascia is incised, a muscle-splitting technique is used to expose the retroperitoneum and mobilize the peritoneum medially. The internal ring and processus vaginalis, if present, are identified and the peritoneum opened at this level, delivering the testis into the field. Once the hernia sac is ligated, the spermatic vessels are dissected from the lateral spermatic fascia as cranial as possible and a Prentiss maneuver is performed by passing the testis under the floor of the inguinal canal to an exit site just above the pubic tubercle. If there is tension on the testis after delivery into the subdartos pouch, an external nylon fixation button helps maintain a dependent scrotal position.

Open Fowler–Stephens Orchiopexy

Division of the testicular vessels in cases of high inguinal or intra-abdominal testis was first described in 1899 by Bevan.[11] However, it was not until 1959 that Fowler and Stephens devised a means to repair the high undescended testis while preserving its blood supply via collateral circulation from the deferential artery and the cremasteric system.[12]

The technique described by Fowler and Stephens was originally a one-stage procedure, but it may also be performed in two stages. If a one-stage repair is to be performed, it is critical early in the dissection that a wide pedicle of peritoneum be preserved with the vas deferens in order to maintain collateral blood flow. It is also

important to remember that the testis is technically a retroperitoneal organ, as is its blood supply and that of the vas deferens.

The technique begins with a high transverse inguinal incision that is carried down to the external oblique fascia. This is opened, allowing access to the inguinal canal and the peritoneum. The peritoneum is opened and the testis is mobilized without transecting any structures proximal to the testis. Once it has been determined that the spermatic vessels will not traverse the distance to the scrotum, they are divided.

The original one-stage procedure is dependent on a long looping vas; however, this has been reported in less than one-third of boys with true intra-abdominal testes.[12] If the patient's anatomy permits, the testicular artery is divided high above the testis followed by mobilization of a wide swath of peritoneum leaving the medial peritoneum between the testis and vas undisturbed. If further length is required, the vas may be straightened by dividing the peritoneum between the redundant vas. The course of the vasal pedicle should be as medial as possible in order to choose the shortest distance to the scrotum which may require a direct placement of the testis and pedicle through a neohiatus in the abdominal wall over the symphysis pubis, or medial to the inferior epigastric vessels. From this point forward, the procedure is carried out as a standard orchiopexy with creation of a dartos pouch with the exception that a nylon fixation button is often necessary.

The anticipated advantage of a two-stage orchiopexy with spermatic vessel ligation is twofold: (1) to allow for development of the collateral blood supply to compensate for division of the main blood supply to the testis, and (2) to allow for greater mobility of the testis in order to place it within the scrotum.[13,14] The two-stage Fowler–Stephens orchiopexy is typically performed by ligating the spermatic vessels in situ as close to the origin as possible, and then returning after 6 months or longer to complete the vasal-peritoneal pedicle mobilization using the standard Fowler–Stephens technique. Koff and Sethi reported excellent results with a technique of low spermatic vessel ligation and demonstrated that high ligation of the spermatic vessels does not need to be performed to preserve testicular viability.[15]

Surgical Management of Nonpalpable Testis

Nonpalpable testis accounts for approximately one-fifth of children with an undescended testis. There are numerous reports attesting to radiographic means of evaluating undescended testis; however, it remains a surgical diagnosis given the low sensitivity and specificity of ultrasound (45% and 77%[16–20]) and the expense, limited availability, and need for sedation with MRI.[20,21] Diagnostic laparoscopy has been used for more than 35 years to identify the presence and location of the nonpalpable testis.[22] Belman and colleagues first reported that 30%–50% of nonpalpable testis will be absent, the majority of which are due to prenatal torsion in the inguinal canal or scrotum. Evidence of prenatal torsion will most commonly be identified as a hemosiderin-laden and/or calcified nubbin on scrotal exploration.[23] Contemporary series support the finding that 55%–65% of patients will have vas and vessels that enter the inguinal canal, although the need for inguinal exploration remains controversial.[24] The quality of laparoscopic images also offers an accurate assessment of the surrounding anatomy and testicular viability, which has a reported accuracy of greater than 95%.[15,16] The accuracy and quality of the information obtained from laparoscopy allows for definitive management or planning of further surgical approaches in the majority of primary undescended testes[25] and in children who have undergone a previous inconclusive open exploration.[26–28]

Diagnostic Laparoscopy for the Nonpalpable Testis

Technique

Diagnostic laparoscopy begins by gaining access to the abdomen with a Veress needle or the preferred open technique. In the classic open technique, a semilunar umbilical incision is carried down to the rectus fascia. The fascia is opened and the peritoneum is sharply incised, allowing the trocar to be placed between the obliterated umbilical arteries. Alternatively, access is gained through a small intraumbilical incision, entering directly into the attached peritoneum at the base of the umbilicus, and using a radially dilating trocar to establish an airtight seal.[29,30] A 5 mm laparoscope is available in most pediatric hospitals, but smaller-diameter laparoscopes with improved optics are becoming more widely available.

Laparoscopic Assessment

Once the camera has been placed, the possible findings in regard to testicular position and inguinal anatomy are

1. Blind-ending vas deferens and vessels above the internal ring (vanishing testis) (Figure 80.12)
2. Cord structures entering the internal ring (viable intracanulicular testis vs. intracanulicular or scrotal atrophic testis) (Figure 80.13)
3. Intra-abdominal testis (Figure 80.14)
4. Testicular agenesis

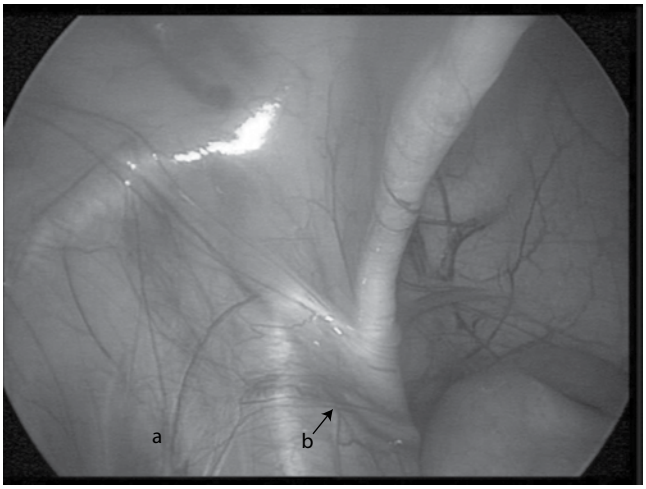

FIGURE 80.12 Finding blind ending and divergent testicular vessels (a) is evidence of a vanishing testicle. The sole finding of a blind ending vas (b) is insufficient evidence to conclude that there is absence of ipsilateral testicular tissue.

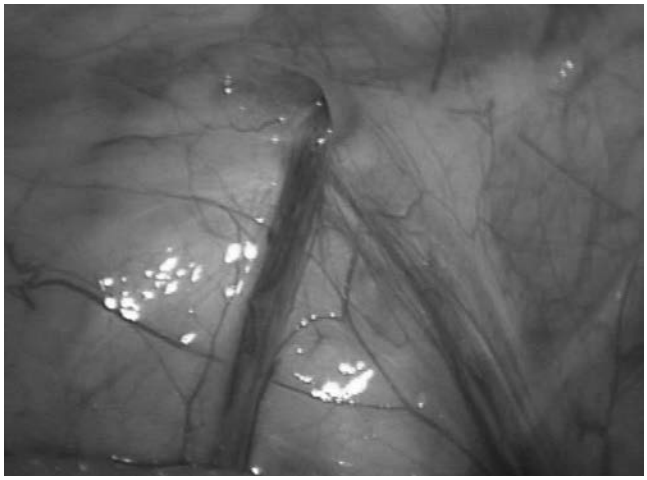

FIGURE 80.13 Laparoscopic view of a left patent processus vaginalis (hernia) with normal cord structures exiting the internal ring.

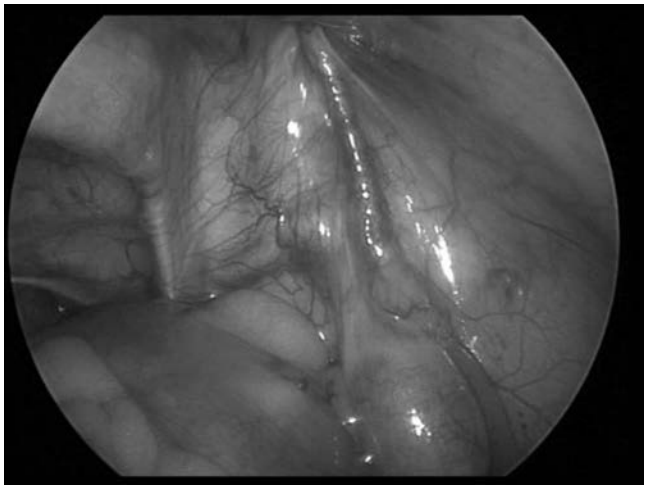

FIGURE 80.14 A Right intra-abdominal testicle >2 cm from the internal ring.

Approximately 36%–64% of children presenting with a unilateral nonpalpable testis will be monorchid.[1,31–37] A vanishing testis is most commonly due to an in utero torsion or compromising vascular event that may have occurred anywhere along the path of decent, but most commonly occurs in the inguinal canal or scrotum. An intra-abdominal vanishing testis will demonstrate the classic anatomy of atretic blind-ending vas and spermatic vessels, usually within a few centimeters of the internal ring. Nonunion of the vas and the testis can occur, so visualization of a blind-ending vas deferens in the absence of vessels is not adequate to make the diagnosis of a vanished testis. In cases of an inguinal or scrotal event, the vessels and vas may be seen entering the inguinal canal, but they will be markedly attenuated when compared with the contralateral side. When blind-ending spermatic vessels are found, no further surgical intervention is necessary. Some investigators have recommended a transscrotal testicular fixation procedure on the normally descended contralateral testis because of the reported risk of abnormal testicular fixation (bell clapper deformity),[38,39] although most feel that this is unnecessary, as prenatal testicular torsion is generally an extravaginal event and should not correlate with increased contralateral risk after the neonatal period.

Management of atretic vessels and vas that enter the inguinal ring is a controversial topic. Atretic vessels are predictive of a nonviable testicular remnant, which will most often demonstrate histological evidence of ischemia and necrosis (fibrosis, hyalinization, calcification, and hemosiderin deposition). There have, however, been reports of viable testicular elements, including residual seminiferous tubuals and germ cells, in up to 13% of testicular remnants.[40–45] Carcinoma in situ has not been reported within these specimens, and it has been argued that the risk of malignant degeneration is remote.[43] Exploration and removal of the atrophic elements therefore appear unnecessary; however, much latitude is granted on the subjective nature of distinguishing between atretic and normal vascularity.

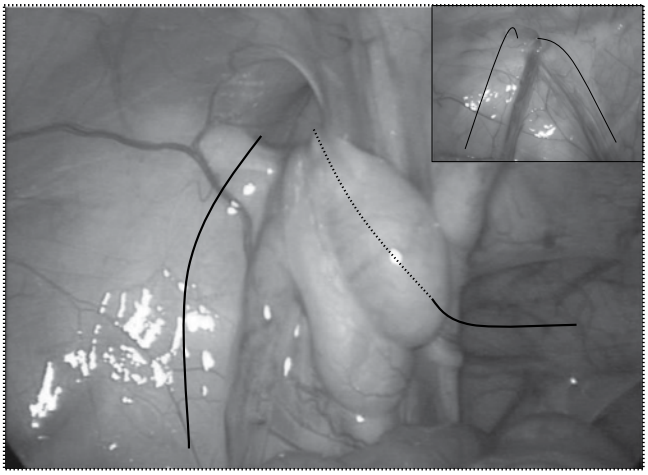
Normal internal spermatic vessels are indicative of an intracanalicular testis, which may be normal but difficult to palpate on physical exam, warranting inguinal exploration. If the processus vaginalis is patent, the laparoscope can be advanced into the inguinal canal in most cases to again help identify the position and viability of the testis.

An intra-abdominal testis usually resides within a few centimeters of the internal ring and is most commonly associated with a patent processus vaginalis, potentially allowing the vas deferens to loop into the inguinal canal. While they are usually close to the internal ring, an intra-abdominal testis can be located anywhere along the path of descent and has also been reported ectopically in perinephric, perihepatic, and crossed ectopic locations. In cases where an intra-abdominal testis is not easily visualized, tracing the spermatic vessels from their origin will usually lead to the testis. Visualization of the spermatic vessels is facilitated by placing the child in the Trendelenburg position and laterally rotating the table to allow the intestines to fall away, exposing the psoas muscle. Rarely, the left colon or cecum may hide the testis, in which case another port can be placed in the contralateral lower abdominal quadrant for laparoscopic dissection. Inspection of the ipsilateral internal ring during diagnostic laparoscopy is also an important step. In 91% of boys with a patent processus vaginalis, the testis will be viable, whereas if the processus is closed, 97% of the testis will be vanished or absent.[33]

Once located, treatment options for an intra-abdominal testis include an orchiectomy (for a nubbin, extreme ectopic, or intra-abdominal testis in an older child with a normal contralateral gonad), primary laparoscopic orchiopexy, and primary or staged laparoscopic Fowler–Stephens orchiopexy. Choosing the appropriate procedure is based on the testis distance from the internal inguinal ring, the perceived redundancy of the vessels beneath the peritoneum, and the size of the child.

Primary Laparoscopic Orchiopexy

The initial dissection begins with taking down the distal attachments sharply at the internal ring which allows for



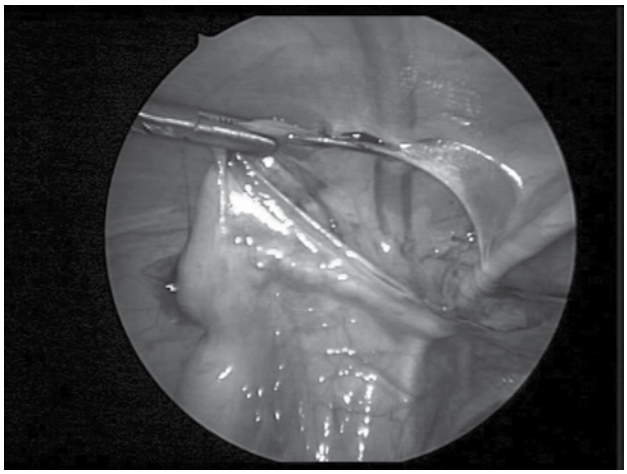


FIGURE 80.15 A left intra-abdominal testicle at the internal ring. The dark lines represent where peritoneotomies are made parallel to the testicular vessels (lateral) and vas deferens (medial) in order to mobilize the testicle on a vascularized peritoneal pedicle flap. The insert shows the same landmarks when an nonpalpable intra-canicular testicle is milked into the abdomen and then mobilized.

identification and eversion of intracanalicular contents (i.e. long looping vas) prior to dissection of the anterior peritoneum. Sharp dissection begins with a peritoneal incision at the internal ring made well lateral to the spermatic vessels, which is carried along the abdominal sidewall parallel to the psoas muscle and cranial toward the origin of the vessels. The second line of dissection is started at the internal ring medial to the vas and carried in a caudad direction following the course of the vas along the pelvic sidewall toward the bladder (Figure 80.15). These two incisions preserve a triangular wedge of peritoneum between the spermatic vessels and vas deferens, with the testis at the apex. It is sometimes necessary to isolate the window of peritoneum between these structures by incising the proximal peritoneum perpendicular to the vessels in order to gain more length. Even after this maneuver, if a single-stage Fowler–Stephens orchidopexy is the intended or possible procedure, the peritoneum between the spermatic vessels and vas has been preserved to prevent disruption to the collateral vasculature. This swath of peritoneum, which includes the vas and vessels, is mobilized away from the posterior retroperitoneum until sufficient length is gained that the testis can be brought to the contralateral internal ring without tension. It is often helpful at this juncture to use a radially dilating trocar introduced over a 2 or 3 mm instrument passed antegrade through the scrotum as an extra port to provide traction, as well as creating the eventual neocanal.[46]

Transferring the testis into the scrotum may be achieved by passing a curved hemostat from the subdartos pouch over the symphysis pubis into the peritoneal cavity if a trocar is not used to create the neocanal. If the antegrade technique is used, a 2–3 mm instrument is passed medial to the epigastric vessels and guided over the top of the pubis through the previously created dartos pouch. This instrument is then used to guide a radially dilating trocar sheath into the abdominal cavity, which is dilated to 5 or 10 mm (depending on the size of the testicle). Once the port has been placed, a locking grasper is used to grasp the gubernacular tissue distal to the testicle and deliver it to the scrotum (Figure 80.16). Regardless of the approach, it is critical for the surgeon to personally monitor the tension on the spermatic cord as the testis is passed into the scrotum to avoid avulsion of the spermatic vessels. While applying distal traction to the testis through the scrotum, further mobilization of the spermatic vessels may be obtained by dissecting the proximal peritoneum away from the spermatic vessels, and carrying the dissection of the spermatic vessels more cephalad toward the kidney. Care must be taken to avoid excessive traction and vascular avulsion as dissection is carried toward the origin of the vessels. Once sufficient length has been gained on the spermatic vessels, the testis is secured in the dartos pouch, as previously described. When there is slight tension on the spermatic cord, placement of an external nylon fixation button for 5–7 days is useful for protecting the testicular position in the scrotum.

Prior to port removal, bleeding should be assessed laparoscopically under low intra-abdominal pressure by releasing the pneumoperitoneum. Upon removing the ports, hemostasis should also be assessed at the port sites, as well as ensuring that the umbilical closure does not include bowel or omentum.

Laparoscopic Fowler–Stephens Orchidopexy

Determining if testicular vessels have sufficient length to allow for a tension-free orchiopexy does not need to be done early in the course of a laparoscopic orchidopexy as long as the distal peritoneal triangle is preserved. This is why laparoscopy is an ideal approach if the operator desires to preserve the spermatic vessels, if at all possible. On the other hand, there is evidence, although controversial, that primary Fowler–Stephens laparoscopic orchiopexies have lower success than staged procedures, so if it is highly likely that vessel division will be required, staging may be preferred. There are no absolute criteria that predict when division of the spermatic vessels will be required, but as a general guideline, a testis within 2 cm of the internal ring can usually be brought down without

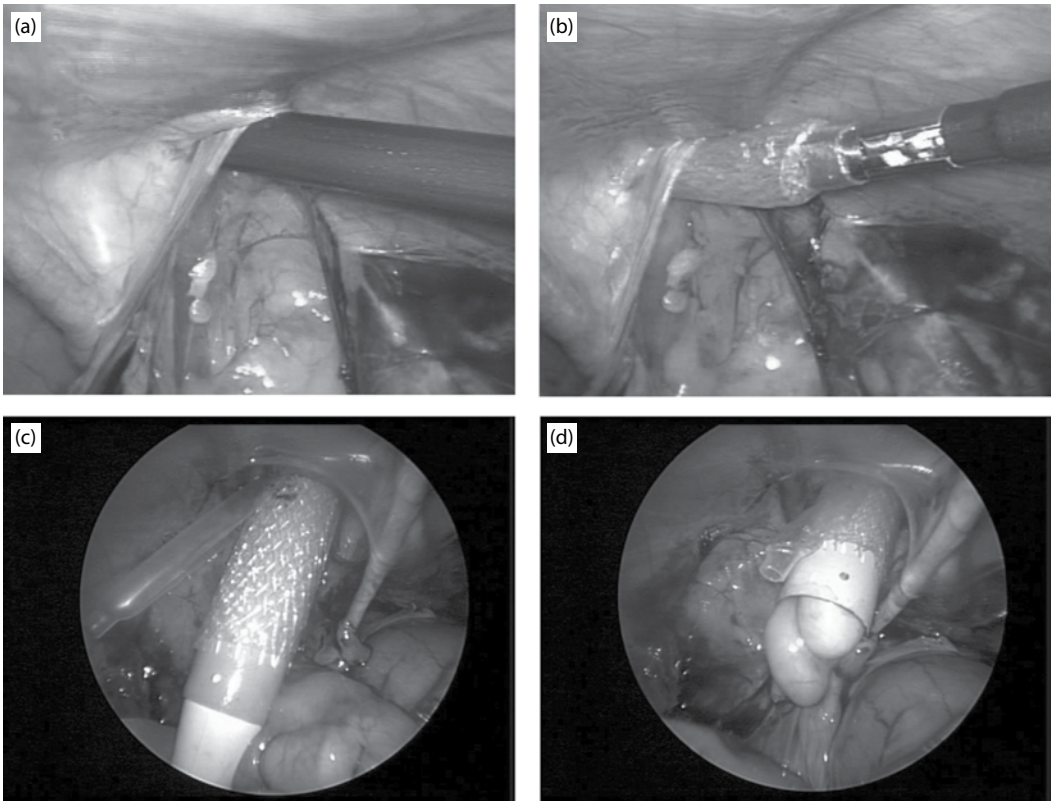

FIGURE 80.16 Delivering the testicle into the scrotum requires developing a neo-hiatus (a–c) to facilitate passage of the testicle, epididymis and cord structures into the scrotum without resistance. This technique minimizes the risk of an avulsion injury (d).

vessel transection, 2–4 cm from the ring may be possible with redundant vessels and vas, and 4 cm and beyond will likely require division of the vessels. Once the determination has been made to perform a staged procedure, vessel ablation is accomplished with surgical clips or a dissection device, such as the harmonic scalpel placed through a contra lateral 5 mm port.

The second stage of the orchidopexy is usually performed 6–9 months later, following principles similar to those of a first-stage procedure. If the vessels were clipped, the procedure begins by dividing the vessels. The gubernaculum can be divided or left intact, depending on whether the native canal or a more medial neocanal is going to be used. A wide peritoneal pedicle is developed by incising the peritoneum on either side of the vas deferens. The wide pedicle of peritoneum is carefully preserved to protect the vasal artery and collateral vasculature that has developed since division of the vessels. The testicle is then delivered into the scrotum and placed into a subdartos pouch as described above for a primary laparoscopic orchiopexy.

Microvascular Autotransplantation

At limited centers with microvascular surgical expertise, microvascular autotransplantation may be utilized in the management of high intra-abdominal testis. The results of testicular autotransplantation in uncontrolled studies appear to be superior to the predicted results reported with division of the spermatic vessels for the high intra-abdominal testis with both laparoscopic-assisted and open approaches.[47–49] Despite the reported success rate, outcomes are heavily dependent on microvascular expertise, which most likely accounts for why this approach has not been more widely adopted. When used, the technique is generally restricted to relocating a high, solitary testis.

Reoperative Orchiopexy

Reoperative orchiopexy is performed in cases of secondary cryptorchism after orchiopexy or inguinal hernia repair. Testes that are at risk for iatrogenic ascent after a hernia repair may be trapped in inguinal scar tissue, or may be ectopic, sitting in a low-lying superficial inguinal pouch or in a retroscrotal plane just beyond the confines of the anatomic scrotum, and at risk for testicular ascent even before inguinal surgery.

For an inguinal approach, the skin incision should be in a previously nonoperated area in order to identify landmarks and to allow approach of the inferior pole of the testis, progressing from normal to scar tissue. After the testis is freed, attention is turned to the spermatic cord, which is often densely adhered to the undersurface of the external oblique fascia. To lessen the risk of injury to the spermatic vessels, dissection lateral and medial to the cord in more normal tissues is performed, and in some cases, it is beneficial to leave a strip of fascia overlying the cord during the initial mobilization. It may also be necessary to mobilize the cord proximally above the internal ring in order to gain length in a now relatively inelastic cord. The usual surgical principles of a standard orchiopexy can then be applied, including positioning the cord more medially if required.

A more contemporary approach to reoperative orchidopexy is through a single scrotal incision.[50] The approach is similar to that of primary scrotal orchidopexy, except that the testis and cord are serially freed from surrounding scar tissue, releasing intrinsic elasticity and, in almost all cases, creating adequate length for scrotal location without the need for proximal dissection. This is our preferred approach to almost all orchiopexies after prior inguinal surgery.

Complications of Orchiopexy

As discussed in previous chapters, laparoscopic procedures are associated with unique risks, which include injuries associated with positioning, gaining access to the abdominal cavity, and intraperitoneal insufflation. Immediate complications that are unique to orchiopexy are avulsion of the testicular vessels, injury to the vas deferens, and damage to the bladder and surrounding vasculature. Testicular atrophy and suprascrotal position are the two major long-term complications with recurrence of inguinal hernia as a less common possibility.

Immediate Complications

Immediate complications of laparoscopic procedures can be avoided with proper positioning and using an open technique to gain peritoneal access.[51] During testicular mobilization, care must be taken to avoid injury to the vas; testicular, femoral, and iliac vessels; and the ureter. Using a gubernacular attachment as a handle, minimizing testicular manipulation, and preserving collateral blood flow between the vessels and the vas are all key steps in preventing immediate injury and long-term atrophy.[52,53] Avulsion of the spermatic vessels due to excessive traction placed on the testicle has been reported.[52,54,55] If the vessels are unintentionally injured, immediate conversion to a Fowler–Stephens orchiopexy may be possible. Injury to the bladder is most likely to occur when creating the neoinguinal hiatus. The risk is increased if the neohiatus is not formed superior to the pubis in a plane lateral to the medial umbilical ligament and medial or lateral to the epigastric vessels. Remaining cognizant of these pelvic landmarks is essential in preventing injury to the bladder or epigastric or femoral vessels.[56] Antegrade passage of the laparoscopic instrument to form the neocanal can be performed while palpating the tip with the receiving finger anterior to the pubis, further decreasing the likelihood of injury. Placement of a urinary catheter to maintain a decompressed bladder will also help to prevent bladder injury and may also serve to alert the physician of an injury to the bladder if grossly bloody urine is detected in the drainage bag.

Torsion of the testicular vessels to the scrotum following delivery has been reported.[57] This complication may be avoided by thoroughly examining the vessels after placement of the testicle into the scrotum to confirm the absence of torsion. If torsion is identified, the testicle is carefully repositioned in the scrotum until the vessels and vasa have a normal interrelationship.

When performing laparoscopic orchiopexy, the associated hernia sac is not ligated and the internal ring is generally not formally closed.[58] However, Metwalli and Cheng describe an indirect inguinal hernia following laparoscopic orchiopexy. In their series, this complication has occurred in 1 of 25 procedures, or 4%, although inguinal hernia after laparoscopic orchidopexy has not been reported in most large series. While they do not advocate for closure of the internal ring in all cases, they suggest that this may be appropriate in select cases where a large internal ring defect is evident.[59] Considering that this is the only reported inguinal hernia after laparoscopic orchiopexy, the risk appears to be well under 1% overall.

Long-Term Outcomes

For open procedures, Docimo reported a significant advantage to maintaining intact spermatic vessels in a retrospective literature review.[60] For primary laparoscopic orchiopexy, contemporary series have reported an overall success ranging from 82% to 100%, atrophy ranging from 2% to 4%, and persistent high testicular position in 0.6%–18%.[49,56,58,61] Overall success with laparoscopic single-stage Fowler–Stephens ranged from 71% to 97%, with 3%–22% atrophy and 0%–7% high testicular position.[46,52,62] As expected, laparoscopic two-stage Fowler–Stephens reported higher overall success rates (88%–96%) and lower rates of atrophy (4%–15%) when compared with single-stage procedures.[52,56,58] The only multi-institutional analysis, including 263 testes, demonstrated 97% success for primary laparoscopic orchidopexy preserving the vessels, 74% success with single-stage Fowler–Stephens laparoscopic orchidopexy, and 88% success with staged Fowler–Stephens orchiopexies.[58] Therefore, both historically and in a contemporary series, there is an advantage to maintaining vessels when possible, and staging procedures when vessels cannot be maintained.

CHAPTER
81

Testicular and Paratesticular Tumors in Children

Lynn L. Woo and Jonathan H. Ross

INTRODUCTION

Prepubertal testis tumors are less common than other pediatric urological malignancies, such as neuroblastoma or Wilms' tumor, and testicular tumors occur less often in children than adults. Historically, management of pediatric testis tumors has been based on experience in adults; indeed, testicular tumors in both adult and pediatric patients share several common features, including presentation with a painless testicular mass that is initially treated with excision of the primary tumor. In both children and adults, testis tumors are very sensitive to platinum-based chemotherapy, which has revolutionized the management of testicular cancer throughout the age spectrum.[1,2] There are, however, important differences between testis tumors occurring in children and adults, which include tumor histopathology, malignant potential, and pattern of metastatic spread. The patients themselves are also dissimilar, with different concerns regarding surgical morbidity and preservation of testicular function. The introduction of the Prepubertal Testis Tumor Registry by the Urological Section of the American Academy of Pediatrics in 1980 allowed for the accrual of valuable epidemiological information.[3] Recent multicenter and prospective clinical trials have further advanced our understanding of these tumors and their management.[4–6]

EPIDEMIOLOGY

There is a bimodal age distribution for testis tumors, with one peak occurring in the first 3 years of life, and a second larger peak occurring in young adulthood.[7,8] The incidence of pediatric testis tumors is 0.5–2.0 per 100,000 children, accounting for 1%–2% of all pediatric tumors.[9–11] Testis tumors are categorized, based on the presumed cell of origin, into stromal tumors and germ cell tumors. In the Prepubertal Testis Tumor Registry of the Urological Section of the American Academy of Pediatrics, the majority of primary testis tumors were yolk sac tumors, followed by teratomas and stromal tumors.[3] A more recent review of the Surveillance, Epidemiology and End Results (SEER) database by Alanee and Shukla also found yolk sac tumor to be the most commonly observed pediatric testis tumor, at 43.5%.[12] Selection bias and underreporting have likely led to an overrepresentation of malignant tumors in registries, however, and several other studies have documented a predominance of benign testis lesions in children.[7,13–15] Indeed, a recent multicenter report found that benign lesions accounted for the majority of primary testis tumors (74%), with teratoma being the most common histological subtype (48%). Yolk sac tumors constituted only 15% of testicular neoplasms in this series.[14] Table 81.1 summarizes the distribution of testis tumors in the Prepubertal Testis Tumor Registry and a multicenter review of prepubertal testicular tumor pathology specimens. Because teratomas and most stromal tumors are benign in children, the percentage of prepubertal testis tumors that have malignant potential is much lower than the 90% of tumors in adults.

Based on the SEER database, authors reported no apparent increase in the incidence rate of testicular tumors in children of ≤14 years old since 1973, and 5-year relative survival rates were 97% for those with localized disease versus 73% for those with distant disease. Interestingly, for children under the age of 15, patients entered as American Indian, Alaskan native, Asian, or Pacific Islanders were most affected by yolk sac tumors, with an incidence rate twice that of Caucasians and eight times that of African American children.[12] The most common testicular malignancies in postpubertal patients are embryonal and mixed germ cell tumors.

EVALUATION

The majority of prepubertal patients with a testicular tumor will present with a painless, firm testicular mass noted by the patient, a parent, or a healthcare provider.[13] Occasionally, patients may present with diffuse testicular enlargement, a hydrocele, or pain secondary to torsion or bleeding into the tumor. Patients with hormonally active stromal-based tumors may exhibit gynecomastia, virilization, or precocious puberty.[16,17] Physical examination can usually distinguish testicular tumors from other scrotal masses, such as hydroceles, hernias, or epididymal cysts. Scrotal ultrasonography is a routine part of the evaluation and assists in both distinguishing extratesticular masses from those within the testis and characterizing tumor architecture. While ultrasound cannot reliably distinguish malignant from benign testicular tumors, hypovascular,

TABLE 81.1 Distribution of tumor types in the 395 primary testis tumors registered in the prepubertal testis tumor registry and 98 tumors in a multicenter consecutive series of patients

Tumor type		Percent of tumors in registry	Percent of tumors in multicenter study
Germ cell	Yolk sac	62	15
	Teratoma/epidermoid cyst	26	62
Stromal	Leydig cell	1	4
	Sertoli cell	3	3
	Juvenile granulosa cell	3	5
	Unspecified stromal	4	1
Gonadoblastoma		1	2

Source: Ross JH et al. *J Urol* 2002;168(4 Pt 2):1675–8; discussion 1678–9; Alanee S, Shukla A. *BJU Int* 2009;104(9):1280–3.

well-demarcated, or cystic tumors are more likely to be benign in children.[18,19]

Tumor markers typically utilized in the evaluation and management of adult testis tumors include human chorionic gonadotropin (HCG) and α-fetoprotein (AFP). While HCG is elaborated in a significant number of mixed germ cell tumors, this tumor type is vanishingly rare in prepubertal patients; therefore, HCG is not a useful marker for this population.[7] On the other hand, AFP is elevated in 90% of patients with yolk sac tumor and is an important marker to distinguish between yolk sac and other tumors (almost all of which are benign). One caveat is that AFP levels are normally high in infancy. However, AFP may be variable in infants; typical levels range from approximately 50,000 ng/mL in newborns to 10,000 ng/mL by 2 weeks of age, 300 ng/mL by 2 months, and 12 ng/mL by 6 months of age.[20] Therefore, AFP levels in patients with yolk sac tumors and benign tumors overlap in the first 6 months of life, making AFP a less helpful tool in distinguishing tumor types in young infants (Figure 81.1).[21]

Since many, if not most, prepubertal patients will have a benign tumor, the metastatic evaluation may be deferred until a histological diagnosis of the primary tumor is obtained. A preoperative metastatic evaluation may be undertaken in patients over 6 months of age with an elevated AFP level, who likely harbor a yolk sac tumor. Metastases from yolk sac tumor typically occur in the lungs and the retroperitoneal lymph nodes. A chest x-ray or chest computerized tomography (CT) scan and abdominal CT should be obtained. Postoperative AFP levels are also followed. The half-life of AFP is approximately 5 days, and failure of an elevated AFP to decline as expected following removal of the primary tumor is evidence of persistent metastatic disease.

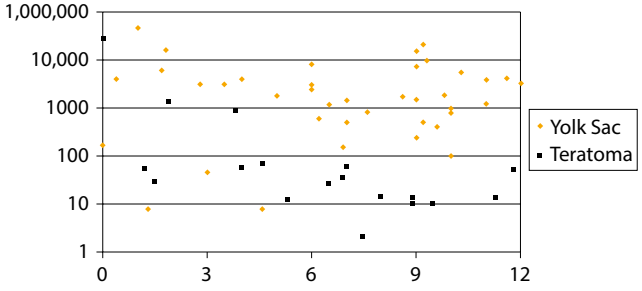

FIGURE 81.1 AFP level (ng/mL) as a function of age (months) for infants with a yolk sac tumor in the Prepubertal Testis Tumor Registry of the Urological Section of the American Academy of Pediatrics. (From Ross JH et al. *J Urol* 2002;168(4 Pt 2):1675–8; discussion 1678–9. Reprinted with permission.)

SURGICAL MANAGEMENT

The initial surgical approach in all patients with a suspicious testicular or paratesticular mass should involve an inguinal incision with early vascular control of the spermatic cord using a vessel loop or Penrose drain. The testicle is then delivered through the inguinal incision. Failure to follow these guidelines, particularly scrotal violation, may increase the recurrence rate in the setting of malignant tumor.[22] In prepubertal patients older than 6 months of age with an elevated AFP, and in most adolescents, radical orchiectomy should be performed.[3] In all other patients, a benign tumor is likely to be present, and testicular preservation will be the preferred goal. Following delivery of the testis, the tunica vaginalis is incised to expose it (Figure 81.2). Lesions involving or immediately adjacent to the tunica albuginea can be circumscribed beyond the tumor margins by making an elliptical incision in the tunica. Deeper lesions can be accessed through an equatorial incision in the testis, while intraoperative sonography has been recommended to localize impalpable lesions, similar to that reported in the adult literature.[23] Intraoperative frozen section has been shown to correlate well with final pathology and plays a key role in decision making.[24] If frozen section reveals a likely malignancy, then the entire testis and spermatic cord up to the internal inguinal ring are removed. If a benign histology is confirmed (usually teratoma), vascular control of the spermatic cord is released, and the remaining testis is closed by reapproximating the tunica albuginea with a running absorbable monofilament suture. The testicle is then returned to the scrotum. Even large tumors can be enucleated with preservation of significant testicular tissue (Figure 81.3).

One concern with this approach is the malignant potential of the remnant testicular tissue. In adults, 88% of testicles with teratoma harbor carcinoma in situ (CIS) elsewhere in the testis; therefore, radical orchiectomy is still an appropriate management in postpubertal patients.[25] However, in studies of prepubertal teratoma, with the exception of one case, no such finding has been evident.[19,26,27] Rushton et al. reviewed the histopathology of 17 prepubertal testes removed for teratoma, and no multifocal tumor or CIS was found in any specimen.[26] In initial small series of testis-sparing surgery for prepubertal benign tumors, there have been no cases of recurrent tumor in the preserved testicular remnant.[19,26,28–30] In 1999, Sugita et al. reported on 27 patients with teratoma, 17 of whom were treated with partial orchiectomy. With a mean follow-up of 10 years, there were no recurrences

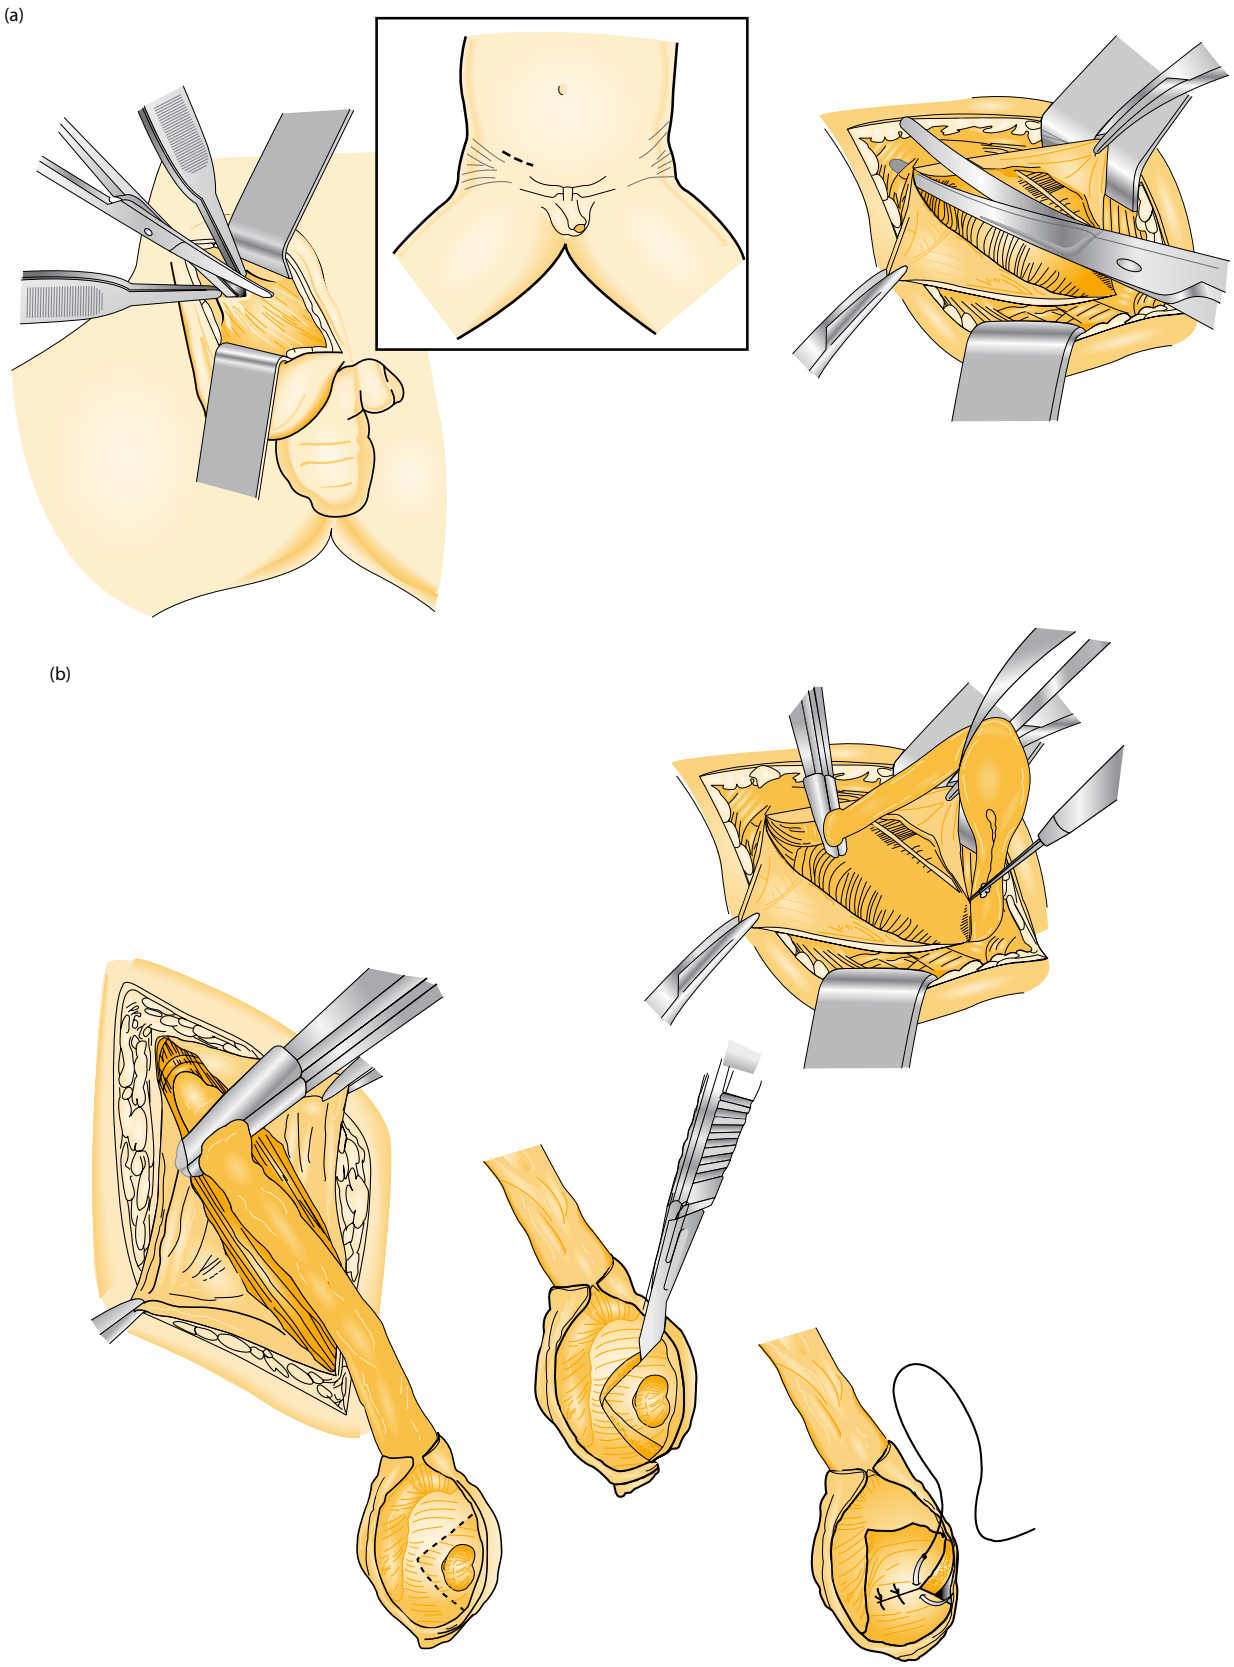

FIGURE 81.2 Inguinal exploration with testis-sparing tumor excision. (a) An inguinal incision is made and Scarpa's fascia is opened exposing the external oblique aponeurosis. This is opened along the length of its fibers through the external ring, exposing the spermatic cord structures. (b) The vessels are temporarily occluded and the testis delivered into the operative field. The hydrocele sac is opened and the tumor sharply excised. If a benign tumor is confirmed on frozen section, then the remnant testis is closed and returned to the scrotum.

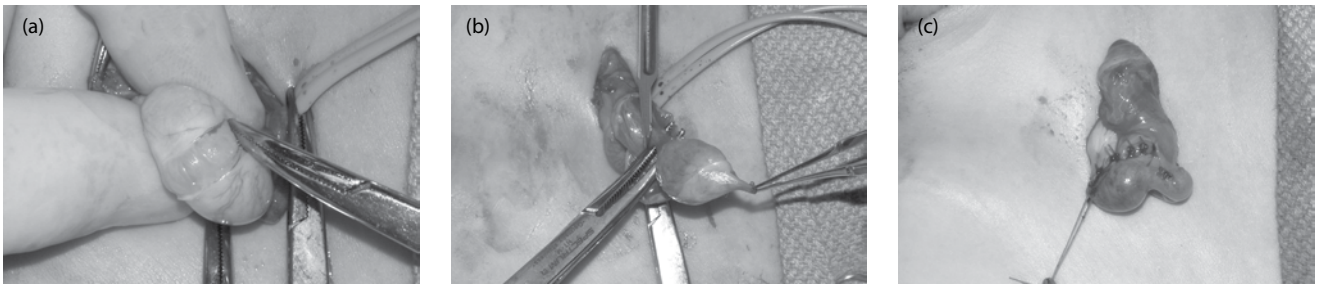

FIGURE 81.3 Enucleation of a benign tumor. (a) With the vessels occluded, an incision is made in the testicular tunix, exposing the cystic tumor. (b) The tumor is enucleated and detached from the testis. (c) The testis is closed with interrupted suture.

and no cases of testicular atrophy.[29] In these studies, testes undergoing testis-sparing tumor excision appear to maintain normal testicular volume postoperatively.

ADJUVANT THERAPY FOR MALIGNANT TESTICULAR TUMORS

There are little data regarding the behavior of mixed germ cell tumors in adolescents, although they appear to exhibit behavior similar to that seen in adults.[31] It is therefore assumed that they should be managed as in adults, with observation, retroperitoneal lymph node dissection (RPLND), and/or chemotherapy, depending on the specific histology and stage of the disease. This seems a reasonable approach until further studies in adolescents with testicular malignancies are undertaken.

Virtually all malignant germ cell tumors in children are yolk sac tumors. A yolk sac tumor is a yellow to pale gray solid tumor. It has been referred to by a variety of other names, including endodermal sinus tumor, orchioblastoma, juvenile embryonal carcinoma, mesoblastoma vitellinum, clear cell adenocarcinoma, extraembryonal mesoblastoma, and archenteronoma.[10] A variety of histological patterns may occur. Positive staining with AFP supports the diagnosis of yolk sac tumor. Classic glomeruloid (Schiller–Duval) bodies and embryoid bodies may be present. These structures are clusters of cells resembling the structures for which they are named (Figure 81.4).

As with most malignancies, adjuvant therapy for yolk sac tumor is based on tumor stage. Different cancer study groups employ different staging systems. However, detailed staging is unnecessary since the number of patients with metastatic testis tumors in all series is very small, and stratifying response rates and tumor behavior based on the extent of metastatic disease is impossible. Indeed, in large studies all metastatic yolk sac tumors are treated the same, regardless of the extent or location of metastatic disease. Therefore, the important distinction for yolk sac tumors is between Stage 1 disease (disease limited to the testis and completely excised) and those tumors with any degree of residual or metastatic disease.

The majority of prepubertal testis tumors present with Stage 1 disease.[3] Recent studies suggest that these patients can be safely managed with observation, followed by chemotherapy for patients in which tumors recur.[4–6,32–34] The United Kingdom Children's Cancer Study Group, the German Society of Pediatric Oncology, and the U.S. Pediatric Intergroup Study (now the Children's Oncology Group) have reported their results employing observation for Stage 1 yolk sac tumor of the testis and platinum-based

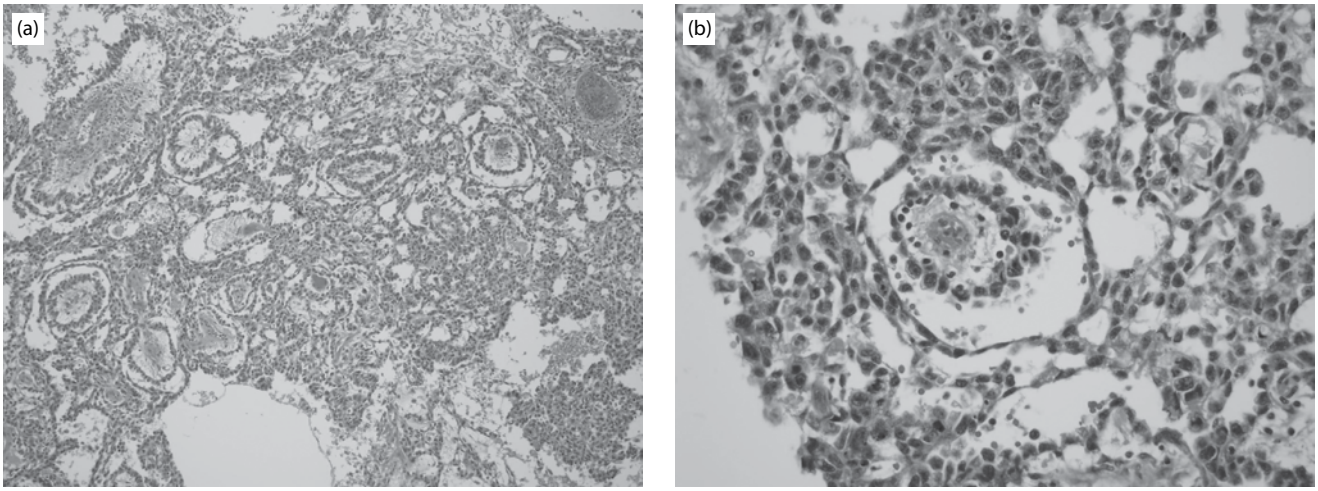

FIGURE 81.4 Yolk sac tumor. (a) The endodermal sinus pattern of yolk sac tumor is characterized by irregular interconnecting labyrinth-like spaces admixed with Schiller–Duval bodies, several of which are readily apparent in this image. (b) Schiller–Duval bodies are pathognomic features of yolk sac tumors and are composed of a fibrovascular papillary structure lined by malignant cells, encircled within a small cystic space that is also lined by flattened malignant cells.

TABLE 81.2 Results of three large multicenter studies of pediatric testicular yolk sac tumors

	Number of patients	Percent with stage 1 tumors	Recurrence rate (%) of stage 1 tumors on observation	Chemotherapy for recurrent or metastatic disease	Percent survival for stage 1 tumors	Percent survival for those with residual disease/ metastases
United Kingdom Children's Cancer Study Group[20]	73	70	22	Bleomycin, etoposide, carboplatin	100	100
German Cooperative Studies[21]	110	95	15	Bleomycin, vinblastine, cis-platinum	100	80
U.S. Pediatric Intergroup Study[22]	79	82	18	Bleomycin, etoposide, cis-platinum	100	100
Total	262	84	17		100	98

chemotherapy for patients with recurrent or metastatic disease. Most patients with recurrent or metastatic disease received four cycles of chemotherapy. The potential toxicities of the chemotherapy regimens employed include myelosuppression, ototoxicity, and renal toxicity from platinum-based agents and pulmonary toxicity from bleomycin. High-grade ototoxicity was rare in the UK study, which utilized carboplatinum rather than cis-platinum. However, carboplatin is more myelotoxic.[4–6]

A summary of the three large multicenter studies is presented in Table 81.2. Eighty-four percent of all patients presented with Stage 1 disease. Overall, the recurrence rate for patients with Stage 1 tumors managed with observation was 17%, and all were cured with chemotherapy. The overall survival of all patients receiving chemotherapy for recurrent or metastatic disease was 98%. Clearly, the outlook for prepubertal testis tumors is excellent. Stage 1 tumors are best managed with orchiectomy and observation. Observation should include frequent chest and abdominal imaging and measurement of AFP levels. Patients with recurrent disease or metastatic disease can expect excellent results with platinum-based multiagent chemotherapy. Future studies will focus on reducing the morbidity for those patients requiring chemotherapy by reducing the number of agents and/or cycles of therapy administered.

Another shift in the management of prepubertal testis tumors has been away from the performance of RPLND, once a standard component of management.[35–37] The rationale for this dissection in select adolescent and adult patients is the likelihood of retroperitoneal disease and the ability to avoid the morbidity of chemotherapy in some patients. Several characteristics of prepubertal tumors argue against its use in children. Most prepubertal patients have clinical Stage 1 disease, and the recurrence rate for these patients with observation alone is only 17%. Nearly all the recurrences can be salvaged with chemotherapy. For those with metastatic disease, it appears that only a minority of prepubertal patients have disease limited to the retroperitoneum.[38] The majority have disease in the chest (with or without retroperitoneal disease). Finally, the morbidity of abdominal surgery is greater for children than for adults. Children have a particularly high rate of postoperative bowel obstruction. It is also unclear that a nerve-sparing approach is technically feasible in small children. For prepubertal testis tumors, RPLND is limited to patients with persistent retroperitoneal masses following chemotherapy—a rare occurrence.

SCROTAL VIOLATION

Scrotal violation by means of scrotal orchiectomy, needle biopsy, or tumor spillage has long been condemned in the surgical management of malignant testicular and paratesticular masses given the theoretic alteration of lymphatic drainage and increased risk of tumor recurrence, both locally and systemically.[39] Prior orchidopexy has also been considered a form of scrotal violation by some authors. Published studies are small in number and limited primarily to the adult population. In these instances, additional treatment has been advocated, including hemiscrotectomy or wide excision of the scrotal scar and removal of the cord remnant through a separate inguinal incision.[40] Similarly, in the case of paratesticular rhabdomyosarcoma, scrotal violation has been managed with hemiscotectomy and/or more intensive chemotherapy, as well as scrotal irradiation.[41] Several groups have questioned the need for adjuvant surgical procedures, however, citing increased morbidity and disfigurement. A meta-analysis of all published series of testicular cancer patients with scrotal violation revealed a small but significant increase in the local recurrence rate (2.9% vs. 0.4%) but no overall increase in the distant recurrence or survival rates. Furthermore, patients with scrotal violation who did not receive local therapy had outcomes similar to those who had.[42] A review by the Children's Cancer Group/Pediatric Oncology Group of 63 patients with Stage 1 testicular germ cell tumors found no statistical significance in event-free survival between those who underwent the correct surgical approach and those who had surgical violations, although 4 patients with scrotal violation did have a higher incidence of disease recurrence.[22] For scrotal violation in the setting of paratesticular rhabdomyosarcoma, Dall'Igna et al. proposed primary reexcision as a nonmutilating alternative to hemiscrotectomy. It is worth noting, however, that eight patients in this series, who did not undergo primary reexcision as recommended, were alive without recurrence at a median of 170 months. Interestingly, this group of eight patients were all prepubertal, between age 2 and 5 years, possibly reflecting the favorable prognosis of younger patients with paratesticular rhabdomyosarcoma.[41]

TERATOMA AND EPIDERMOID CYST

Teratoma is the most common benign tumor in prepubertal patients, ranging from 8% to 48% in various series.[3,12,14] The median age of presentation is 13 months, although there have been several reports of patients presenting in the neonatal period.[21,43] Histologically, teratomas consist of tissues representing the three germinal layers: endoderm, mesoderm, and ectoderm. Consequently, cartilage, fat, bone, muscle, and neural elements may be seen in the specimen. Ultrasound may demonstrate a heterogeneous mass, reflecting cystic and solid components, with internal calcifications.[44] The findings of diploid DNA content with an absence of cellular atypia or widespread mitotic activity are characteristic.[45] AFP levels are not elevated in patients with pure teratoma.

Epidermoid cysts are benign tumors composed entirely of keratin-producing epithelium and are distinct from dermoid cysts, which contain skin and skin appendages, and teratomas, which contain derivatives of other germ cell layers. Both teratomas and epidermoid cysts are universally benign in prepubertal children. On ultrasound, most epidermoid cysts appear as discrete intratesticular masses with areas of increased echogenicity corresponding to the keratin debris or peripheral calcification.[46,47]

The benign nature of these tumors favors testis-sparing surgery.[48] At the time of inguinal exploration, an excisional biopsy with frozen section should be performed to confirm the diagnosis.[19,26] In older children with teratoma, surrounding testicular parenchyma should be carefully evaluated for histological evidence of pubertal changes. If present, then orchiectomy should be performed, given the malignant potential in postpubertal males. Biopsies of surrounding testicular parenchyma are probably unnecessary in prepubertal patients.[26,27,30] While 88% of testes removed for adult teratoma contain areas of intratubular germ cell neoplasia, this has generally not been the case for epidermoid cysts or for pediatric teratoma.[19,25–27]

For patients with epidermoid cyst and prepubertal patients with teratoma, no radiographic studies or follow-up for the development of metastatic disease are required. Because of the potential for malignancy, postpubertal patients with teratoma should be evaluated and followed on the same protocol as adults with potentially malignant germ cell tumors.

GONADAL STROMAL TUMORS

Stromal tumors include Leydig, Sertoli, and juvenile granulosa cell tumors, and mixed or undifferentiated tumors. They represent a rare and heterogenous group of neoplasms originating from nongerm cells, with differing biologic activity and clinical features.[49] Stromal testis tumors are very rare in children, and there are no large studies to guide their management. However, anecdotal reports and small series in the literature offer some experience on which to base therapy.[17,49] Leydig cell testis tumors usually present between 5 and 10 years of age with a painless testis mass and precocious puberty. Small series and case reports of unilateral lesions have documented the uniformly benign nature of these neoplasms in children, in contrast to the 10% of these tumors that are malignant in adults.[10,17] A single report of malignant bilateral Leydig cell tumors with pulmonary metastases and hemoptysis in a 9-year-old boy has been published, although it is unclear if true lung involvement by the tumor was pathologically confirmed.[50] Congenital adrenal hyperplasia (CAH) can also lead to precocious puberty and testicular masses and must therefore be excluded through laboratory evaluation. Patients with Leydig cell tumors typically have elevated testosterone levels with low or normal gonadotropin levels, whereas patients with CAH will usually have elevated levels of 17-hydroxyprogesterone. Because of their benign behavior in prepubertal children, Leydig cell tumors may be treated by testis-sparing excision.[51,52] Persistence of androgenic effects may be due to a contralateral tumor, but this is rare in children. Because Leydig cell tumors are sometimes difficult to detect on physical exam, ultrasound may be necessary to rule out a contralateral tumor. Even after successful removal of a solitary tumor, androgenic changes may not be completely reversible, and some children may proceed through premature puberty due to activation of the hypothalamic–pituitary–gonadal axis.

Sertoli cell tumors are also exceedingly rare in children. The median age of patients in the Prepubertal Testis Tumor Registry was 6 months, with a range of 4 months to 10 years.[17] Sertoli cell tumors are usually well circumscribed with a creamy, white lobulated appearance. Cysts are common. Microscopically, an interlacing network of loose fibrous stroma and parenchyma, composed of small cells with irregular hyperchromatic nuclei, is observed, which recapitulates the appearance of immature seminiferous tubules containing Sertoli cells.[53] Approximately 10% of adult Sertoli cell tumors are malignant. Sertoli cell tumors are usually hormonally inactive in children, although they may occasionally cause gynecomastia or precocious puberty secondary to estrogen or androgen elaboration. While all reported cases to date have been benign in children under 5 years of age, there have been a few cases of malignant Sertoli cell tumors in older children.[54,55] Orchiectomy is usually sufficient treatment in infants and young children. A metastatic evaluation could be considered in older children and in patients with worrisome histological findings, including vascular invasion, high mitotic index, and tumor necrosis.[17,55] When metastatic disease is present, aggressive combination treatment, including RPLND, chemotherapy, and radiation therapy (XRT), should be considered.

The large-cell calcifying Sertoli cell tumor is a clinically and histologically distinct entity with a higher incidence of multifocality and hormonal activity.[10,56–59] These tumors are composed of large cells with abundant cytoplasm and varying degrees of calcification, ranging from minimal amounts to massive deposits. While standard Sertoli cell tumors are more common in adults, large-cell calcifying Sertoli cell tumors are found predominantly in children and adolescents. Most present with a testicular mass. Approximately one-fourth of patients have bilateral and multifocal tumors. The presence of calcifications results in a characteristic ultrasound appearance, including multiple hyperechoic areas. Approximately one-third of patients with large-cell calcifying Sertoli cell tumor have an associated genetic syndrome and/or endocrine

abnormality. The two most commonly associated syndromes are Peutz–Jeghers syndrome, characterized by mucocutaneous pigmentation and hamartomatous intestinal polyposis, and Carney's syndrome, characterized by myxomas of the skin, soft tissues, and heart; myxoid changes of the breast; lentigines of the face and lips; cutaneous blue nevi; Cushing's syndrome; pituitary adenoma, and schwannoma.[60,61] Screening for these syndromes in patients with large-cell calcifying Sertoli cell tumors is important since the patients and their first-degree relatives are at risk for the potentially lethal associated anomalies. While occasionally malignant in adults, large-cell calcifying Sertoli cell tumors have been universally benign in patients under 25 years of age, and inguinal orchiectomy is sufficient treatment for children.

Juvenile granulosa cell tumor is a stromal tumor bearing a light microscopic resemblance to ovarian juvenile granulosa cell tumor. However, the histological origin of this tumor in testicles is unclear. Granulosa cell tumors occur almost exclusively in the first year of life, most in the first 6 months. Of 22 tumors diagnosed in newborns in the Prepubertal Testis Tumor Registry, 6 were juvenile granulosa cell tumors, 6 were yolk sac tumors, and 6 were unspecified stromal tumors.[43] Structural abnormalities of the Y chromosome and mosaicism are common in boys with juvenile granulosa cell tumor.[54] Several cases have been described in association with ambiguous genitalia.[62] These tumors are hormonally inactive and benign. Although these children should undergo chromosomal analysis, no treatment or metastatic evaluation is required beyond testis-sparing excision.[17,63]

Undifferentiated stromal tumors consist of areas of gonadal stromal neoplasia and undifferentiated regions of spindle cells that may exhibit a high mitotic rate. These stromal tumors have an epidemiology similar to that of granulosa cell tumors.[17] Although some of these tumors have histological characteristics commonly associated with malignancy, most behave in a benign fashion. There are inadequate data in the literature to formulate rigid guidelines for managing these tumors. While aggressive behavior has not occurred in young infants, there are reports of such behavior in older children. Unfortunately, histological features do not appear to correlate with invasive or metastatic potential. Since orchiectomy cures most of these patients, aggressive treatment is probably not appropriate in the absence of radiographic evidence of metastatic disease. However, given the uncertainty, postoperative evaluation and follow-up for the development of metastatic disease seems prudent for patients with this rare tumor.

GONADOBLASTOMA

Gonadoblastomas are benign tumors that typically arise in dysgenetic gonads. They contain both germ cell and stromal elements.[64] Dysgenetic or "streak" gonads are gonads that have failed to develop normally and contain fibrous tissue and primitive ovarian structures. If the gonad has features of primitive testicular development, it is usually referred to as a dysgenetic testis rather than a streak gonad. Gonadoblastoma arises almost exclusively in the dysgenetic gonads of patients with a Y chromosome or evidence of some Y chromatin in their karyotype. Dysgenetic gonads in patients without Y chromatin, such as patients with Turner's syndrome or XX gonadal dysgenesis, seem to be at little risk. Gonadoblastomas have been reported in 3% of true hermaphrodites, up to 15% of those with partial androgen insensitivity, and 10%–30% of patients with mixed gonadal dysgenesis or pure gonadal dysgenesis in the presence of Y chromatin.[65–67] They also occur commonly in dysgenetic testes.[68] While gonadoblastomas are benign, they are prone to malignant degeneration, and overt malignant behavior is seen in 10% of cases.[66] While most cases of malignancy occur after puberty, there have been cases reported in young children as well.[66] Therefore, early prophylactic removal of dysgenetic gonads is recommended. If malignant elements are present, a metastatic evaluation should be undertaken. Dysgerminoma (or seminoma) is the most common malignancy to occur in association with gonadoblastoma. Like their counterpart in normal testicles, these tumors are very radiosensitive, and the oncologic outlook for these patients is generally favorable.

TESTIS TUMORS IN CONGENITAL ADRENAL HYPERPLASIA

CAH in boys, most often secondary to 21-hydroxylase deficiency, typically presents with precocious puberty. Adrenal rests, which are commonly found along the spermatic cord and in the testicular hilum in normal, healthy patients, may hypertrophy in patients with CAH, leading to testicular nodules clinically indistinguishable from testicular tumors. These lesions are known as testicular adrenal rest tumors (TARTs) and may be associated with infertility in this subset of patients.[69] They can also be seen in other diseases with elevated adrenocorticotropic hormone (ACTH) levels, such as Nelson's syndrome or Cushing's disease.[70] The clinical picture can be confused with Leydig cell tumor, which can also cause precocious puberty. In patients with CAH, these nodules are often multifocal and bilateral. The diagnosis of CAH can generally be made by demonstrating an elevated serum 17-hydroxyprogesterone level. In this setting, TARTs will usually resolve or significantly decrease in size with steroid replacement. Appropriate decreases in their size after medical treatment can give an indication as to the adequacy of steroid management.[71–74] If appropriate regression is observed, the patient may be followed with serial examinations.[75] Any TART that fails to respond should be biopsied. Large nodules that fail to shrink may be safely enucleated, which can help maximize future fertility potential.[16,74,75]

LEUKEMIA

Historically, the urologist played an important role in the evaluation of patients with acute lymphoblastic leukemia (ALL) because of the concept that the testis was a site protected from therapy by the "blood–testis barrier." Approximately 20% of ALL patients have microscopic

involvement at diagnosis, and pretreatment biopsy was common.[76] Following treatment, biopsy was undertaken to detect the 10% of patients with persistent testicular disease. However, with current chemotherapy, most patients with microscopic testicular involvement achieve a complete remission. Conversely, some patients without histological evidence of testicular involvement at diagnosis will ultimately relapse in the testicles. Therefore, pretreatment testicular biopsy is no longer recommended since it does not predict those at risk for persistent or relapsing disease. Modern treatment has reduced the posttreatment relapse rate to less than 1%. Therefore, posttreatment biopsy in the absence of clinical evidence of persistent disease is also unnecessary.[77] Rare patients with persistent or recurrent testicular enlargement following chemotherapy should undergo testicular biopsy to confirm the presence of ALL. In most cases, the patient will have relapsed at other sites and further systemic treatment will be required. Typically, the testicles are also treated with radiation.

PARATESTICULAR MASSES

Paratesticular structures include the spermatic cord, epididymis, appendiceal remnants, and tunica vaginalis. Benign lesions (leiomyoma, fibroma, lipoma, and hemangioma) and malignant lesions, such as the corresponding sarcomas, can be seen across all age groups but are rarely reported in the prepubertal population, with the exception of paratesticular rhabdomyosarcomas.[78] Inguinal exploration, frozen section, and testicular sparing are recommended for benign extratesticular tumors of <3 cm in size, while inguinal orchiectomy remains the standard of care for malignant lesions.[10,79]

Paratesticular rhabdomyosarcomas account for approximately 7% of all rhabdomyosarcomas in children and are derived from mesenchymal elements of the paratesticular tissues.[80] Grossly, the cut surface has a white-gray color with areas of hemorrhage and cystic degeneration. Several histological patterns, including embryonal, pleomorphic, and alveolar, are described and correlate with tumor behavior and prognosis. Metastases occur most often to regional lymph nodes, lung, and/or bone.[81] Like primary testicular tumors in children, paratesticular rhabdomyosarcoma presents as a firm mass, with a bimodal age distribution of 3–4 months and the teenage years. Despite the highly malignant nature of these neoplasms, the majority of paratesticular rhabdomyosarcomas exhibit the more favorable embryonal histology, and overall 5-year survival exceeds 80% in several recent series. Several studies have demonstrated a poorer prognosis in boys older than 10 years, with alveolar histology, unresectable retroperitoneal disease, and/or distant metastases.[80,82–84] Management consists of radical inguinal orchiectomy with associated metastatic evaluation, including abdominal and chest CT, liver function tests, and bone scan. Based on classification according to pathologic group and stage, various combinations of chemotherapeutic agents, including vincristine, dactinomycin, cyclophosphamide or ifosfamide, and doxorubicin are administered. Likewise, disease classification dictates the need for XRT. Patients with completely resected, localized paratesticular rhabdomyosarcomas of embryonal histology do not require XRT; those with retroperitoneal involvement receive XRT. Staging ipsilateral RPLND is recommended in all boys older than 10 years, regardless of CT findings, followed by intensified radio- and chemotherapy with vincristine, dactinomycin, and cyclophosphamide in those with positive nodes.[83,85]

FERTILITY CONSIDERATIONS

Future fertility for children with cancer is increasingly being recognized as a major component of quality of life. Fertility preservation is among the goals of achieving good outcomes for cancer survivors and can be particularly challenging in prepubertal patients. Alkylating agents used in chemotherapy and radiation are toxic to male germ cells. While the prepubertal testis appears to be more resistant to injury than the postpubertal testis, oligozoospermia, which can sometimes be reversible, has been well described in patients who received combination chemotherapy as children.[86] A recent study of young males found that boys 0–4 years at age of treatment were more likely to sire a pregnancy than those who were 15–20 years old at the time.[87] Due to a slower rate of turnover, Leydig cells are less vulnerable than germ cells to the effects of chemotherapy and low-dose radiation, and while Leydig cell dysfunction may be observed following cancer treatment, most boys go on to have normal puberty with normal testosterone levels. The present options for actively retaining the reproductive capacity of young children undergoing cancer treatment remain experimental and include cryopreservation of spermatogonial stem cells, xenotransplantation, and in vitro maturation of spermatozoa.[88] For adolescent males undergoing treatment that can adversely affect fertility, sperm banking should be offered. This approach is underutilized despite the fact that Tanner 4 or 5 boys as young as 12 years old can successfully provide a usable sample. In one study, 86% of 238 boys 12–19 years old were successful at providing usable semen.[89]

CONCLUSION

Testicular tumors are rare in the prepubertal population, and the majority of these lesions are benign, with mature teratoma the most frequently observed pathology. Yolk sac tumor is the most common malignant testicular mass seen in children and usually presents with an elevated AFP. For testicular tumors occurring in prepubertal patients with normal AFP, testicular-sparing surgery should be considered. Favorable prognosis with excellent survival rates is typically observed. Adolescents present with tumors typically seen in adults and are generally managed in a similar fashion, although data specific to adolescent patients are lacking. Future goals in the management of pediatric testis tumors should be aimed at reducing the morbidity of treatment for patients with favorable disease, including strategies to limit the intensity of therapy, minimize radiation exposure during follow-up, and optimize preservation of fertility.

CHAPTER 82

Tumors of the Retroperitoneum

Gordon A. McLorie and Guy Hidas

INTRODUCTION

Retroperitoneal tumors of nonrenal origin are relatively uncommon in children. The most significant are neuroblastoma, sacrococcygeal teratoma (SCT), the rare childhood pheochromocytoma, and adrenal carcinoma. This chapter focuses on these four tumor types, with primary emphasis on the first two. The listing given in Table 82.1 of nonrenal retroperitoneal tumors is included for completeness.

NEUROBLASTOMA

Neuroblastoma accounts for 8%–10% of all childhood cancers. Following the original description by Virchow in 1864, it has continued to capture the imagination and interest of pediatricians, surgeons, and scientists. Historic landmarks in the biology of neuroblastoma include the understanding of the relationship of this childhood malignancy to the secretion of neuroactive substances in 1957, followed by the ability to establish a biochemical diagnosis based on the urinary secretion of catecholamines. Cushing described its transition in biologic activity from a malignant tumor to one of a benign nature, while Beckwith and Perrin[1] noted that clusters of neuroblastic nodules resembling neuroblastoma in situ were an incidental finding in the adrenal glands in children dying of other diseases. These clues provided the initial impetus that led to the recognition of the now well-known phenomenon of spontaneous regression of some neuroblastomas. Newer advances in molecular research have provided significant further insight into the biology of neuroblastoma. Furthermore, the paradigms described for neuroblastoma have acted as a template for diagnostic staging and applications of molecular and genetic insights to clinical therapies of other childhood malignancies. Fingerprinting the tumor's molecular characteristics (beyond MYCN proto-oncogene expression) has allowed stratification of children with neuroblastoma into distinctive clinical subsets. These stratification and staging methodologies provide better applications of therapeutic options and appropriate balancing of therapies that are more aggressive to children with poor prognostic disease. They also allow us to pursue a goal of less aggressive therapies to be used for those children in whom better prognosis can be defined.[2]

Recent insights have unfolded as a result of neonatal screening programs in Japan and Canada. In these programs, the secretion of urinary vanillylmandelic acid (VMA) in the newborn has been used as a method of neuroblastoma detection. However, early detection has neither reduced the occurrence nor improved the prognosis of those children who are discovered to have higher-grade tumors in later infancy and childhood. This has led to the thesis that the tumors detected during neonatal screening programs are those that have a natural propensity for spontaneous resolution.[3,4] The results suggest that mass screening for neuroblastoma, while feasible, is unlikely to alter the course of those patients destined to succumb to the disease.

Clinical and Biological Features

Neuroblastoma ranks as the most common extracranial solid malignancy of childhood[5] and early infancy. The incidence may be increasing slightly.[5,6] In children presenting with neuroblastoma, 65% will occur in the retroperitoneum, of which 40% will originate in the adrenal gland.[7]

Few, if any, environmental risk factors have been identified for neuroblastoma. Recently, maternal vaginal infections, their treatment, and prenatal maternal hormone use have been weakly suggested to increase the risk of neuroblastoma in offspring.[8] Pesticide exposure has been suggested as being associated with an increased risk of carcinogenesis in children compared with adults; the risk included, but was not specific for, neuroblastoma.[9]

While newer molecular modalities are helping to refine prognostic groupings and treatment assignment, the overwhelming variables distinguishing high- from low-risk groups continue to be age at diagnosis, tumor stage, and histologic grade.[10] Diagnosis before 12 months of age is more clinically favorable than later diagnosis.

Any predisposition for neuroblastoma appears to follow an autosomal dominant pattern, as elucidated by the two-hit hypothesis of Knudson and Strong.[11] Also described for Wilms' tumor and pheochromocytoma, inherited forms of neuroblastoma may occur in patients who harbor a mutation in a gene that preexisted in a parental germ line (preconception or germinal mutation). A subsequent spontaneous mutation of the other copy of the same gene (a somatic mutation) in a cell of the appropriate background (neural crest cell) leads to malignant transformation of that cell. This has led to estimates that more than one-fifth of all neuroblastoma may be of the inherited variety.[11] The occurrence of nonfamilial neuroblastoma must therefore

TABLE 82.1 Nonrenal retroperitoneal tumors

Benign	Malignant
Lymphangioma	Neuroblastoma
Neurofibroma	Pheochromocytoma
Ganglioneuroma	Sacrococcygeal teratoma
Lipoma	Nongenitourinary pelvic
Sacrococcygeal teratoma	Rhabdomyosarcoma
	Lymphoma
	Liposarcoma
	Fibrosarcoma
	Leiomyosarcoma
	Malignant fibrous
	Histiocytoma
	Secondary tumors

await these two critical mutations or "hits" as two independent spontaneous events. This explains the reduced likelihood (incidence) of nonfamilial or sporadic disease. With one of two mutations possibly present in all cells of a given child with a strong family history of neuroblastoma, it is easy to see why earlier incidence, bilaterality and multifocality, and higher recurrence rates are the norm in those with familial disease. Exceptions to the two-hit hypothesis have been reported (familial neuroblastoma in older children), suggesting that other genetic mechanisms may also underlie familial disease.[12] While several reports exist of neuroblastoma being found in children with a chromosomal abnormality, few chromosomal predispositions have been definitively associated with neuroblastoma. Abnormal rearrangements have been described involving chromosomes 1 and 17 (see below). Deletions involving 1p36 have implicated this region as containing a neuroblastoma tumor suppressor gene, and gains in the 17q region have been associated with poor prognosis.[12–17] Finally, loss of heterozygosity (LOH), a molecular phenotype characterized by the loss of the subtle differences that normally exist between the two allelic (parental) copies of any gene signifying that one of the copies is missing, has been identified as a more general phenomenon in neuroblastoma. Subjects with LOH are therefore homozygous instead of heterozygous for that particular chromosomal region. When a disease becomes evident in association with LOH in particular regions of a chromosome, this implies that the missing region of that chromosome encodes a gene or genes responsible for suppressing that disease, i.e., tumor suppressor genes. Although LOH does not identify the missing gene itself, LOH in neuroblastoma has been reported present in a number of chromosomes, including 1p, 11q, 14q, 2q, 9p, and 18q.[18]

Clinical Manifestations: Primary, Metastatic, and Paraneoplastic Features

The presenting signs and symptoms are variable and may reflect the effects of the tumor, the presence of metastatic disease, or the results of tumor hormone production. As mentioned earlier, prenatal screening may also identify neuroblastoma. Infants may present with an abdominal mass that is often huge. A unique feature of neuroblastoma in children is the potential for widespread liver metastatic disease that may signify stage 4S disease (Figure 82.1).

Children with stage 4S have a potential survival rate of up to 90%, in spite of metastases to either the liver, skin, or bone marrow, but not to cortical bone. Subcutaneous nodules are another manifestation of this early presentation.[20] In some patients, tumors regress spontaneously. Alternatively, metastases may regress following excision of the primary tumor.[21,22] In children older than 1 year of age, the size of the abdominal mass is variable and may not be the presenting symptom. Malaise and/or pain reflecting the presence of metastatic disease is the presenting complaint in up to 60%. Anemia (from bone marrow involvement in 50% of patients) is also a common presenting sign. The new or sudden onset of constipation or urinary retention may herald the well-known propensity of neuroblastoma to invade the spinal cord. In addition, transient pain attributable to bony metastases may mimic rheumatoid arthritis. Lung or brain metastases are common sites of relapse and late-stage disease.

Paraneoplastic syndromes occur in fewer than 5% of neuroblastoma patients. Intractable diarrhea may result from the secretion of vasoactive intestinal peptide (VIP).[23]

FIGURE 82.1 Neuroblastoma metastatic to liver. Stage 4S neuroblastoma underwent spontaneous regression. (From Snyder HM, et al. Paediatric oncology. In Walsh PC et al. eds., *Campbell's Urology*, 5th edn. Philadelphia: WB Saunders, 1986, 2269. With permission.)

However, this symptom, mimicking malabsorption syndrome, is more often associated with the better-differentiated ganglioneuroma or intermediately differentiated ganglioneuroblastoma. Resolution follows removal of the tumor. Another unusual symptom is cerebellar ataxia and opsomyoclonus (dancing feet, dancing eyes; myoclonic encephalopathy of infants). This syndrome is of unknown pathogenesis and is more often associated with thoracic tumors.[7] While symptoms of catecholamine excess (palpitations, tachycardia, and hypertension) are rare in neuroblastoma, they can occur from excess circulating tumor-derived norepinephrine. However, norepinephrine is less potent than its metabolite, epinephrine, in inducing these symptoms. These symptoms are more commonly found in patients with pheochromocytoma. The responsible enzyme is phenylethanolamine *N*-methyl transferase (PNMT), which plays a role in the conversion of norepinephrine to epinephrine.

Gross, Histologic, Molecular Pathology, and Markers

Neuroblastomas arise from cells of neural crest origin, which ultimately form the sympathetic nervous systems (sympathogonia). The sites of origin may be found at any location in the sympathetic nervous system, with more than one-half occurring in the neonatal abdominal cavity, and up to two-thirds from the adrenal gland. The remainder occur in the sympathetic ganglia and, more rarely, in the organ of Zuckerhandel. The spectrum of biologic behavior or potential of these tumors is broad. Malignant neuroblastomas comprise the majority. Ganglioneuroblastoma and ganglioneuroma represent progressively more benign forms of the tumor, reflecting more indolent clinical manifestations, better prognoses, and distinct morphology and biochemical profiles.

The histopathologic features that define the malignant potential are unique. Homer–Wright pseudorosettes, the diagnostic histologic presence of eosinophilic neutrophils surrounded by neuroblasts, occur in only one-half of cases.[24] The presence of associated neuropils (pigmented neuritic processes) is pathognomonic for neuroblastoma. The other type of cell is the Schwann cell, which may be recruited into the tumor and comprises the Schwannian stroma, which makes up the mesenchymal component of the tumor. The degree of histologic differentiation is classified according to a variety of schemes, but the most popular is that developed by Shimada, which has recently been revised by Joshi (Table 82.2), and a combination of the two is the basis of planned prospective trials.[26,27]

TABLE 82.2 Histopathologic classifications of Shimada and Joshi

Prognosis	Histopathologic Features/Age
Favorable	
Shimada	Stroma rich, all ages, no nodular pattern
	Stroma poor, age 1.5–5 years, differentiated, MKI < 100
	Stroma poor, age <1.5 years, MKI < 200
Joshi	Grade 1, all ages; grade 2, <1 year
Unfavorable	
Shimada	Stroma rich, all ages, nodular pattern
	Stroma poor, age >5 years
	Stroma poor, age 1.5–5 years, undifferentiated
	Stroma poor, age 1.5–5 years, differentiated, MKI > 100
	Stroma poor, age <1.5 years, MKI > 200
Joshi	Grade 2, age >1 year; grade 3, all ages

Source: Brodeur GM, Castleberry RP. Neuroblastoma. In Pizzo PA, Poplack DG, eds., *Principles and Practice of Pediatric Oncology*. Philadelphia: JB Lippincott, 1997, 7712. With permission.

Note: Grade 1 = low mitotic rate (<10 mitotic figures per 10 high power fields) and calcification present; grade 2 = either low mitotic rate or calcification present; grade 3 = neither low mitotic rate nor calcification present.

Abbreviation: MKI, mitosis–karyorrhexis index (number of mitoses and karyorrhexis per 5000 cells).

Molecular Pathology

Molecular understanding of neuroblastoma has identified several newer features of the disease that may aid in all aspects of its management, including diagnosis, natural history, prognostic stratification, and treatment selection. These include analyses of nuclear and chromosomal material, and neuronal phenotyping through assessment of various neuron-associated growth factors. While karyotyping has identified specific chromosomal abnormalities (see below), analysis of DNA ploidy has also revealed significant information. Paradoxically, neuroblastomas of the hyperdiploid variety are more likely to respond favorably to chemotherapy. Diploid or near-diploid tumors are associated with higher-stage disease (including unresectable tumors), poorer prognosis, a lower response to chemotherapy, and recurrence or progression.[28–31]

The most widely reported genetic marker for neuroblastoma has been amplification of the MYCN (or N-myc) proto-oncogene.[22,32] The association between MYCN amplification and high-grade,[33] advanced-stage disease at presentation, rapid progression, and overall poor prognosis is well established. Recently, an etiologic relationship between MYCN and neuroblastoma has been demonstrated by two complementary studies. Chan and coworkers from The Hospital for Sick Children in Toronto reported that elevations in MYCN protein expression in neuroblastoma tissues are independently associated with poor prognosis in high-stage disease (3, 4, and 4S) even in the absence of MYCN gene amplification.[34] Furthermore, MYCN protein levels were prognostic, independent of the most significant variables of age or stage,[34] thus strongly supporting the concept that MYCN expression is directly involved in the cellular events of neuroblastoma progression. Conversely, in the subgroup of patients who did well with normal MYCN gene expression, MYCN protein levels were undetectable.[34] In a related animal study, the targeted overexpression of the MYCN gene in neuroectodermal cells led to the development of neuroblastoma in MYCN transgenic mice.[35] MYCN tumorigenesis is further augmented in the absence of the recognized tumor

suppressor genes NF1 or RB1.[35] This demonstrates that MYCN's transforming effect can be influenced by other genes, consistent with the emerging concept of multistep processes in malignant transformation. MYCN gene amplification is present in approximately 40% of patients with advanced stage 3 or 4 disease (compared with <10% in low-stage patients), and its absence augurs a slower disease progression in these patients.

As mentioned above, deletions of chromosome 1 and gains in chromosome 17 have been shown to carry strong prognostic information in advanced neuroblastoma. A landmark report from a collaborative group in Europe has shown a very powerful association between gains in chromosome 17q and adverse neuroblastoma outcome. The study is important because of its large numbers, the availability of all clinical and genetic data variables for 85% of the patients in the cohort, and the close coordination between a team of basic and clinical researchers. In total, 313 children from six European centers were studied. Often, but not exclusively, the gain of 17q was linked to the loss of 1p. Most significantly, in univariate and multivariate analyses, 17q gain was independently predictive of poor outcome (30.6% 5-year survival with 17q gain vs. 86% 5-year survival without 17q gain).[36]

A longstanding notion in tumorigenesis states that transformation (neoplasia) is the result of aberrant differentiation pathways leading away from the normal cell phenotype. As a result, neuroblastoma may represent an aberration of normal neuronal development. As such, several neuronal differentiation markers have been investigated in this disease, including chromogranin A, neuropeptide Y, and receptors for neurotropins, such as nerve growth factor. Neuropeptide Y is detectable in abundance in the serum of neuroblastoma patients and may be useful in following tumor burden both before and after therapy.[37] In tumor tissue, it reaches its highest levels in poorly differentiated neuroblastoma, compared with ganglioneuroblastoma or ganglioneuroma.[37] Conversely, chomogranin A derivatives may become useful markers of more favorably differentiated tumors.[38]

Acting through various receptors, neurotropic factors are, by definition, involved in the differentiation of neural tissues. One family of neurotropin receptors, the tyrosine kinase receptors TRK-A, TRK-B, and TRK-C, is showing promise in understanding neuroblastoma biology. It appears that TRK-A gene expression is associated with favorable outcome, yielding its highest expression in more well-differentiated tumors.[39,40] Furthermore, TRK-A levels are inversely correlated with MYCN gene expression.[39] Expression of TRK-C and shortened forms of TRK-B also portends a better outcome.[39] Together, these observations have also led to speculation that functioning, intact neurotropin/TRK receptor pathways in these tumors may be further linked to their propensity to mature (differentiate) into ganglioneuromas, or regress through a cell death pathway (from a presumed eventual unavailability of factor for the receptor, or receptor malfunction). However, as our knowledge of the role of these pathways evolves, it is becoming clear that they carry potential as powerful markers of disease, or even as molecular therapeutic targets to manipulate neuroblastomas to assume differentiation or regression pathways.

Drawing on the foregoing discussion, neuroblastomas may be stratified into specific prognostic subgroups based on the genetic interplay represented by MYCN expression, LOH, DNA ploidy, and neurotropin receptor expression. Combined with age and stage, three genetic neuroblastoma profiles can be determined with differing survival rates (Table 82.3).

Diagnosis, Staging, and Treatment

The diagnosis of neuroblastoma is confirmed by histologic sampling of tumor tissue or bone marrow. Standard light and electron microscopic evaluation may be followed by immunohistochemical identification of tissue of neuronal origin. The vast majority of the tumors secrete catecholamines synthesized from the amino acid tyrosine in the following sequence: dopa, dopamine (both excreted as homovanillic acid [HVA]), and finally norepinephrine. In contrast to pheochromocytomas, neuroblastomas lack the ability to convert norepinephrine to epinephrine. Norepinephrine and epinephrine are both excreted as VMA.

Imaging Techniques

Traditionally, the presentation of an abdominal neuroblastoma has been either by the discovery of an abdominal mass on physical examination, or the result of investigations to explain symptoms related to either metastatic disease or the neuroendocrine manifestations of the tumor.

TABLE 82.3 Genetic neuroblastoma profiles

Feature	Type 1	Type 2	Type 3
MYCN amplification	None	None	Present
DNA ploidy	Hyperdiploid	Near diploid	Near tetraploid
LOH	Rare	25%–50%	Present
Neurotropin gene expression	High	Low/absent (except TRK-B, high)	
Age	1 year	>1 year	
Stage	1, 2, 4S	3, 4	
3-year survival	95%	25%–50%	<5%

Abbreviation: TRK, tyrosine kinase receptor.

Abdominal ultrasonography will detect a great percentage of those tumors that occur in the abdominal cavity. Occasionally, they are found as an incidental finding in the course of pursuing an otherwise unrelated symptom. With increased sonographic screening, this has now become a more common cause for presentation of these tumors.[42] In the authors' recent experience at a large children's hospital, there have been two instances in the past year when children who were being followed in the course of an investigation for antenatal hydronephrosis had neuroblastomas that became apparent and had not been present on prior examinations (Figure 82.2a–c).

Diagnostic imaging techniques are evolving and improving with great rapidity, and there is no consensus as to which method is best. The choices include ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI). The availability and the noninvasive nature of ultrasonography endorse this technology as the choice for the initial screening test. The time required for both CT and MRI makes their selection for young children more critical. Either of these techniques may be used to delineate and define the extent of the disease. Availability may be the most critical determinant of which should be used. CT imaging currently seems to be the most widely available modality[43] (Figures 82.2 and 82.3).

In seeking metastatic disease, a chest radiograph is a useful initial step. Radioisotope bone scanning using technetium-99m–methylene diphosphonate is more accurate than a standard x-ray skeletal survey for the detection of bony metastases (Figure 82.4).

Prognostic Markers

Both clinical and biochemical markers have evolved that are helpful in the management of neuroblastoma. The best recognized are the traditional clinical parameters of age at diagnosis and tumor stage. Patients diagnosed at 1 year of age appear to show consistently better survival outcomes than older children, even in the presence of advanced disease at presentation. Survival also stratifies dramatically with respect to disease stage, with 75%–90% 5-year survival for stage 1, 2, and 4S patients, compared with 10%–30% 2-year survival for stage 3 and 4 disease.

Various biochemical and cell-associated parameters have also been assessed for their prognostic ability in the management of neuroblastoma. Serum ferritin is elevated

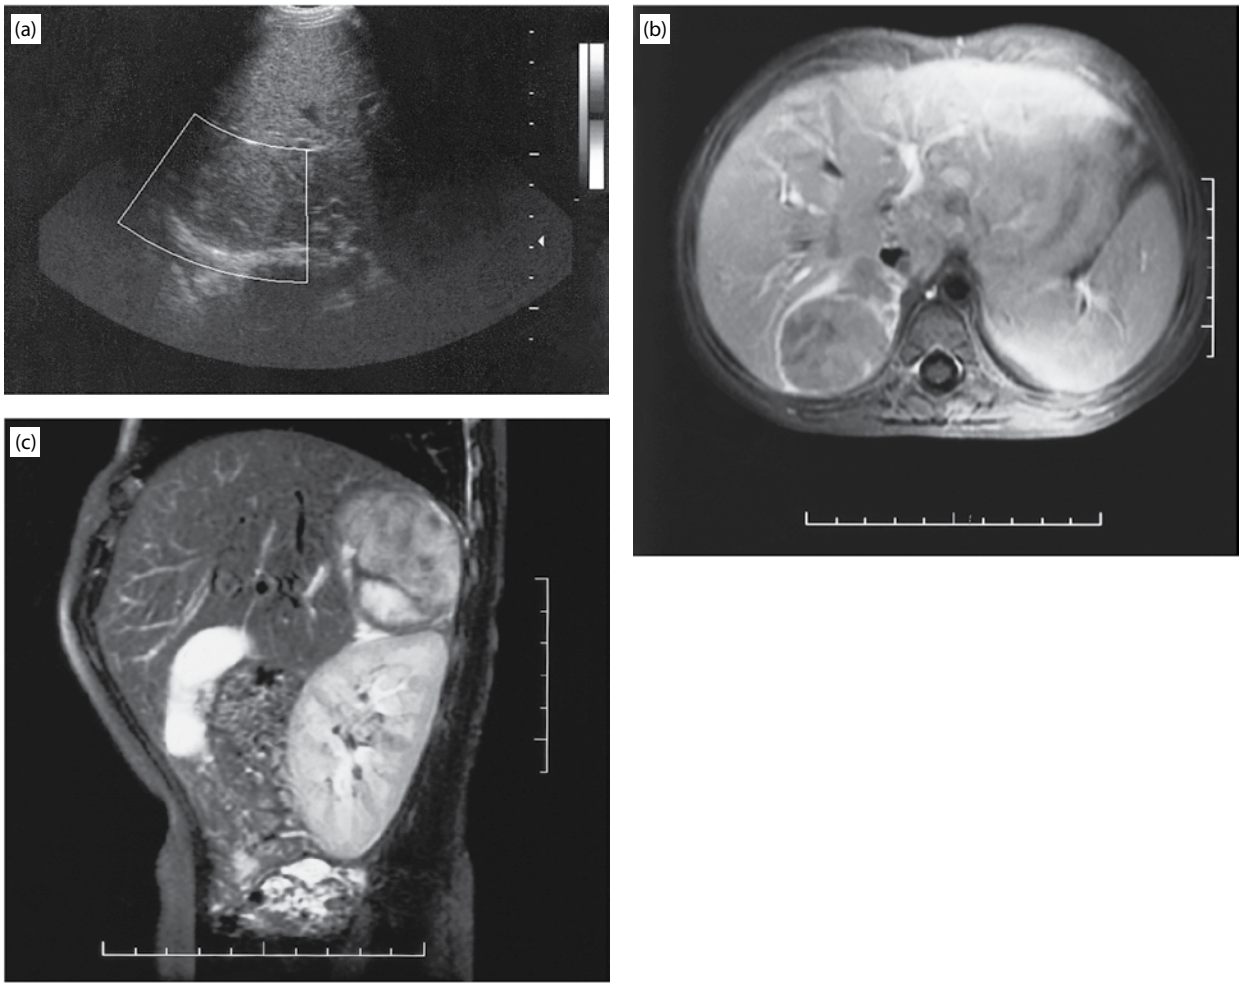

FIGURE 82.2 (a) Ultrasound image discovered in a 1-year-old child as "incidentaloma" in the course of investigating contralateral antenataly diagnosed hydronephrosis. Prior sonogram 6 months earlier with good views of the same area showed no evidence of mass lesion. (b and c) Transverse and sagittal MR images of the same lesion, showing relationships in the retroperitoneum.

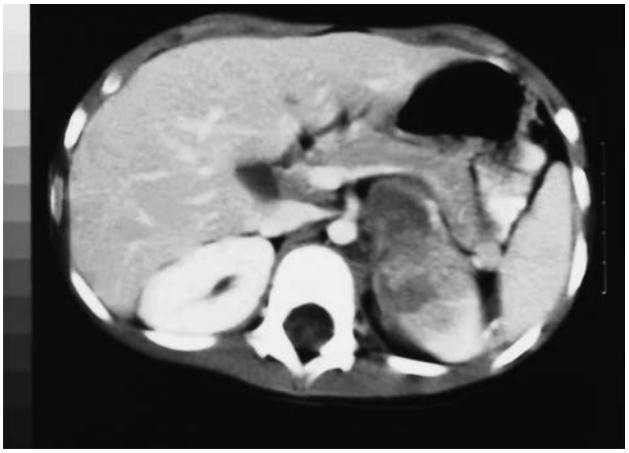

FIGURE 82.3 Transverse CT scan of retroperitoneal recurrence of a previously excised stage 3 neuroblastoma.

during periods of rapid tumor growth and/or large tumor burden. Whether this reflects a growth requirement for ferritin by the tumor or is a product of neuroblastoma cell metabolism is unknown. Ferritin levels appear to discriminate between stage 4 and stage 4S disease.[44] Lactate dehydrogenase (LDH) is elaborated nonspecifically in several tumor types, including neuroblastoma, where it may reflect rapid tumor cell turnover and[44] tumor burden. Neuron-specific enolase is a cytoplasmic enzyme found in cells of neural[45] origin. Neuroblastoma prognosis appears worse if elevated levels are detected in serum, although this marker is not specific to neuroblastoma.[45] Serum and tissue ganglioside GD2 is a glycosphingolipid shed by neuroblastoma tumor cells. It may reflect tumor burden, and decreasing levels may be seen as a positive response to successful reduction of tumor load. The presence of GD2 on the cell surface has attracted interest in targeting this molecule using immunotherapy strategies.[46–48] Finally, matrix metalloproteinases (MMPs) are cellular enzymes required to break down the extracellular matrix and facilitate cell movement through the matrix during the metastatic process. Very recently, tumor cell expression of a membrane-associated MMP was found to correlate with advanced stage and poor outcome in neuroblastoma.[49]

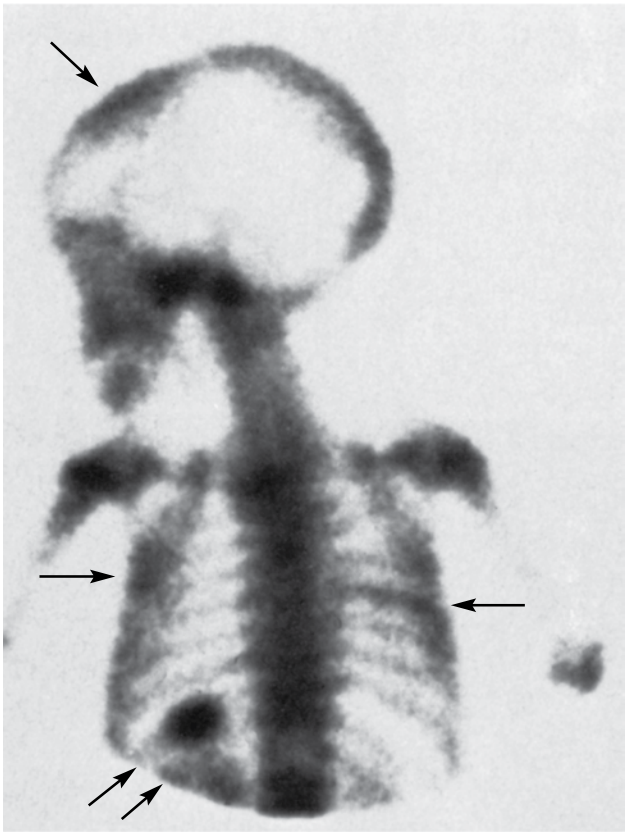

FIGURE 82.4 Posterior view of thorax and skull. Increased uptake is seen in the skull–upper thoracic spine and left and right ribs (arrows) as a result of metastatic neuroblastoma. The decreased uptake at T12 is an unusual manifestation of metastatic tumor. The right suprarenal uptake of tracer is within the primary tumor (double arrow).

Staging

A disease with such diverse manifestations as neuroblastoma in childhood needs a comprehensive staging system to allow precise diagnostic criteria and a method for categorizing and quantifying disease. Such a staging system then acts as a template upon which diagnostic criteria can be applied to various subgroups of disease, and permits definition of outcome measures that will allow collaboration between centers in implementing and assessing clinical trials. An international working group published the outcome of its deliberations in 1988.[50] The staging system recommended is known as the International Neuroblastoma Staging System (INSS), and the response criteria are referred to as the International Neuroblastoma Response Criteria (INRC). This staging system has now replaced previous systems by Evans, originally established by the Pediatric Oncology Group (POG). Table 82.4 outlines the three staging systems, thus facilitating some comparison of previously published data.[51–53]

Treatment

Therapy of neuroblastoma requires close coordination of medical, surgical, and radiation oncologists and clearly represents a prime example of multimodal cancer therapy. Surgical intervention plays a dual role. At the time of diagnosis, open or laparoscopic approaches may be necessary to obtain adequate and thorough samples for histologic and molecular diagnosis and marker analysis. Needle biopsy materials are most often inadequate for these purposes. For selected tumors, primary surgical excision may be possible, particularly for small, locally confined cases. In this regard, laparoscopic surgery may be considered and has been used successfully for small tumors identified by screening.[54] Given that infant screening detects tumors that are generally biologically favorable, laparoscopic surgery may be a safe modality on oncologic grounds. Open surgical dissection is also employed to both assess response to therapy and excise residual disease after initial courses of chemotherapy have been completed. Recent reports have suggested a higher incidence of nephrectomy in children with neuroblastoma who were treated with primary surgical intervention.[55,56]

TABLE 82.4 Neuroblastoma staging system

Evans and D'Angio	POG	INSS
Stage I	*Stage A*	*Stage 1*
Tumor confined to the organ or structure of origin.	Complete gross resection of primary tumor, with or without microscopic residual. Intracavitary lymph nodes, not adhered to and removed with primary (nodes adhered to or with tumor resection may be positive for tumor without upstaging patient to stage C), histologically free of tumor. If primary in the abdomen or pelvis, liver histologically free of tumor.	Localized tumor with complete gross excision without microscopic residual disease; representative ipsilateral lymph nodes negative for tumor microscopically (nodes attached to and removed with the primary tumor may be positive).
Stage II	*Stage B*	*Stage 2A*
Tumor extending in continuity beyond the organ or structure of origin but not crossing the midline. Regional lymph nodes on the ipsilateral side may be involved.	Grossly unresected primary tumor. Nodes and liver same as stage A.	Localized tumor with incomplete gross excision; representative ipsilateral nonadherent lymph nodes negative for tumor microscopically.
Stage III	*Stage C*	*Stage 2B*
Tumor extending in continuity beyond the midline. Regional lymph nodes may be involved bilaterally.	Complete or incomplete resection of primary. Intracavitary nodes not adhered to primary histologically positive for tumor. Liver as in stage A.	Localized tumor with or without complete gross excision, with ipsilateral nonadherent lymph nodes positive for tumor. Enlarged contralateral lymph nodes must be negative microscopically.
Stage IV	*Stage D*	*Stage 3*
Remote disease involving the skeleton, bone marrow, soft tissue, distant lymph node groups, etc. (see stage IV-S).	Any dissemination of disease beyond intracavitary nodes (i.e., extracavitary nodes, liver, skin, bone marrow, and bone).	Unresectable unilateral tumor infiltrating across the midline, with or without regional lymph node involvement; or localized unilateral tumor with contralateral regional lymph node involvement; or midline tumor with bilateral extension by infiltration (unresectable) or by lymph node involvement.
Stage IV-S	*Stage DS*	*Stage 4*
Patients who would otherwise be stage I or II, but who have remote disease confined to the liver, skin, or bone marrow (without radiographic evidence of bone metastases on complete skeletal survey).	Infants of $<$1 year of age with stage IV-S disease (see Evans and D'Angio).	Any primary tumor with dissemination to the distant lymph nodes, bone, bone marrow, liver, skin, and/or other organs (except as defined for stage 4S).
		Stage 4S
		Localized primary tumor as defined for stage 1, 2A, or 2B with dissemination limited to the skin, liver, and/or bone marrow (limited to infants of $<$1 year of age).

Chemotherapy is a major component of the treatment of neuroblastoma. Both single-agent and synergistic multiagent drug regimens are used, combining cell cycle–specific and cell cycle–independent drugs to achieve the maximum ratio of therapeutic benefit to toxicity. Ionizing radiation has a role in neuroblastoma treatment as the tumor is radiosensitive. It is most useful in achieving local control, on the one hand, and palliation of disease uncontrollable by other modalities, on the other. As a primary modality, however, radiotherapy is limited by the extensive metastatic proclivity of many neuroblastomas. The agent methyliodobenzylguanidine (MIBG), used in the localization of neuroblastomas and pheochromocytomas, has been studied for its ability to bind to neuroblastoma tumors systemically and carry with it radioligands such as iodine-131 that are toxic to the tumor cells.[48,57,58] This approach has also been used as a surgical adjunct to guide tumor tissue resection using the gamma camera intraoperatively once the tumor is radiolabeled by preoperative injection of [^{131}I]MIBG.[59]

Given the aggressive nature of advanced- and higher-staged disease, efforts continue to attempt improved disease control in this subset of patients while refining therapy to limit toxicity in lower-stage and more favorable disease.

Treatment Strategy

The ability to stratify patients into distinctly risk-related groups, by application of the varied but highly accurate histologic and molecular diagnostic and staging methodologies, has permitted the much more judicious and specific use of the therapeutic regimens.

Stage 1 and 2 tumors (low risk) are treatable by primary surgical resection alone, with no need for initial chemotherapy or radiotherapy. A prognosis of up to 89% survival has been reported in this group of patients.[2,58,60] Stage 4S tumors will undergo spontaneous remission and are thus considered low risk. However, if symptoms are present related to severe hepatic metastatic disease or respiratory compromise, they may benefit from chemotherapy or radiation therapy in small doses.

Stage 3 tumors (intermediate risk) still have an excellent overall survival rate of up to 89%,[60] but chemotherapy is advised following primary surgical excision. Second-look surgery may also be appropriate after chemotherapy. The goal of therapy in this group is to reserve more intense therapy for those children with biologically unfavorable tumors.

Patients with stage 4 disease (high risk) have derived minimal benefits from even the most intensive regimens. Multiagent chemotherapy remains the standard primary treatment strategy for these patients. There have been isolated applications of ablative chemotherapy and bone marrow transplantation, and these intensive therapeutic approaches are currently being explored in multicenter trials. The overall prognosis in this group of children remains very low (15%–35% survival).[61]

Ganglioneuroma

A more histologically benign counterpart of neuroblastoma is the ganglioneuroma. Ganglioneuroblastoma is an intermediate malignant classification between ganglioneuroma and neuroblastoma, and for treatment purposes is regarded with neuroblastoma. Ganglioneuromas are most often seen in older children and present as abdominal masses. It is intriguing to hypothesize that late development of a more benign variant may represent a "second hit," but these tumors do not exhibit an "explosive" form of metastatic behavior.[62] Nonetheless, by virtue of their inexorable growth and distortion of adjacent tissues, they can have a very morbid clinical course. Such a case is illustrated in Figure 82.5a–c, in which both gastrointestinal and genitourinary tissues are grossly displaced. The urologic system, in particular, may exhibit such profound destruction that urinary diversion may be deemed necessary. The figures illustrate the results of MRI, which can provide eloquent detail of the soft tissue involvement by these tumors, while there is no evidence of direct histologic invasion of the compressed tissues (Figure 82.6).

The correlation of the MRI features with latent malignant potential in these tumors has recently been documented by Ichikawa et al.[63] They were able to show that punctate calcification on the CT scan and low or intermediate attenuation are common in ganglioneuromas. The MR images are mainly of low intensity on T_1-weighted images and of high intensity on T_2-weighted

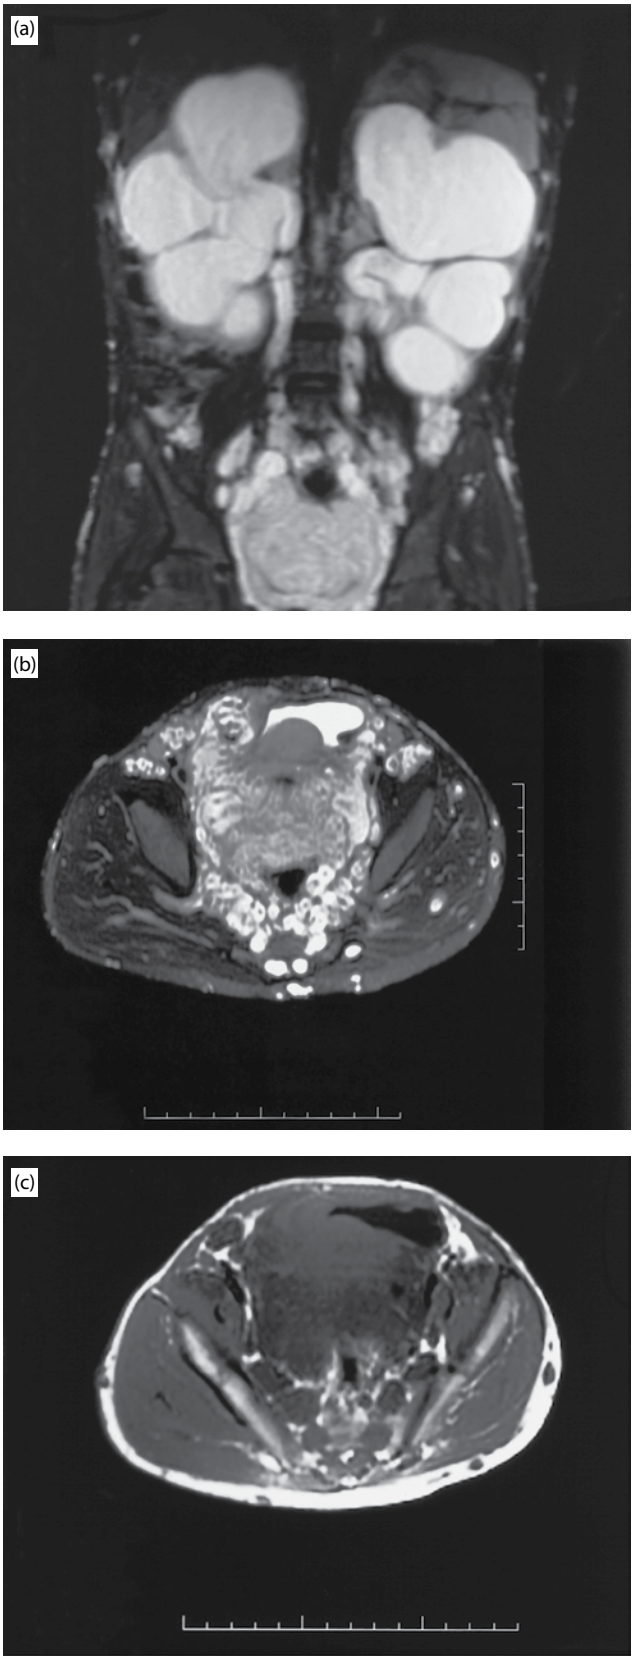

FIGURE 82.5 (a) MR scan of a patient with a ganglioneuroma, showing obstruction of the ureters. (b) Primary neuronal masses displacing the bladder anteriorly and the rectum posteriorly. (c) T_2-weighted image of the same pelvic area as in (b), showing the different appearance of neural tissues.

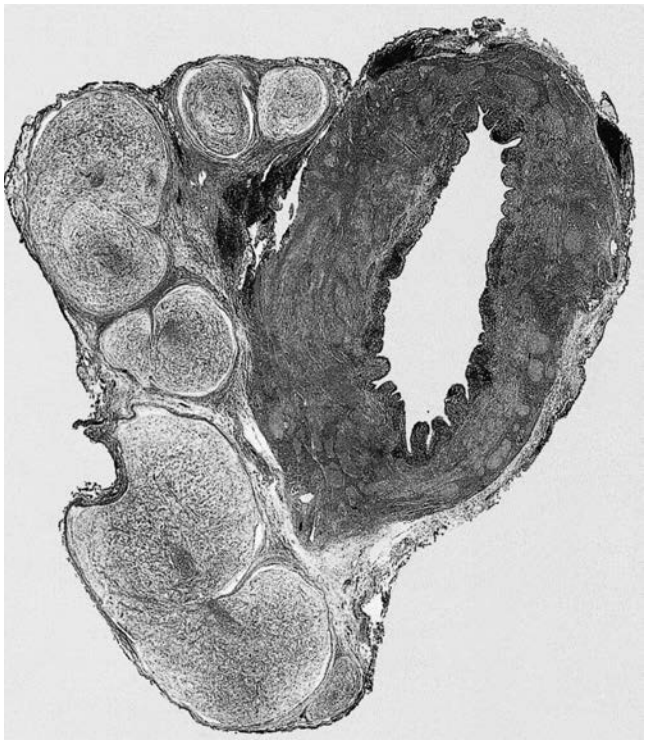

FIGURE 82.6 Pathologic section of area of excised ureter, with ureter encased in, but not invaded by, tumor tissue.

images. Dynamic MR studies show a lack of early involvement but gradually increasing enhancement. The authors concluded that the absence of these features, judged "typical" for ganglioneuroma, should suggest a potential for a more malignant course. The slow-growing nature of ganglioneuromas may also have a devastating effect on vascular and neurologic function by virtue of its compressive effects on adjacent structures. Figure 82.7 demonstrates extension along the sacral nerve prior to the appearance of clinical degeneration. This and other cases have demonstrated the potential for clinical morbidity that may be associated with ganglioneuroma despite its nonmetastatic nature. To prevent these localized effects, incomplete surgical resection may be justified in the absence of effective chemotherapy or radiotherapy.

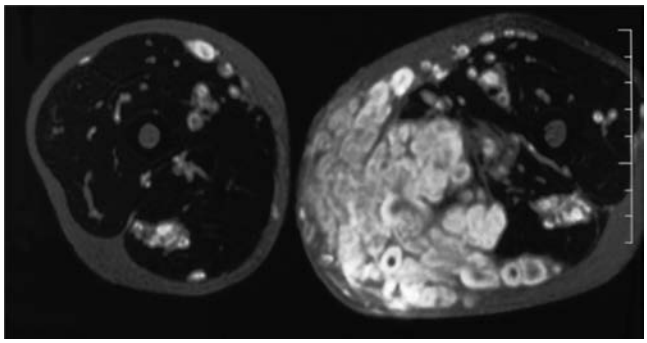

FIGURE 82.7 Extension of ganglioneuroma down the sheath of the sacral nerve.

PHEOCHROMOCYTOMA

Clinical Features and Presentation

Pediatric pheochromocytoma is an extremely uncommon primary tumor of the adrenal medulla, although it is the most common hyperfunctioning form of this tissue in children. Over a period of 5 years at The Hospital for Sick Children in Toronto, of 30 patients presenting with a primary adrenal tumor, only 1, a 16-year-old girl, had a pheochromocytoma. The tumors arise in the autonomic system, with 90% originating in the adrenal gland. Catecholamine production is the norm and is the basis for both the clinical manifestations and laboratory diagnosis. Pediatric pheochromocytomas can be seen in association with a variety of diseases, including neurofibromatosis, von Hippel–Lindau disease, Sturge–Webber syndrome, and multiple endocrine neoplasia (MEN-2). Those associated with MEN-2 are more likely to occur later in life and are more likely to be bilateral.

Imaging, Biochemical Features, and New Prognostic Markers

The diagnosis of pheochromocytoma in childhood is suggested by the rare coexistence of hypertension and abdominal mass detectable on sonographic evaluation. Nonpalpable pheochromocytoma causing secondary hypertension in children is exceedingly rare. The diagnosis is confirmed by means of either serum or urine confirmation of hypersecretion of catecholamines.

As stated previously, the principal catecholamine that produces the classic characteristic symptoms of flushing, palpitations, hypertension (vasoconstriction), and anxiety in patients with pheochromocytoma is epinephrine. Epinephrine is a metabolite of its precursor, norepinephrine. The latter is a less potent mediator of the clinical constellation seen in pheochromocytoma. However, compared with neuroblastoma, both catecholamines are more commonly produced by pheochromocytomas. Pheochromocytomas, particularly those of adrenal origin, produce the enzyme PNMT, which converts norepinephrine to epinephrine. As such, the norepinephrine-to-epinephrine ratio has been used to distinguish pheochromocytomas of adrenal from those of extraadrenal origin.

With respect to diagnostic imaging, the initial methodology in suspected cases is ultrasonography (Figure 82.8). Thereafter, either CT or MRI can be employed to confirm the diagnosis of an adrenal or a para-adrenal mass (Figure 82.9). Serologic or creatinine-specific measures of catecholamine excretion in the urine are then undertaken. The most specific diagnostic imaging methodology is radionucleotide scanning using [^{131}I]MIBG scintigraphy (Figure 82.10). With this approach, the sensitivity is greater than 90%.[64] [^{131}I]MIBG scanning is particularly valuable in the localization of tumors located outside the adrenal gland.[65,66]

One of the persisting challenges in pheochromocytoma management remains the inability to define precisely whether a given tumor is benign or malignant. The current gold standard criterion for malignancy remains the

FIGURE 82.8 Ultrasound image of a left suprarenal tumor in a 16-year-old child presenting with hypertension.

appearance of metastases. As a predictor of malignancy, this is analogous to predicting that automobile brakes are defective based on the occurrence of a collision. Clearly, more accurate markers for determining the malignancy of pheochromocytoma are needed. Recent studies have identified biologic features of pheochromocytomas that may hold promise in determining the metastatic proclivity of the tumor. For example, telomeres are composed of repeated nucleotide sequences on the ends of chromosomes. During normal cell aging, they progressively shorten during successive normal cell replications. In normal cells, this shortening is thought to be associated with waning activity

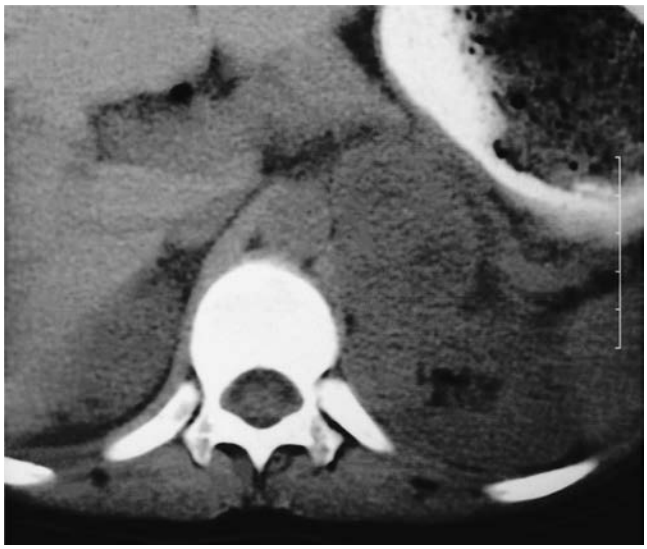

FIGURE 82.9 CT image of left suprarenal pheochromocytoma, as seen in ultrasound in Figure 82.8.

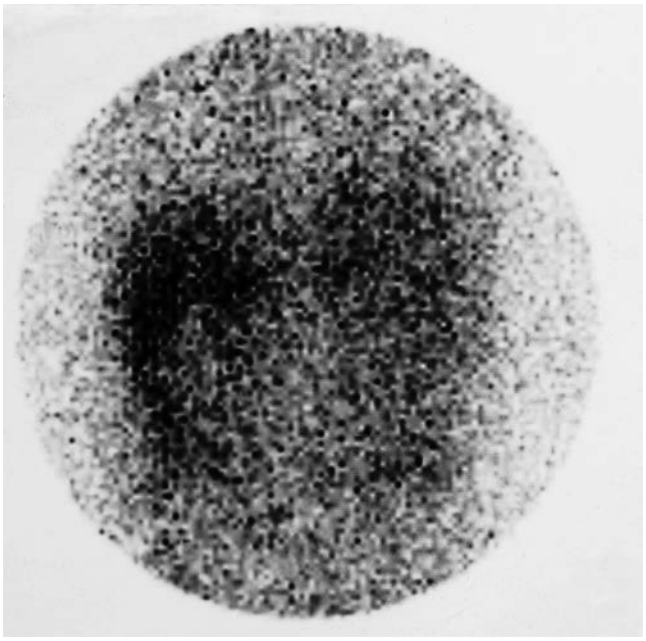

FIGURE 82.10 MIBG abdominal scan, with uptake of radionuclide in the left suprarenal area, in a 16-year-old with pheochromocytoma.

of the enzyme that produces the telomeres. Recent retrospective molecular analysis of pheochromocytoma tumors known to be benign or malignant reveals that telomerase, the RNA polymerase enzyme responsible for the production of telomeres, shows increased activity exclusively in tumors known to be malignant.[67,68] Similarly, antibody-based approaches that detect proliferating cells are being used increasingly to describe the malignant phenotype in tumors. One such antibody, MIP-1, selectively recognizes cells engaged in the cell cycle (i.e., scheduled to undergo mitosis, but not necessarily in the process of mitosis). Its predictability was explored in a survey of pheochromocytomas in which malignancy was confirmed by the existence of metastases. A positive MIB-1 labeling index (defined as >3% of tumor cells staining positive for MIB-1 vs. the total number of cells counted) showed a specificity of 100% (benign tumors stained negative) and sensitivity of 50% (half of the malignant tumors stained positive).[69] Although sensitivity was poor, the ability to define benign disease accurately in this manner would be clinically reassuring.

Therapy

The historic importance of pheochromocytomas with respect to surgery is not the technical nature of their excision, but the associated anesthetic risks. These relate to the potential for drastic changes in the excretion of catecholamines upon manipulation and subsequent removal of the tumor. The challenges revolve around stabilization of blood pressure intraoperatively and the prevention of potential cardiovascular collapse at the time of tumor removal or ligation of the veins delivering catecholamines to the systemic circulation. In infants, particularly in the preoperative state, these risks pose a great concern. In view

of the high specificity and reduced invasiveness of modern serologic and radionuclide diagnostic methodologies, risk factors are reduced. As in adults, the mainstay of preoperative therapy includes blockade of α-adrenergic receptors (phenoxybenzamine) accompanied by adequate systemic volume repletion once the vasoconstrictive and volume-contracted state has been overcome. Cardiac β-blockade (propranolol) in every case to prevent reflex tachyarrythmias remains controversial but should at least be considered in selected cases. Clearly, preoperative pharmacologic management of affected children should be undertaken in collaboration with the pediatric endocrinologist and anesthesiologist. If adequate blockade and volume replacement are achieved preoperatively, manipulation of the tumor is usually not accompanied by large variations in blood pressure, and large additional volume requirements are usually not found necessary upon tumor removal.

Open surgical excision by the flank or posterior lumbotomy approach has been the classic means of treatment. However, Rutherford et al.[70] have published an excellent review of the laparoscopic experience of excision of these tumors. They noted that patients treated laparoscopically have a significant reduction in recovery time, as well as a low complication rate. It may well be that this will become the most widely accepted method of surgical excision.

SACROCOCCYGEAL TERATOMA

SCT is the most common neoplasm in the newborn, and one of the first tumors successfully excised surgically.[71] Virchow coined the term *teratoma*, referring to a coccygeal growth with diverse anatomic characteristics. The tumors originate from all three embryologic tissues: ectoderm, mesoderm, and endoderm. Although they have provoked great interest because of their occurrence early in life and their dramatic appearance at birth, they have achieved even more current interest because of the facility and frequency with which they can be diagnosed by antenatal ultrasonography.[72–77] The appearance and character of the tumors are highly variable since they may be internal or external. SCTs have no known etiology. They are usually benign, but may undergo malignant degeneration.

Pathology

A teratoma is a neoplasm composed of multiple tissues that are foreign to the area in which it arises. Teratomas are grouped into those benign lesions with mature tissue (70%), those having malignant anaplastic elements (20%), and a third, embryonic group (10%), which may contain histologically immature-appearing benign tissue that does not progress to mature organ formation.[78] This latter group carries a generally favorable prognosis following total excision. In the benign varieties, elements such as skin, teeth, central nervous system (CNS) tissue, cartilage, bone, and respiratory and alimentary mucosa may be seen.

Infants diagnosed with SCT at greater than 1 year of age, as well as older children, are more likely to have malignant elements. To detect these elements, the pathologist must undertake an extensive search through all the varied elements within the tumor. The term *yolk sac* or endodermal sinus tumor is the name appropriately used for the malignant elements in such tumors. These tissues represent a separate element of the teratomatous cell line. Elevated serum levels of α-fetoprotein may be seen in these cases.

Clinical Features and Presentation

The traditional mode of presentation of these tumors has been discovery at birth. In most developed countries where antenatal sonography is now either mandatory or prevalent, they are discovered by antenatal sonography.[73–77] A recent review[79] of antenatally diagnosed SCTs demonstrated a high incidence of *in utero* mortality (19%) coupled with a perinatal mortality of 14%. The incidence of premature labor in this series was 50%. Thus, although the pathology of SCT is often benign, the overall outcome is associated with considerable morbidity and mortality. Those clinical features in the antenatal state that correlated with a poorer prognosis included polyhydramnios (an early sign of fetal distress and predictor of placental megaly-hydrops fetalis), tumor hypervascularity or the presence of a solid tumor (a risk factor for both malignancy and vascular steal syndrome), large tumor size at delivery (>10 cm in its greatest dimension), and a fast rate of tumor growth relative to cranial growth.

A solid tumor is the most ominous predictor of poor outcome. A fetus with a solid tumor has a mortality rate of 66% compared with a mortality of 11% for cystic or mixed tumors. Thus, mothers carrying a fetal diagnosis of SCT at the time of clinical obstetric presentation are definitely at risk for prenatal and perinatal complications. The presence of polyhydramnios appears to be a relative predictor or warning sign of premature labor.

There is a 5%–25% association with other congenital anomalies in infants with benign SCT. Seventy-five percent of the infants are female, harboring primarily benign tumors. The sex distribution is more evenly distributed between males and females in those whose tumors develop malignant degeneration.

Classification

The classification of SCT was proposed in 1974 by Altman and includes type 1, totally external; type 2, primarily external with an internal component; type 3, almost completely internal; and type 4, totally internal (Figure 82.11).[80]

Today, since most SCTs may well be diagnosed in the antenatal state following obstetric ultrasonography, an improved prognosis may be anticipated following delivery by cesarean section. The latter is advised as an initial attempt to decrease perinatal mortality and morbidity. The major early cause for morbidity relates to tumor rupture, for which cesarean section is the best prophylaxis. In Altman's classification, large tumors were defined as being greater than 10 cm, and these appear to be associated with greater morbidity.

When not diagnosed prior to birth, external tumors are found at delivery. Internal tumors may present as an abdominal mass, with the diagnosis of SCT noted by neonatal ultrasonography.

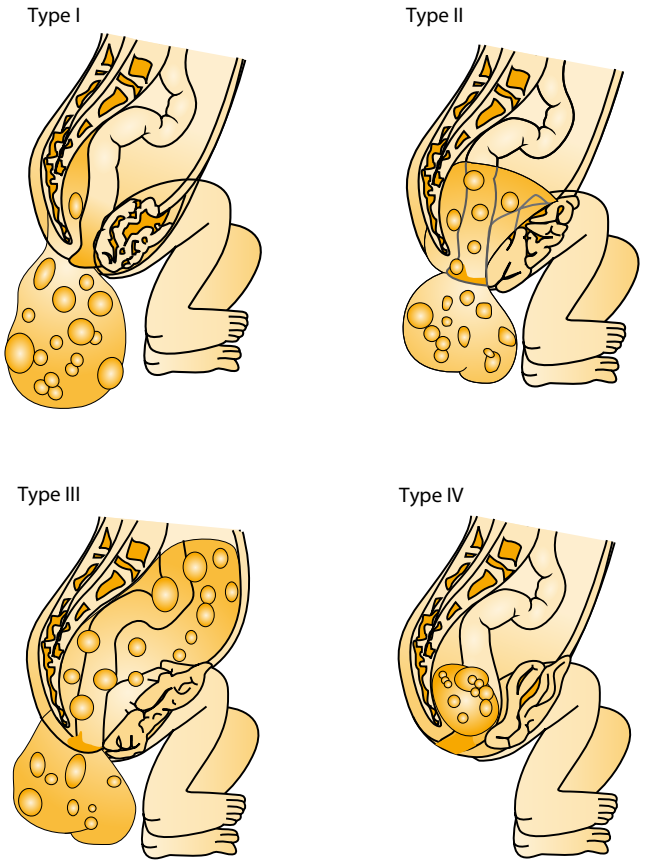

FIGURE 82.11 Classification of SCTs. Type I: Tumors are predominantly external (sacrococcygeal) with only a minimal presacral component. Type II: Tumors present externally but with a significant intrapelvic extension. Type III: Tumors are apparent externally, but the predominant mass is pelvic and extends into the abdomen. Type IV: Tumors are presacral with no external presentation. (From Altman RP et al. *J Pediatr Surg* 1973;9:389. With permission.)

Laboratory

Tumors that undergo malignant degeneration may produce α-fetoprotein and/or β-human chorionic gonadotropin (β-hCG). These proteins are indicators of malignant degeneration in the dermal sinus or choriocarcinomatous components of the tumor.[71,81]

Imaging

Imaging studies for complete assessment include CT and MRI. Radiographic detection of calcification does not distinguish between benign and malignant tumors (Figures 82.12 and 82.13).

Treatment

With the increasing availability of antenatal diagnosis, the question of antenatal intervention has had a logical appeal. Other forms of intrauterine therapy, such as intrauterine transfusion and decompression of a dilated urinary tract, have been successful as early as 16 weeks' gestational age. However, large or completely external SCTs have not yet been uniformly successfully approached surgically.[82,83] It has been speculated that ligating the blood supply to the tumor prenatally may be effective in decreasing its size and/or controlling the hyperdynamic state in the perinatal period.[84,85] In spite of the attractive apparent potential for intrauterine treatment, no success has been seen in antenatal treatment or antenatal surgical excision.

Postnatal therapy of SCT is primarily surgical. Devascularization of the tumor may be of benefit; however, this is best applied as the first intraoperative component of surgical removal.[84,85] Complete surgical excision should be the rule, with *en bloc* removal of the involved portion of the coccyx.

The two clinical groups of presentation include those that appear early in the neonatal period with large, benign tumors, and those that appear later (>1 year of age),

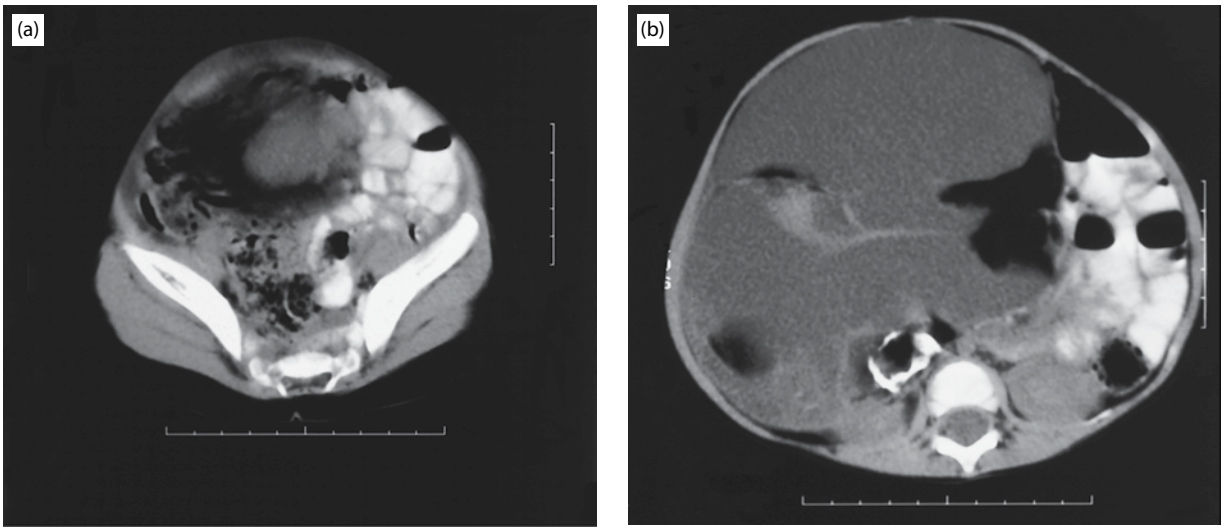

FIGURE 82.12 CT images of cystic teratoma in a 6-month-old child, arising from the pelvis (a) and filling the abdomen (b).

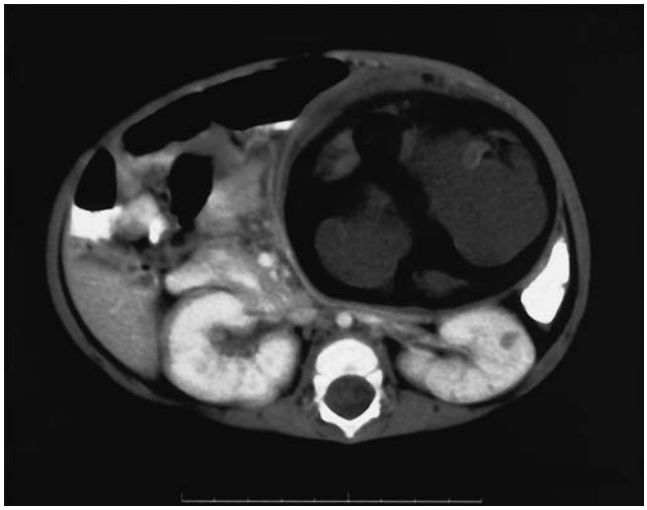

FIGURE 82.13 CT image of a more solid teratoma filling the central abdomen in a 6-month-old child.

which are often smaller, fixed, and malignant. In the first group, total removal is the rule and is best achieved by a midline sacral or chevron incision. The coccyx should be removed in the process of excising the tumor. With the retroperitoneal extension of the teratoma, urinary, internal genital, and gastrointestinal organs may be displaced. They can usually be dissected free, with minimal injury to the viscera, and good access to the vascular supply of the tumor is usually afforded by this retroperitoneal approach. However, in more extensive cases, anterior abdominal exploration may be warranted. A generous surgical exposure to obtain control of the presacral vessels is recommended. Avulsion of the vessels is a hazard to be avoided. In some rare instances, SCT may involve the dura or extend to the spine. This potential extension can be defined by meticulous preoperative imaging.[86–88] An inadvertent entry into the dura may result in a cerebrospinal fluid leak, which is associated with a higher morbidity. Modern imaging techniques, particularly MRI, will allow a much more achievable definition of these potential extensions to the CNS.

The second group of patient presentation is represented by those children in whom tumors present at an age beyond 1 year. These tumors are generally symptomatic, fixed, and firm. Diagnosis is established by ultrasound and/or physical examination and confirmed by CT or MRI. These tumors are often of a malignant variety, and serum α-fetoprotein is a sensitive marker. The appropriate surgical approach is initially directed at biopsy, followed by either multiagent chemotherapy or radiotherapy, in an attempt to decrease the size of the tumor, followed by surgical removal.

Results of Therapy

There are only rare reports of success in therapy in the antenatal stage.[83] In postnatal excisions, those undertaken in infancy for both external and internal SCT are remarkably successful in achieving complete removal of tumors with relatively little long-term morbidity.[89,90,91] Incontinence is rare. However, in those cases where high sacrococcygeal extension is present, necessitating transabdominopelvic excision, long-term fecal soiling and incontinence may be more prevalent. These sequelae may be related to more direct injury of skeletal muscular components or to some more occult neurogenic impairment of the viscera.[92] These sequelae may also be seen in the newborns after the excision of large, benign tumors.

Malignant SCT is rare in children under 6 months of age, but beyond that, the incidence rises sharply.[93] Malignant tumors may invade adjacent tissues or may recur in up to 40% of cases. During the 1990s, chemotherapeutic regimes added considerably to the improved outcomes.[94–97]

Long-Term Follow-Up

A recent evaluation of long-term follow-up in children with SCT showed that mature teratomas may have a recurrence rate of up to 11%. Further treatment with surgical excision and combined chemotherapy resulted in an 85% cure rate.[98] On long-term follow-up, a 3% recurrence rate was noted for immature teratomas. They were detected by a rising α-fetoprotein level 6 months after the initial procedure. These responded well to local excision. Endodermal sinus tumors detected and treated initially with surgical excisions represented only 9% of the tumors presenting at birth, whereas they represented 27% of the patients presenting at an older age. With long-term follow-up, 89% are still alive in spite of the higher recurrence rate.

ADRENAL CARCINOMA

Adrenal carcinoma represents fewer than 0.0001% of neoplastic tumors in children. The most common presentation is abnormal virilization, occurring in two-thirds.[99] Symptoms consistent with Cushing's syndrome account for most of the remainder. Individual case reports have reported occasional aldosterone-secreting tumors. Given the widespread availability of ultrasound imaging technology, the most common presentation may now be that of an incidental finding on an abdominal ultrasound.

Adrenocortical tumors may also be a component of more global genetic malformations. These include children with congenital adrenal hyperplasia, multiple endocrine syndromes (MEN-1), and Beckwith–Wiedemann syndrome.

Clinical Presentation

Virilizing Adrenal Tumors

Of the functioning adrenal cortical tumors, virilizing forms account for two-thirds, usually occurring in children older than 2 years. The tumors produce dehydroepiandrosterone (DHA), a weak androgen but one that is converted to Δ-4-androstenedione and testosterone, which are more potent virilizing hormones. Boys with such tumors present with signs of precocious puberty. Girls respond with an increase in clitoral size, similar to that seen with congenital adrenal hyperplasia (Figure 82.14). Pubic and axillary hair may be seen in children of either gender.

FIGURE 82.14 Virilizing adrenal carcinoma in a 5-year-old girl. Note the clitoral hypertrophy and pubic hair. There is no posterior labial fusion, as would be seen in congenital adrenal hyperplasia.

Alternate causes of premature virilization in boys include interstitial cell tumors of the testis or a delayed manifestation of congenital adrenal hyperplasia. Clinical evaluation may give some clues toward distinguishing the underlying etiology. Unilateral or asymmetric testicular enlargement suggests a Leydig cell tumor. In patients with centrally stimulated precocious puberty, testicular enlargement is bilateral. With virilizing adrenal tumors, the testes are usually small.

The differential diagnosis in female children includes ovarian arrhenoblastoma and other rare tumors of the adrenal cortex.

Cushing's Syndrome

Approximately one-third of children with adrenocortical tumors have the stigmata of Cushing's syndrome. Carcinoma may be responsible in up to one-half, with the others having bilateral adrenal hyperplasia. A benign adenoma may rarely be seen. The clinical appearance is in response to the excessive production of cortisol. This leads to protein catabolism, increased gluconeogenesis, and the typical obesity associated with cortisol excess. The moon facies and truncal obesity (Figure 82.15) of Cushing's disease are generally obvious when they are present in infants.

The differential diagnosis in patients exhibiting excess adrenocortical activity includes adrenal adenomas and iatrogenic administration of steroids. This latter iatrogenic excess is commonly seen in children receiving transplanted organs.

Feminizing Adrenal Tumors

Feminizing adrenal tumors are rare. They occur more frequently in males, and in these cases, the more commonly seen primary gynecomastia must be excluded.

Diagnostic Evaluation

The critical diagnostic feature is the biochemical demonstration of adrenal hyperfunction. Urinary steroids typically show a markedly elevated 17-ketosteroid level. The free cortisol, DHA, and 17-hydroxysteroid levels may also be elevated.[100] Radioimmune assays of serum hormonal levels usually show elevation of DHA, Δ-4-androstenedione, testosterone, and cortisol.[101,102] Serum estrogen levels are elevated in the rare feminizing cases.[103] Occasionally, an elevated serum aldosterone level can be demonstrated in cases of adrenocortical carcinoma.[104]

In Cushing's syndrome caused by adrenocortical carcinoma, the plasma cortisol level and urinary corticosteroids are markedly elevated above the levels typically seen with adrenal hyperplasia or an adrenal adenoma. A significant elevation in 17-ketosteroids, pregnanetriol, and estrogens may suggest carcinoma. The adrenocorticotropic hormone (ACTH) stimulation test produces no change in adrenocortical carcinomas, whereas those with adrenal hyperplasia show an exaggerated normal response. In exogenous obesity, which occasionally may enter the differential diagnosis, the ACTH test result is normal. When benign adenomas are present, the ACTH test exhibits a subnormal response. Metyrapone blocks 11-hydroxylation in the adrenal cortex and leads to a fall in cortisol level with an increase in endogenous ACTH. Thus, a test with metyrapone produces results similar to those produced by the ACTH test. The diurnal variation usually seen in normal cortisol levels is absent with both tumors and adrenal hyperplasia. Dexamethasone blocks ACTH release in normal patients. The dexamethasone suppression test is useful to separate adrenal hyperplasia from tumors in that a large dose (8 mg) typically suppresses hyperplasia but not a tumor (Table 82.5).[105,106]

Modern diagnostic imaging has led to the greatest advances over the past decade. (See the "Imaging Techniques" section under "Neuroblastoma.") In addition to the ultrasound findings, MRI scanning has led to tremendous advances in the ability to distinguish adrenal carcinoma from benign adenomas.[107,108]

Treatment

Treatment of adrenal cortical carcinoma is surgical. In children, open surgical removal may be accomplished by large, transverse abdominal incisions or, in some instances, by extended flank incisions. Laparoscopic removal is now widely used in adults, but the current lack of small instrumentation limits its use in children.[109] The advances in imaging allow more limited surgical approaches than may have been previously encountered. A tumor diameter of more than 5 cm is a reasonable predictor of malignancy, whereas small adenomas may be approached in a more limited manner. Preoperative care must recognize the need for corticosteroid replacement in cases where corticoid excess is anticipated.

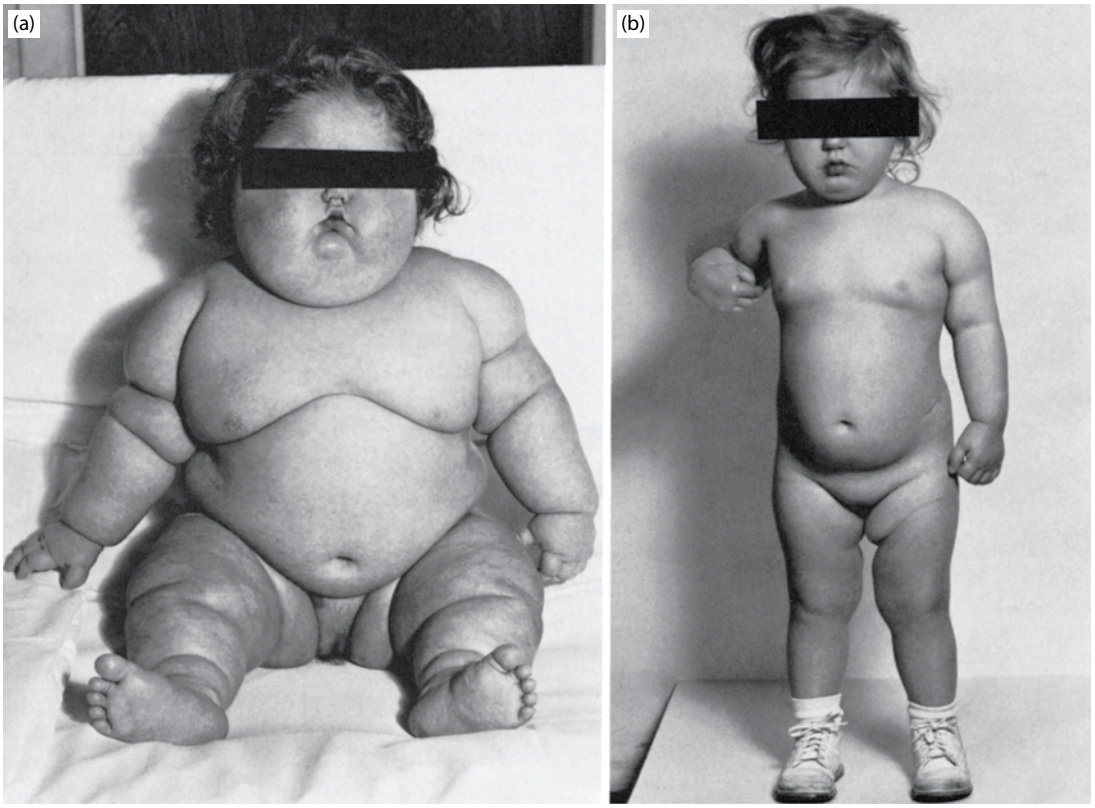

FIGURE 82.15 (a) Striking features of cortisol excess in a 17-month-old girl with adrenocortical carcinoma. In addition, pubic hair and mild enlargement of the clitoris were present. (b) At 10 months after removal of the adrenocortical carcinoma, there was complete regression of the signs of Cushing's syndrome.

The prognosis for adrenal carcinoma is poor. Surgery is the primary motive therapy, and chemotherapy has not been effective in controlling widespread disease.

LYMPHANGIOMAS

Lymphangiomas are benign tumors composed of a mass of anastomosing lymphatic channels. These are rare and most commonly affect the extremities. Most are congenital and may not become evident until a few years of age. When in the retroperitoneum, they are found by the evaluation of abdominal pain, which may be caused by the onset of spontaneous hemorrhage into the mass. However, they may extend through the inguinal canal and present with the misdiagnosis of hernia. Diagnosis is made on CT, at which time the low-density characteristic of lymphatic tissue is noted.

Surgical excision of the majority of the wall of the tumor is ideal, but may not be technically possible without causing significant damage to adjacent organs. Large cysts may be drained into the peritoneal cavity.

NEUROFIBROMA

Patients with neurofibromatosis (von Recklinghausen's disease) may present with abdominal neurofibromas similar to, but as a more benign variant of, ganglioneuromas. As

TABLE 82.5 Test results with various adrenocortical lesions

	Plasma cortisols		Dexamethasone test[a]			
Condition	**Concentration**	**Diurnal rhythm**	**Low-dose suppression**	**High-dose suppression**	**Metyrapone test response**	**Plasma ACTH**
Normal	Normal	Yes	Yes	Yes	Yes	Normal
Cushing's disease	High	No	No	Yes	Yes	Increases
Tumor	High	No	No	No	No	Decreases
Non-ACTH-dependent hyperplasia	High	No	No	No	No	Decreases
Ectopic ACTH syndrome	High	No	No	No	No	Increases

[a] Low dose = 0.22 mg/10 kg for 2 days; high dose = 0.84 mg/10 kg for 3 days.

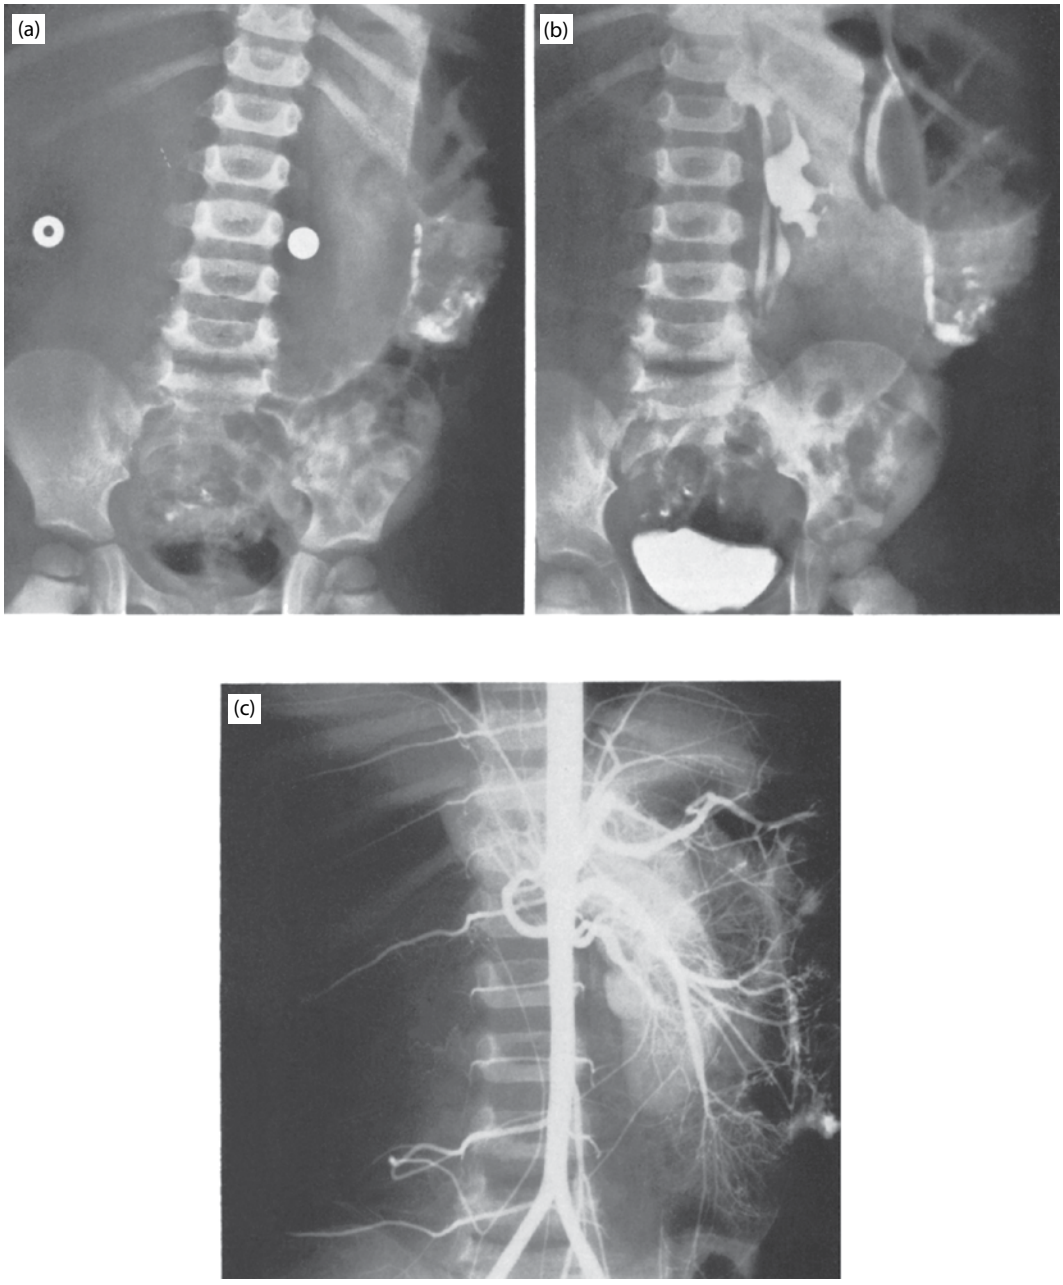

FIGURE 82.16 Retroperitoneal lipoma. (a) Abdominal film (kidney, ureter, and bladder) demonstrating a retroperitoneal mass obliterating the right psoas shadow and displacing the bowel to the left. (b) Excretory urogram showing the right kidney and ureter displaced across the midline to the left. Note the absence of hydronephrosis. (c) Aortogram shows displacement of the right renal artery. The right kidney is now superior to the left kidney. The absence of neovascularity suggests the benign nature of the tumor.

outlined in the previous section on benign ganglioneuromas, partial excision may be an appropriate surgical treatment.

LIPOMA

Retroperitoneal lipomas are usually benign, presenting as an abdominal mass in infants and young children (Figure 82.16). CT defines the characteristically low-density lesions. These are generally benign and well encapsulated. Local excision is the treatment of choice.

OTHER MALIGNANT RETROPERITONEAL TUMORS

Hodgkin's and non-Hodgkin's lymphomas may involve intra-abdominal viscera, including the urinary and gastrointestinal tracts. Lateral deviation of the ureters is the most common genitourinary feature; however, ureteral obstruction may be the primary presenting symptom. Ureteral catheterization may become necessary in advance of chemotherapy.

Liposarcoma

Liposarcoma is rare in children, being seen more often in the teenage years leading into young adulthood. If it is identified early, surgical excision may result in complete cure.

Fibrosarcoma

Fibrosarcoma may be difficult to distinguish from neurofibroma. These lesions also occur primarily in the extremities, although retroperitoneal sites may be seen.

CHAPTER 83

Tissue Engineering for Pediatric Urology

Steve J. Hodges and Anthony Atala

INTRODUCTION

Human organs are exposed to a variety of possible injuries from the time the fetus develops. Individuals may suffer from congenital disorders, cancer, trauma, infection, inflammation, iatrogenic injuries, or other conditions that may lead to organ damage or loss and necessitate eventual reconstruction or replacement. Whenever there is deficient organ function, replacement may be achieved with artificial organs or organ transplantation. These are flawed therapies, however, as artificial organs are not able to replace all physiologic functions and cannot fully integrate functionally into body systems, while organ transplantation is marred by donor shortages and immunologic rejection, and requires chronic and morbid medical therapy. In most cases, the replacement of lost or deficient tissues with functionally equivalent autologous tissues would improve the outcome for patients immensely. Tissue engineering therapies have been developed in order to achieve this goal.

The development of functional organ systems from the building blocks of cells, scaffolding, and growth factors is a Herculean task, however, as evidenced by the few successful tissue engineering technologies currently in clinical use. There have been successes, though, as seen by functioning autologous bioengineered tissues that have been implanted in humans—including trachea, blood vessels, pulmonary valves, endothelialized vascular stents, and urinary bladder.[1] An examination of the building blocks of tissue engineering strategies, as well the successful applications of these techniques in human clinical applications, provides an insight into the difficulties facing scientists as they seek to develop more complex bioengineered organs.

TISSUE ENGINEERING: STRATEGIES FOR TISSUE RECONSTITUTION

The field of regenerative medicine encompasses various areas of technology, such as tissue engineering, stem cells, and cloning. One of the major components of regenerative medicine, tissue engineering, follows the principles of cell transplantation, materials science, and engineering toward the development of biological substitutes that can restore and maintain normal function. Tissue engineering strategies generally fall into three categories: the use of acellular matrices (where matrices are used alone and which depend on the body's natural ability to regenerate for proper orientation and direction of new tissue growth), the use of simple cells, and the use of matrices combined with cells. The main obstacles that must be overcome for the clinical application of these strategies are localizing reliable, immunocompatible cell sources; developing biocompatible and functional scaffolding; and providing growth factors and vascularization for bioengineered organs.

Acellular tissue matrices are usually prepared by manufacturing artificial scaffolds, or by removing cellular components from tissues via mechanical and chemical manipulation to produce collagen-rich matrices.[2–5] These matrices tend to slowly degrade on implantation and are generally replaced by the extracellular matrix (ECM) proteins that are secreted by the ingrowing cells. Cells can be used in combination with scaffolds or injected as simple cell therapy, either with carriers (such as hydrogels) or alone.[6]

CELL SOURCES

When cells are used for tissue engineering, a small piece of donor tissue must be harvested and dissociated into individual cells. These cells are either implanted directly into the host or expanded in culture, attached to a support matrix, and then reimplanted into the host after expansion. The source of donor tissue can be heterologous (such as bovine), allogeneic (same species, different individual), or autologous. Ideally, both structural and functional tissue replacement will occur with minimal complications. The most preferred cells to use are autologous cells, where a biopsy of tissue is obtained from the host, the cells are dissociated and expanded in culture, and the expanded cells are implanted into the same host.[4,7–18] The use of autologous cells, although it may cause an inflammatory response, avoids rejection, and thus the deleterious side effects of immunosuppressive medications can be avoided.

One of the limitations of applying cell-based regenerative medicine techniques toward organ replacement has been the inherent difficulty of growing specific cell types in large quantities. Even when some organs, such as the liver, have a high regenerative capacity in vivo, cell

growth and expansion in vitro may be difficult. By studying the privileged sites for committed precursor cells in specific organs, as well as exploring the conditions that promote differentiation, one may be able to overcome the obstacles that could lead to cell expansion in vitro. For example, urothelial cells could be grown in the laboratory setting in the past, but only with limited expansion. Several protocols were developed over the last two decades that identified the undifferentiated cells, and kept them undifferentiated during their growth phase.[9,19–21] Using these methods of cell culture, it is now possible to expand a urothelial strain from a single specimen that initially covers a surface area of 1 cm^2 to one covering a surface area of 4202 m^2 (the equivalent area of one football field) within 8 weeks.[9] These studies indicated that it should be possible to collect autologous bladder cells from human patients, expand them in culture, and return them to the human donor in sufficient quantities for reconstructive purposes.[9,19,22–26] Major advances have been achieved within the last decade on the possible expansion of a variety of primary human cells, with specific techniques that make the use of autologous cells possible for clinical application.

A recent discovery may well influence cell sourcing for regenerative medicine strategies. A new type of interstitial cell, termed telocytes, has been isolated, and these cells have been found to be crucial to the process of evolution of progenitor cells toward mature development. Their architecture (tracks for migrations) and paracrine secretions (including microRNA) provide the environment for progenitor cell maturation. These cells have been found in many organs, including myocardium, and have been demonstrated to be crucial to neoangiogenesis following myocardial ischemia. These cells and their signals may hold clues to creating more appropriate milieus for precursor cell development and angiogenesis.[27]

An area of concern in the field of tissue engineering in the past was the source of cells for regeneration. The concept of creating engineered constructs involves initially obtaining cells for expansion from the diseased organ. A study recently showed that cultured neuropathic bladder smooth muscle cells possess and maintain different characteristics than normal smooth muscle cells in vitro, as demonstrated by growth assays, contractility, and adherence tests in vitro.[28] *However, when neuropathic smooth muscle cells were cultured in vitro, and seeded onto matrices and implanted in vivo, the tissue-engineered constructs showed the same properties as the tissues engineered with normal cells.*[29] It is known that genetically normal progenitor cells, which are the reservoirs for new cell formation, are programmed to give rise to normal tissue, regardless of whether the niche resides in either normal or diseased tissues. The stem cell niche and its role in normal tissue regeneration remains a fertile area of ongoing investigation.

In circumstances where source cell gene expression may be pathologically altered, gene-modifying techniques have been aggressively explored—including epigenetic therapies and gene transfer techniques (using viral vectors or polymer-based gene delivery). Although the precise control of new gene expression remains complex, the use of gene delivery in combination with varying cell populations may expand the cell sources available for regeneration.[27]

ALTERNATE CELL SOURCES

Stem Cells

Most current strategies for tissue engineering depend on a sample of autologous cells from the diseased organ of the host. However, for many patients with extensive end-stage organ failure, a tissue biopsy may not yield enough normal cells for expansion and transplantation. In other instances, primary autologous human cells cannot be expanded from a particular organ, such as the pancreas. In these situations, pluripotent human embryonic stem cells are envisioned as a viable source of cells, as they can serve as an alternative source of cells from which the desired tissue can be derived.[30]

Human embryonic stem cells exhibit two remarkable properties: the ability to proliferate in an undifferentiated, but pluripotent state (self-renew), and the ability to differentiate into many specialized cell types.[31] They can be isolated by immunosurgery from the inner cell mass of the embryo during the blastocyst stage (5 days postfertilization), and are usually grown on feeder layers consisting of mouse embryonic fibroblasts or human feeder cells.[32] More recent reports have shown that these cells can be grown without the use of a feeder layer,[33] and thus avoid the exposure of these human cells to mouse viruses and proteins. These cells have demonstrated longevity in culture by maintaining their undifferentiated state for at least 80 passages when grown using current published protocols.[34,35]

Human embryonic stem cells have been shown to differentiate into cells from all three embryonic germ layers in vitro. Skin and neurons have been formed, indicating ectodermal differentiation.[36–38] Blood, cardiac cells, cartilage, endothelial cells, and muscle have been formed, indicating mesodermal differentiation.[39–41] And pancreatic cells have been formed, indicating endodermal differentiation.[42] In addition, as further evidence of their pluripotency, embryonic stem cells can form embryoid bodies, which are cell aggregations that contain all three embryonic germ layers, while in culture, and can form teratomas in vivo.[43]

Adult stem cells have the advantage of avoiding the ethical issues associated with embryonic cells, and also, they do not transdifferentiate spontaneously to a malignant phenotype. The use of adult stem cells is limited for clinical therapy due to the difficulties encountered with cell expansion to large quantities.

Fetal stem cells derived from amniotic fluid and placentas have been recently described and represent a novel source of stem cells. The cells express markers consistent with human embryonic stem cells, such as OCT4 and SSEA-4, but do not form teratomas, and do not spontaneously transdifferentiate to a malignant phenotype. The cells are multipotent and are able to differentiate into all three germ layers. In addition, the cells have a high replicative potential and could be stored for future self-use, without the risks of rejection, and without ethical concerns.[44]

THERAPEUTIC CLONING

While there has been tremendous interest in the field of nuclear cloning since the birth of Dolly in 1997, the first successful nuclear transfer was reported more than 50 years ago by Briggs and King.[45] Cloned frogs,[45] which were the first vertebrates derived from nuclear transfer, were subsequently reported by Gurdon in 1962,[46] but the nuclei were derived from nonadult sources. In the past several years, tremendous advances in nuclear cloning technology have been reported, indicating the relative immaturity of the field. Dolly was not the first cloned mammal to be produced from adult cells; in fact, live lambs were produced in 1996 using nuclear transfer and differentiated epithelial cells derived from embryonic discs.[47] The significance of Dolly was that she was the first mammal to be derived from an adult somatic cell using nuclear transfer.[48] Since then, animals from several species have been grown using nuclear transfer technology, including cattle,[49] goats,[50,51] mice,[52] and pigs.[53]

Two types of nuclear cloning, reproductive cloning and therapeutic cloning, have been described, and a better understanding of the differences between the two types may help to alleviate some of the controversy that surrounds these technologies. Banned in most countries for human applications, reproductive cloning is used to generate an embryo that has genetic material identical to that of its cell source. This embryo can then be implanted into the uterus of a female to give rise to an infant that is a clone of the donor. On the other hand, therapeutic cloning is used to generate early-stage embryos that are explanted in culture to produce embryonic stem cell lines whose genetic material is identical to that of its source. These autologous stem cells have the potential to become almost any type of cell in the adult body, and thus would be useful in tissue and organ replacement applications.[54] Therefore, therapeutic cloning, which has also been called somatic cell nuclear transfer, may provide an alternative source of transplantable cells. According to data from the Centers for Disease Control, it has been estimated that approximately 3000 Americans die every day of diseases that could have been treated with stem cell–derived tissues.[34] With current allogeneic tissue transplantation protocols, rejection is a frequent complication because of immunologic incompatibility, and immunosuppressive drugs are usually administered to treat and hopefully prevent host versus graft disease.[55] The use of transplantable tissue and organs derived from therapeutic cloning may potentially lead to the avoidance of immune responses that typically are associated with transplantation of nonautologous tissues.[44]

While promising, somatic cell nuclear transfer technology has certain limitations that require further improvements before therapeutic cloning can be widely applied in replacement therapy. Currently, the efficiency of the overall cloning process is low. The majority of embryos derived from animal cloning do not survive after implantation.[56–58] In practical terms, multiple nuclear transfers must be performed in order to produce one live offspring for animal cloning applications. The potential for cloned embryos to grow into live offspring is between 0.5% and 18% for sheep, bovine, pigs, and mice.[59] However, greater success (80%) has been reported in cattle,[60] which may be in part due to the availability of advanced bovine supporting technologies, such as in vitro embryo production and embryo transfer, which have been developed for this species for agricultural purposes. To improve cloning efficiencies, further improvements are required in the multiple complex steps of nuclear transfer, such as enucleation and reconstruction, activation of oocytes, and cell cycle synchronization between donor cells and recipient oocytes, that will more readily produce viable sources of cells.

Furthermore, common abnormalities have been found in newborn clones if they survive to birth, including enlarged size with an enlarged placenta ("large-offspring syndrome");[61] respiratory distress; defects of the kidney, liver, heart, and brain;[62] obesity;[63] and premature death.[64] *These may be related to the epigenetics of the cloned cells, which involve the reversible modifications of the DNA or chromatin, while the original DNA (genetic) sequences remain intact.* Faulty epigenetic reprogramming in clones, where the DNA methylation patterns, histone modifications, and overall chromatin structure of the somatic nuclei are not being reprogrammed to an embryonic pattern of expression, may explain the above abnormalities.[54] Reactivation of key embryonic genes at the blastocyst stage is usually not present in embryos cloned from somatic cells, while embryos cloned from embryos consistently express early embryonic genes.[65,66] Proper epigenetic reprogramming to an embryonic state may help to improve the cloning efficiency and reduce the incidence of abnormal cloned cells.

BIOMATERIALS

For cell-based tissue engineering, once cells have been cultured and expanded, they are seeded onto a scaffold synthesized using the appropriate biomaterial. In tissue engineering, biomaterials replicate the biologic and mechanical function of the native ECM found in tissues in the body by serving as an artificial ECM. As a result, biomaterials provide a three-dimensional space for the cells to form into new tissues with appropriate structure and function, and also can allow for the delivery of cells and appropriate bioactive factors (e.g., cell adhesion peptides and growth factors) to desired sites in the body.[67] As the majority of mammalian cell types are anchorage dependent and will die if no cell adhesion substrate is available, biomaterials provide a cell adhesion substrate that can deliver cells to specific sites in the body with high loading efficiency. Biomaterials can also provide mechanical support against in vivo forces such that the predefined three-dimensional structure is maintained during tissue development. Furthermore, bioactive signals, such as cell adhesion peptides and growth factors, can be loaded along with cells to help regulate cellular function.

The ideal biomaterial should be biocompatible in that it is biodegradable and bioresorbable to support the replacement of normal tissue without inflammation. Incompatible materials are destined for an inflammatory or foreign body response that eventually leads to rejection

and/or necrosis. In addition, the degradation products, if produced, should be removed from the body via metabolic pathways at an adequate rate that keeps the concentration of these degradation products in the tissues at a tolerable level.[68] Furthermore, the biomaterial should provide an environment in which appropriate regulation of cell behavior (e.g., adhesion, proliferation, migration, and differentiation) can occur such that functional tissue can form. Cell behavior in the newly formed tissue has been shown to be regulated by multiple interactions of the cells with their microenvironment, including interactions with cell adhesion ligands[69] and with soluble growth factors. In addition, biomaterials provide temporary mechanical support that allows the tissue to grow in three dimensions while the cells undergo spatial tissue reorganization. The properly chosen biomaterial should allow the engineered tissue to maintain sufficient mechanical integrity to support itself in early development, while in late development, the properly chosen biomaterial should have begun degradation such that it does not hinder further tissue growth.[67]

Generally, three classes of biomaterials have been utilized for engineering tissues: naturally derived materials (e.g., collagen and alginate), acellular tissue matrices (e.g., bladder submucosa and small intestinal submucosa [SIS]), and synthetic polymers (e.g., polyglycolic acid [PGA], polylactic acid [PLA], and poly(lactic-co-glycolic acid) [PLGA]). These classes of biomaterials have been tested with respect to their biocompatibility.[70,71] Naturally derived materials and acellular tissue matrices have the potential advantage of biological recognition. However, synthetic polymers can be produced reproducibly on a large scale with controlled properties of their strength, degradation rate, and microstructure.

Collagen is the most abundant and ubiquitous structural protein in the body and may be readily purified from both animal and human tissues with an enzyme treatment and salt or acid extraction. Collagen implants degrade through a sequential attack by lysosomal enzymes. Controlling the density of the implant and the extent of intermolecular cross-linking can regulate the in vivo resorption rate. The lower the density, the greater the interstitial space and generally the larger the pores for cell infiltration, leading to a higher rate of implant degradation. Collagen contains cell adhesion domain sequences (e.g., RGD) that exhibit specific cellular interactions. This may assist in retaining the phenotype and activity of many types of cells, including fibroblasts[72] and chondrocytes.[73]

Alginate, a polysaccharide isolated from seaweed, has been used as an injectable cell delivery vehicle[74] and a cell immobilization matrix[75] owing to its gentle gelling properties in the presence of divalent ions, such as calcium. Alginate is relatively biocompatible and approved by the Food and Drug Administration (FDA) for human use as wound dressing material. Alginate is a family of copolymers of D-mannuronate and L-guluronate. The physical and mechanical properties of alginate gel are strongly correlated with the proportion and length of polyguluronate block in the alginate chains.[74]

Acellular tissue matrices are collagen-rich matrices prepared by removing cellular components from tissues.[2–5] The matrices are often prepared by mechanical and chemical manipulation of a segment of tissue. The matrices slowly degrade upon implantation and are replaced and remodeled by ECM proteins synthesized and secreted by transplanted or ingrown cells.

Polyesters of naturally occurring α-hydroxy acids, including PGA, PLA, and PLGA, are widely used in tissue engineering. These polymers have gained FDA approval for human use in a variety of applications, including sutures. The ester bonds in these polymers are hydrolytically labile, and these polymers degrade by nonenzymatic hydrolysis. The degradation products of PGA, PLA, and PLGA are nontoxic, natural metabolites and are eventually eliminated from the body in the form of carbon dioxide and water. The degradation rate of these polymers can be tailored from several weeks to several years by altering crystallinity, initial molecular weight, and the copolymer ratio of lactic to glycolic acid. Since these polymers are thermoplastics, they can be easily formed into a three-dimensional scaffold with a desired microstructure, gross shape, and dimension by various techniques, including molding, extrusion,[76] solvent casting, phase separation techniques, and gas foaming techniques.[77] Many applications in tissue engineering often require a scaffold with a high porosity and ratio of surface area to volume. Other biodegradable synthetic polymers, including poly(anhydrides) and poly(ortho-esters), can also be used to fabricate scaffolds for tissue engineering with controlled properties.[78]

A recently developed polymer, polyhedral oligomeric silsesquioxane/poly(carbonateurea) urethane (POSS-PCU), is a highly biocompatible nanocomposite that has demonstrated many of the ideal characteristics for tissue engineering numerous implants.[1]

Other advances in biomaterial engineering include the development of conducting polymers that may find roles in neural tissue engineering, and ionic polymer metal composites that can induce movement with appropriate stimulation, and therefore may serve roles in the development of artificial muscles or dynamic sensors.[1]

GROWTH FACTORS

A key component to scaffold function is the presence of the appropriate growth factors for cell growth and maturation. Growth factors may be produced by cells themselves (autocrine) or the surrounding environment (paracrine). Scientists have employed various strategies to enhance desirable growth factor production, in order to promote the cell growth and maturation needed for particular organ systems. Some investigators have attempted to influence cell growth factor production with gene therapy, by incorporating genes for growth factor transcription in the transplanted cells. Others have sought to simply inject the growth factors into the cells' milieu, but this method often results in rapid dissipation of the agents due to diffusion.[79]

A novel method of growth factor use in tissue engineering involves the incorporation of growth factors into carriers or cell scaffolds. The goals of these techniques are to provide localized and controlled release of the growth factors necessary for cell development. Extensive research is underway to define the exact combination of growth

factors needed for specific organ growth and maturation, with an emphasis on the use of these factors to induce more rapid cell development and differentiation, appropriate cell function and orientation, and ECM development and vascularization.[80]

In addition to the influence of growth factors, the simple topography of a scaffold has been demonstrated to greatly affect cell growth. For example, the shape of grooves in scaffolds can influence cell proliferation and cell alignment, and assist in cell differentiation.[1]

VASCULARIZATION

One of the restrictions of the engineering of tissues is that cells cannot be implanted in volumes exceeding 3 mm^3 because of the limitations of nutrition and gas exchange.[81] To achieve the goals of engineering large complex tissues, and possibly internal organs, vascularization of the regenerating cells is essential.

Three approaches have been used for vascularization of bioengineered tissue: (1) incorporation of angiogenic factors in the bioengineered tissue, (2) seeding ECM with other cell types in the bioengineered tissue, and (3) prevascularization of the matrix prior to cell seeding. Angiogenic growth factors may be incorporated into the bioengineered tissue prior to implantation, in order to attract host capillaries and enhance neovascularization of the implanted tissue. There are many obstacles to overcome before large entire tissue-engineered solid organs are produced. Recent developments in angiogenesis research may provide important knowledge and essential materials to accomplish this goal.

The modern strategies of neo-organ vascularization have investigated the aforementioned use of growth factors and cytokines such as vascular endothelial growth factor (VEGF), progenitor cells, biomaterials, or fabricated vessel conduits, or combinations of those techniques. Because tissue engineering is often required in the setting of severe tissue damage (such as following radiation for tumor therapy) and immediate oxygenation of a large construct may be needed (where neoangiogenesis may not be possible or rapid enough), the in vivo creation of arteriovenous loops has been favored, and the most efficacious vascularization of solid organs has been found to be accomplished with the anastomosis of prevascularized constructs in combination with the local and controlled release of angiogenic growth factors.[27]

CLINICAL APPLICATIONS

The assimilation of all these complex technologies into functional bioengineered organs is a complex task. By examining the early attempts at the application of tissue engineering for clinical use, the difficulties and challenges facing scientists in the future are more clearly delineated. The application of bioengineered organs for human use has been addressed in a logical fashion, beginning with the simplest organ systems (e.g., skin) and extending to hollow organs (e.g., bladder) and finally complex solid organs (e.g., kidneys).

Urethra

Different approaches have been suggested for the regeneration of urethral tissue. Woven PGA (Dexon®) meshes without cells have been used to reconstruct the urethra in dogs.[82,83] Furthermore, PGA has been used as a cell carrier to engineer tubular urothelium in vivo. SIS without cells and a homologous free graft of acellular urethral matrix were used as grafts for urethroplasty in rabbit models.[84,85]

Bladder-derived acellular collagen matrix has proven to be a suitable graft for repair of urethral defects, and the created neourethras showed normal urothelial lining and organized muscle bundles in the rabbit model.[5] The above results were confirmed clinically in a series of patients with a history of failed hypospadias repair wherein the urethral defects were repaired with human bladder acellular collagen matrices.[86]

The described techniques, using nonseeded acellular matrices, were applied experimentally and clinically in a successful manner for onlay urethral repairs. However, when tubularized urethral repairs were attempted experimentally, adequate functional urethral tissue regeneration was not achieved, and complications, predominantly graft contracture and stricture formation, were noticed). On the contrary, seeded tubularized collagen matrices have performed better in animal studies. In a rabbit model, urethroplasty was performed with tubularized collagen matrices seeded either with cells or without cells. The matrices seeded with autologous cells formed new tissue, which was histologically comparable to that of native urethra. The tubularized collagen matrices without cells, however, led to limited tissue development, fibrosis, and stricture formation. These findings were also confirmed clinically.[87]

Bladder

Currently, gastrointestinal segments are commonly used as tissues for bladder replacement or repair.[88,89] Because of the problems encountered with the use of gastrointestinal segments, numerous investigators have attempted alternative reconstructive procedures for bladder replacement or repair, such as the use of tissue expansion, seromuscular grafts, matrices for tissue regeneration, and tissue engineering with cell transplantation.[88]

Cell-seeded allogeneic acellular bladder matrices are one of the few strategies of bioengineered bladder replacement with human clinical applications. The early work with this technology was performed in dogs, where a group of experimental canines underwent a trigone-sparing cystectomy with closure of the trigone without a reconstructive procedure, or reconstruction with a nonseeded bladder-shaped biodegradable scaffold, or reconstruction using a bladder-shaped biodegradable scaffold that delivered seeded autologous urothelial cells and smooth muscle cells.[16]

The results were promising, with the cystectomy-only and nonseeded controls demonstrating decreased capacities and compliance compared with the preoperative values, while the cell-seeded tissue-engineered bladders showed increased capacity and compliance, with histology

depicting normal cellular organization, consisting of a trilayer of urothelium, submucosa, and muscle.[16]

Preliminary clinical trials for the application of this technology have been performed and have had promising results. Recently published data demonstrated that engineered autologous bladder tissue may be used to safely augment the bladder in children with end-stage bladder disease secondary to myelomeningocele.[90] In this study, seven patients, aged 4–19, with high pressure or poorly compliant bladders were selected as candidates for autologous augmentation cystoplasty. Bladder biopsies were obtained from each patient, and smooth muscle and urothelial cells were cultured, expanded, and seeded on composite scaffolds. Approximately 7 weeks after the biopsy, the autologously generated neobladders were used for bladder reconstruction with or without omental wrapping. At a mean follow-up of 46 months, the increase in bladder volume and compliance was greatest in the engineered bladders coated in the omental wrap. Bowel function returned promptly after surgery; there were no metabolic complications, stone formation, or mucous production; and renal function was preserved. In addition, engineered bladder biopsies demonstrated normal structural architecture and phenotype. Thus, this study provided good evidence in support of the use of engineered bladder tissue (created with autologous cells seeded on a composite scaffold, and wrapped in omentum following implantation), for patients in need of cystoplasty.

Ureter

Ureteral nonseeded matrices have been used as scaffolds for the growth of ureteral tissue in rats. The acellular matrices promoted the regeneration of the ureteral wall components.[91] Ureteral replacement with polytetrafluoroethylene (Teflon) grafts in dogs resulted in poor functional results.[92] Nonseeded ureteral collagen acellular matrices were tubularized and used to replace segments of canine ureters. The nonseeded acellular matrix tube was not able to successfully replace the resected segment of the ureter.[93]

Cell-seeded biodegradable polymer scaffolds have proved to be more successful in reconstruction of ureteral tissues. In one study, urothelial and smooth muscle cells isolated from bladders and expanded in vitro were seeded onto tubular PGA scaffolds and thereafter implanted subcutaneously into athymic mice. The urothelial cells proliferated to form a multilayered luminal lining, while the smooth muscle cells organized into multilayered structures surrounding the urothelial cells and pronounced angiogenesis was observed. The degradation of the polymer scaffolds resulted in formation of natural urothelial tissues. This approach was also used to replace ureters in dogs by transplantation of smooth muscle and urothelial cells on tubular polymeric scaffolds.[94]

Kidney

Solid organs are the most challenging to reconstruct by tissue engineering techniques because of their complex structure and function. Due to these complexities, some scientists approach the replacement of solid organ function, such as liver or kidney, with bioartificial approaches, combining the function of the organ's predominant cells with an artificial structure and organization.

An example of this strategy is extracorporeal renal replacement. Although dialysis is currently the most prevalent form of renal replacement therapy, the relatively high morbidity and mortality have spurred investigators to seek alternative solutions involving ex vivo systems. In an attempt to assess the viability and physiologic functionality of a cell-seeded device to replace the filtration, transport, metabolic, and endocrinologic functions of the kidney in acutely uremic dogs, a combination of a synthetic hemofiltration device and a renal tubular cell therapy device containing porcine renal tubules in an extracorporeal perfusion circuit was introduced. It was shown that levels of potassium and blood urea nitrogen (BUN) were controlled during treatment with the device. The fractional reabsorption of sodium and water was possible. Active transport of potassium, bicarbonate, and glucose and a gradual ability to excrete ammonia were observed. These results showed the technologic feasibility of an extracorporeal assist device that is reinforced by the use of proximal tubular cells.[95]

Using similar techniques, a tissue-engineered bioartificial kidney consisting of a conventional hemofiltration cartridge in series with a renal tubule assist device containing human renal proximal tubule cells was used in patients with acute renal failure (ARF) in the intensive care unit. The initial clinical experience with the bioartificial kidney and the renal tubule assist device suggests that renal tubule cell therapy may provide a dynamic and individualized treatment program as assessed by acute physiologic and biochemical indices.[96]

The ultimate goal of tissue engineering, however, is the growth of fully functional and fully integrated replacement organs. Thus, another approach toward the achievement of improved renal function involves the augmentation of renal tissue with kidney cell expansion in vitro and subsequent autologous transplantation. The feasibility of achieving renal cell growth, expansion, and in vivo reconstitution with the use of tissue engineering techniques has been explored.

Most recently, an attempt was made to harness the reconstitution of renal epithelial cells for the generation of functional nephron units. Renal cells were harvested and expanded in culture. The cells were seeded onto a tubular device constructed from a polycarbonate membrane, connected at one end with a Silastic catheter that terminated into a reservoir. The device was implanted in athymic mice. Histologic examination of the implanted devices over time revealed extensive vascularization with formation of glomeruli and highly organized tubule-like structures. Immunocytochemical staining confirmed the renal phenotype. Yellow fluid was collected from inside the implant, and the fluid retrieved was consistent with the makeup of dilute urine in its creatinine and uric acid concentrations.[6] Further studies have been performed showing the formation of renal structures in cows using nuclear transfer techniques.[97] Challenges await this technology, including the expansion of this system to larger, three-dimensional structures.

Uterus and Vagina

Congenital malformations, such as cloacal exstrophy and intersex disorders, may not have sufficient uterine tissue for future reproduction. The possibility of engineering functional uterine tissue, using autologous cells, was investigated.[98] For this reason, autologous rabbit uterine smooth muscle and epithelial cells were harvested and then cultured and expanded in vitro. Thereafter, the cells were seeded onto uterine-shaped biodegradable polymer scaffolds, which were consequently used for subtotal uterine tissue replacement. Six months after implantation, histological, immunohistochemical, and Western blot analyses confirmed the presence of normal uterine tissues. Biomechanical analyses and organ bath studies showed that the functional characteristics of these tissues were similar to those of normal uterine tissue.

Several pathologic conditions, including congenital malformations and malignancy, can adversely affect normal vaginal development or anatomy. Vaginal reconstruction is challenging due to the lack of native tissue. Vaginal epithelial and smooth muscle cells of female rabbits were harvested and expanded in culture. These cells were seeded onto biodegradable polymer scaffolds, and the cell-seeded constructs were then implanted into nude mice for up to 6 weeks. Immunohistochemical, histological, and Western blot analyses confirmed the presence of vaginal tissue phenotypes. Electrical field stimulation studies in the tissue-engineered constructs showed functional properties similar to those of normal vaginal tissue. When these constructs were used for autologous total vaginal replacement, functional vaginal structures were noted in the tissue-engineered specimens; however, implanting the non-cell-seeded structures resulted in stenotic structures.[99]

Testicle

Androgen substitution is necessary in patients with testicular dysfunction to allow normal somatic development. Testicular dysfunction is treated with periodic intramuscular injections of chemically modified testosterone and, more recently, transcutaneously with skin patch applications. However, long-term nonpulsatile testosterone therapy can cause multiple problems, including erythropoiesis and bone density changes.

For these reasons, a system was designed wherein Leydig cells were microencapsulated for controlled testosterone release. Purified Leydig cells were isolated and encapsulated in an alginate–poly-L-lysine solution. The encapsulated Leydig cells were injected into castrated animals, and serum testosterone was measured regularly. The animals were able to maintain their testosterone levels during long-term observation.[100] These studies suggest that it may be feasible in the future to use microencapsulated Leydig cells to replace or supplement testosterone in patients where anorchia or acquired testicular failure is present.

Penis

One of the major components of the phallus is corporal smooth muscle. The creation of autologous functional and structural corporal tissue de novo would be beneficial. In order to look at the functional parameters of the engineered corpora, acellular corporal collagen matrices were obtained from donor rabbit penis, and autologous corpus cavernosal smooth muscle and endothelial cells were harvested, expanded, and seeded on the matrices. The entire rabbit corpora were removed and replaced with the engineered scaffolds. The experimental corporal bodies demonstrated intact structural integrity by cavernosography and showed similar pressure by cavernosometry when compared with the normal controls. The control rabbits without cells failed to show normal erectile function throughout the study period. Mating activity in the animals with the engineered corpora appeared normal by 1 month after implantation. The presence of sperm was confirmed during mating, and was present in all the rabbits with the engineered corpora. The female rabbits mated with the animals implanted with engineered corpora and also conceived and delivered healthy pups. Animals implanted with the matrix alone were unable to demonstrate normal mating activity and failed to ejaculate into the vagina.[101]

Silicone is used as biomaterial for penile prostheses; however, biocompatibility remains a concern.[102,103] The appliance of a natural prosthesis composed of autologous cells may be advantageous. The feasibility of using autologous engineered cartilage rods in situ was investigated.[104] Chondrocytes were harvested from rabbit ears and grown and expanded in culture. The cells were then seeded onto biodegradable poly-L-lactic acid–coated PGA polymer rods and implanted into the corporal spaces of the rabbit penis. At retrieval, the presence of well-formed, milky-white cartilage structures within the corpora was noted at 1 month. The polymeric structures were fully degraded by 2 months. No evidence of erosion or infection in any of the implantation sites was observed. Further studies were performed to assess the long-term functionality of the cartilage penile rods in vivo. The animals can copulate and impregnate their female partners.

Engineered bulking agents in urology

Both vesicoureteral reflux and urinary incontinence are frequent conditions affecting the genitourinary system for which injectable bulking agents can be used for endoscopic treatment. The ideal substance for the treatment of reflux and incontinence should be easily injectable, nonantigenic, nonmigratory, volume preserving, and safe for use in humans. In clinical practice, hyaluronic acid, dextranomers, and collagen are commonly used.[105,106] Animal studies have shown that chondrocytes can be easily harvested, cultured together with alginate in vitro. The suspension can then be injected endoscopically, and the elastic cartilage subsequently formed is able to act as a bulking agent to correct vesicoureteral reflux without any evidence of obstruction.[107] The first human application of cell-based bulking agents occurred with the injection of chondrocytes for the correction of vesicoureteral reflux in children and for urinary incontinence in adults.[108,109]

The use of autologous smooth muscle cells was also explored for treatment of both urinary incontinence and vesicoureteral reflux.[110] The use of cultured myoblasts

for the injection treatment of stress urinary incontinence has also been investigated.[111,112] Additionally, the use of injectable muscle precursor cells has been investigated as a potential treatment of urinary incontinence due to irreversible urethral sphincter injury or maldevelopment.[113] A clinical trial involving the use of muscle-derived stem cells (MDSCs) to treat stress urinary incontinence has also been performed. Biopsies of skeletal muscle were obtained, and autologous myoblasts and fibroblasts were cultured. Under ultrasound guidance, myoblasts were injected into the rhabdosphincter, and fibroblasts together with collagen were injected into the submucosal space. One year following injection, the thickness and function of the rhabdosphincter had significantly increased and all patients were continent.[114]

Injectable muscle-based gene therapy and tissue engineering were combined to improve detrusor function in a bladder injury model, and may potentially be a novel treatment option for urinary incontinence.[115]

CONCLUSION

Tissue engineering efforts are currently being undertaken for almost every major type of tissue and organ within the body. Most of the effort expended to engineer these organs has occurred within the last decade. Tissue engineering techniques require a cell culture facility designed for human application. Personnel who have mastered the techniques of cell harvest, culture, and expansion, as well as polymer design, are essential for the successful application of this technology. Before these engineering techniques can be applied to humans, however, further studies need to be performed in many tissues.

In addition to the challenges mentioned above, there are numerous other hurdles that face the tissue engineers of tomorrow. For example, physiologically accurate bioreactors must be developed and refined if complex organs are to be grown and functionalized prior to implantation in humans. Also, a refinement in the approaches to tissue engineering must be achieved, as scientists explore whether preengineered, functional bioengineered replacement organs must be produced to repair tissue function, or whether the goal of tissue engineering should be to use simple biomaterials, cells, or growth factors to induce the repair or regrowth of these damaged organs.

Study Designs and Hierarchy of Evidence

Luis H. P. Braga, Melissa McGrath, and Armando J. Lorenzo

INTRODUCTION

In this chapter, the different types of research designs, with their potential advantages and limitations, are presented. Understanding these issues is essential to determining the strength of the evidence behind study results. Common hierarchies of different study designs in evidence-based medicine are reviewed. A system for grading the quality of evidence is also provided.

Evidence-based practice involves finding the available evidence, assessing its validity, and then using the strongest available evidence in conjunction with clinical judgment to inform decisions regarding patient care.

The hierarchy of evidence places systematic reviews and randomized controlled trials (RCTs) as the highest levels of evidence, whereas case reports and expert opinion are the lowest (Figure 84.1). Due to the intrinsic particularities of the pediatric urology field, it is useful to think of the various study designs not as a hierarchy, but as categories of evidence where the strongest, most practical, and ethical design should be used. Furthermore, the quality of each individual study should be assessed for strengths and weaknesses by checking the methodological safeguards against bias that are relevant to each particular study design.

RESEARCH DESIGN

Clinical research can be experimental or observational. Observational studies can identify an association between two variables, but cannot establish a cause-and-effect relationship. To address the question of causation, RCTs are the preferred choice.[1] In such type of trials, the intervention is under the control of the investigator, whereas in observational studies, the researcher observes patients at a point in time (cross-sectional studies) or over time (longitudinal studies). If the observations are made by looking forward and gathering new data, the study is prospective; if the event of interest has already occurred, the study is retrospective.

EXPERIMENTAL STUDIES

When conducting an experimental study, the allocation of interventions to individuals is under the control of the investigator and thus can be randomized. Experimental studies can be either controlled (with a comparison group) or uncontrolled. Uncontrolled studies provide weaker evidence, and they are typically performed early in an area of research to explore the safety of a new intervention or to gather baseline data for planning more definitive trials.[2] Controlled experimental studies or RCTs are the gold standard by which all clinical research is judged.

RANDOMIZED CONTROLLED TRIALS

The fact that randomization keeps study groups as similar as possible from the outset, together with other methodological safeguards against bias, such as blinding and allocation concealment, makes RCTs the best study design to minimize bias. "Bias is any factor or process that deviates the results or conclusions of the study away from the truth, causing either over or underestimation of the effects of an intervention."[1]

In clinical trials, unknown genetic, environmental, or psychosocial factors may affect the outcome of interest. Randomization, if done properly, reduces the risk that these unknown factors will be unbalanced between study groups. Allocation concealment can be achieved by using opaque envelopes, randomization tables, or computer-generated sequences. Dates of birth (even or odd), chart numbers, or any other type of alternating sequence is inappropriate because research personnel may be able, either directly or indirectly, to guess the randomization sequence. Although sometimes called pseudo- or quasi-randomized trials, these studies are considered nonrandomized.

The vast majority of surgical trials are open trials because both surgeons and patients are aware of the type of intervention being applied. Nevertheless, three other groups or individuals can and should be blinded whenever possible: outcome assessors, data analysts, and investigators who write trial results.[3] In order to preserve that, the allocation code is not broken until these components are completed. Although blinding of statisticians is a common practice, blinding of investigators writing the report is rarely done. The use of sham therapy in surgical trials (to blind patients) has been a long-debated issue due to ethical concerns.[4]

Evidence has shown that surgical interventions, especially when performed to reduce subjective symptoms such as pain, may be associated with a pronounced placebo

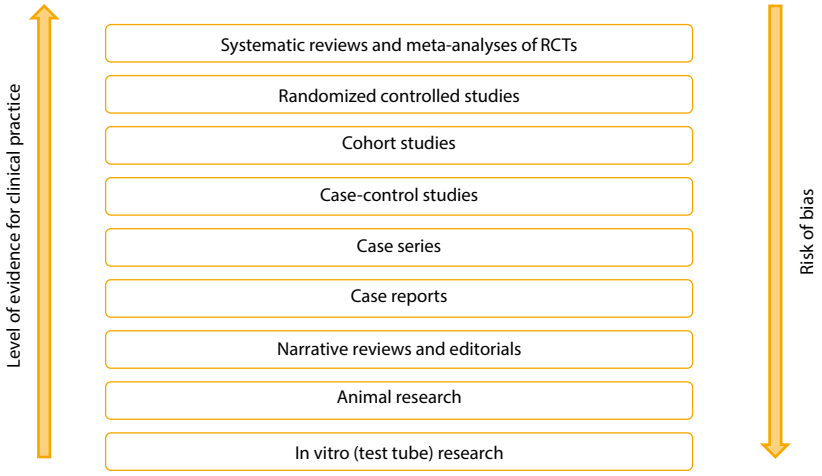

FIGURE 84.1 Hierarchy of evidence for clinical research.

effect.[5] A recent trial by Moseley and colleagues randomized 180 patients with osteoarthritis of the knee to receive arthroscopic debridement, arthroscopic lavage, or sham surgery. The investigators found that although both active therapies produced clinical benefit, neither was statically superior to the sham procedure.[6]

RCTs are not appropriate or feasible for all surgical interventions. It has been estimated that nearly 60% of surgical research questions could not be answered by an RCT, even in ideal clinical circumstances.[7] Furthermore, even when an RCT is appropriate, choosing the trial design can be challenging, as each one has its strengths and limitations.

Designing an RCT is not an easy task, especially when it involves thousands of patients. Herein, we present two reasons why it is necessary to have large RCTs in order to produce reliable results. First, the pathophysiology of most diseases is multifactorial, and given that most interventions target just one or two risk factors, it is unlikely that any particular intervention will have more than a moderate-sized treatment effect, or sometimes no effect if many confounders or biases are present.[8]

The second reason why we need large RCTs relates to a common error in interpreting the statistical significance of trial results, despite the size of the study and number of events.[8] Consider two hypothetical RCTs, each evaluating the effects of cranberry juice versus placebo in patients at risk of urinary tract infection (UTI). Both trials use identical high-quality methodology. The first trial randomizes 200 patients to receive cranberry juice and 200 to receive placebo, and fewer patients assigned to get cranberry juice develop a UTI (2 vs. 18 patients, $p = 0.02$). The second trial randomizes 8000 participants to receive cranberry juice and 8000 to receive placebo, and fewer participants receiving cranberry juice get a UTI (400 vs. 500 patients, $p = 0.02$). Given that both trials used the same high-quality methodology and achieved the same level of statistical significance, one would assume that we should view both results with similar confidence, but this should not be the case. Although the results have the same probability of representing a true finding (same p values), there is a substantial difference in the fragility of those p values. If only four events were added to the treatment group in the first trial, the p value would become 0.13. In contrast, adding two events to the treatment group in the second trial results in no meaningful impact on the p value, which would remain 0.02. Therefore, large trials are needed to ensure reliable estimates of treatment effects (Tables 84.1 and 84.2).

TYPES OF RANDOMIZED CONTROLLED TRIALS

Parallel Trials

Most RCTs make use of a parallel design, in which participants are randomized to two or more groups of equal size and each group is exposed to a different intervention. Parallel trials with more than one treatment arm (matched to a control arm) provide an opportunity to study multiple interventions; however, this also demands larger sample sizes to ensure that such trials are adequately powered to detect clinically important differences between interventions (Figure 84.2).[9]

Crossover Trials

A crossover trial design ensures that each study participant will receive all study interventions; however, the order in which they receive the interventions is random. As such, each participant acts as his or her own control, and individual patient characteristics that may influence response are therefore accounted for. Crossover trials produce within-patient

TABLE 84.1 Results from hypothetical set of trials

Trial 1			
Outcome	Treatment A ($n = 200$)	Placebo ($n = 200$)	p Value
UTI	2	18	0.02
Trial 2			
Outcome	Treatment B ($n = 8000$)	Placebo ($n = 8000$)	p Value
UTI	400	500	0.02

Outcome	Treatment B	Placebo	*p* Value
	(*n* = 8000)	(*n* = 8000)	
UTI	404	500	0.02

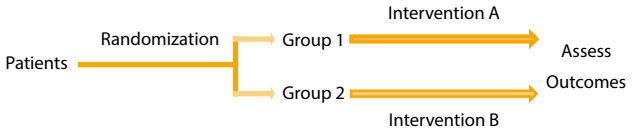

FIGURE 84.2 Parallel design RCT.

comparisons, and thus require fewer subjects than parallel trials to produce statistically significant results.[9]

On the other hand, interactions between interventions may occur with crossover trials, which may interfere with the sample size calculation. Interactions are more common when interventions have similar mechanisms of action, occurring when the effect of one intervention influences the other. For example, in the case of a negative interaction in which the overall effect of individual interventions is reduced when they are provided together, the sample size will need to be increased to detect the same clinically important difference as if there was no interaction.[9]

Factorial Design Trials

A factorial design RCT allows interventions to be evaluated both individually and in combination with one another. Therefore, two or more hypotheses can be explored in one experiment and the effect of combination therapy can be assessed. For example, in an RCT using a 2 × 2 factorial design, participants are allocated to one of four possible combinations: (1) treatment A, (2) treatment B, (3) treatment A and B, or (4) no treatment (Figure 84.3).[9]

n-of-1 Trials

A criticism of the aforementioned RCT designs is that they may provide good information on treatment outcome

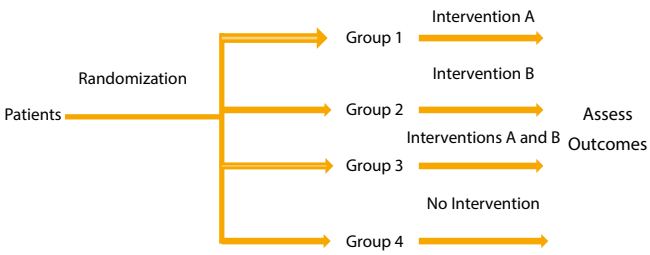

FIGURE 84.3 Factorial design RCT.

for the average patient, but are poorly equipped to provide individual-specific clinical information. RCTs that include only one patient are possible, and require limited resources. Such *n*-of-1 studies are conducted by systematically varying the management of a patient's illness during a series of treatment periods (alternating between experimental and control interventions) to confirm the effectiveness of treatment in that individual patient.[10] The number of pairs of interventions often varies from two to seven. This number is not prespecified, and the clinician and the patient can decide to stop the trial whenever it becomes clear that important differences between interventions have or have not been observed.

Observational Studies

As stated previously, RCTs may not be necessarily appropriate, ethical, or feasible in all situations. In general, questions of therapy are best answered by RCTs (or meta-analyses of RCTs, if available), whereas questions of diagnosis and prognosis may be best addressed by observational studies. Observational studies, which are frequently undertaken in surgery, provide weaker empirical evidence when compared with experimental studies because they are more prone to confounding and bias. Cohort and case-control studies both have been shown to exaggerate treatment effect estimates by up to 150% or reduce the actual effectiveness by up to 90%.[2]

To a large extent, the type of observational study done depends on the prevalence of the disease or condition and on issues related to human resources and costs. Usually, several methods of answering a research question are possible, and the strongest design should be used.

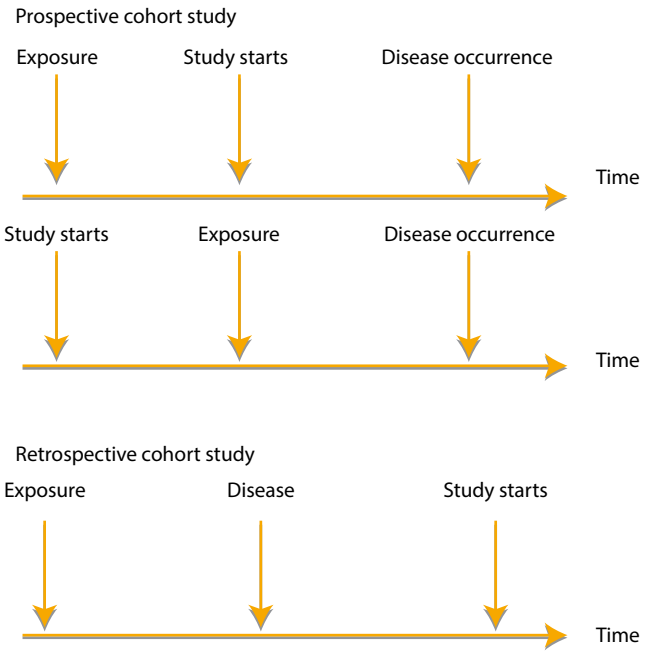
TYPES OF OBSERVATIONAL STUDIES

Cohort (Incidence) Study

In a cohort study, it is known at the outset whether people have been exposed to a treatment or possible causal agent (i.e., a type of trauma, surgical procedure, or drug), and patients are divided into groups or cohorts (exposed vs. nonexposed) on this basis. They are then followed forward in time (prospectively) for years or even decades to see how many in each group develop a particular outcome. These studies are usually less expensive and easier to administer than RCTs. They may also be ethically more acceptable because a potentially beneficial treatment is not withheld, and conversely, a possibly harmful treatment is not given. Cohort studies are susceptible to bias by having different loss to follow up numbers and lack o control over risk assignment. The major disadvantage is that one can never be sure that the cohorts were well matched for prognostic factors and there were no other confounding factors.[9]

A variation of a cohort study is a longitudinal study in which there is only one group. This group is composed of individuals who have a positive screening test or who have all been diagnosed with a disease in an early stage. Patients are then followed and evaluated on a repeated

basis to assess the development of the disease or for measurement of particular outcomes.[9]



Case-Control Study

This is a retrospective observational study in which the proportion of cases with the potential risk factor is compared with the proportion of controls (individuals without the disease or event) with the same risk factor. This is a relatively quick and inexpensive study and is often the best design for rare disorders or when the lag time between exposure and outcome is long. As with cohort studies, case-control studies are vulnerable to unmeasured confounding factors. Cases and controls must have had an equal likelihood of developing the disease under investigation in their baseline preexposure states.[9]

To understand the phenomenon of "confounding," one needs to consider the potential relation between an exposure (e.g., novel surgical technique) and an outcome (e.g., revision surgery or postoperative infection). The term *confounding* refers to a situation when one finds a spurious association or misses a true association between an exposure variable and an outcome variable as a result of a third factor or group of factors referred to as confounding variables.[11]

Therefore, factors that are linked to exposure and outcome are referred to as confounders. The impact of these factors must be assessed and addressed in the controls by matching members of the treatment and control groups on known confounding variables. Confounding is essentially an intrinsic limitation of observational studies (e.g., cohort studies and case-control studies) but is usually well addressed by large and well-designed RCTs. Nevertheless, small RCTs can occasionally run into problems with confounding simply owing to chance if their treatment groups are unbalanced with respect to participants' baseline characteristics.[11]

Confounding can be dealt with at the stage of study design (before collecting the data) or at the stage of data analysis (after collecting the data).[12] The commonly used methods to control for confounding factors and improve the internal validity of a study are randomization, restriction, matching, stratification, multivariable regression analysis, and propensity score analysis.[12]

Cross-Sectional (Prevalence) Studies

A cross-sectional study is a descriptive study of the relationship between an outcome (disease or trauma) and other factors. It usually takes a snapshot of a defined population at a specific point in time. Cross-sectional studies are effective in determining the prevalence of a disease or event (the proportion of the population that has the outcome of interest at a particular point in time) and the coexistence of associated variables. They do not give us information about the disease or event incidence (the proportion of the population that gets the outcome of interest over a specific period of time). Although these studies are relatively easy and inexpensive to carry out, a major limitation is that accurate reporting of the exposure and/or outcome of interest may depend on patients' recall of past events.[9]

Case Reports and Case Series

Case reports and case series are often used to describe a rare disorder or a novel aspect of a less rare condition, a new treatment or innovation, or adverse effects of an intervention. They often provide a great amount of information, which cannot be conveyed in a trial. The description of cases may alert surgeons to important new problems and then allow hypotheses to be generated, leading to focused studies of better design. Case reports and case series are of little use in guiding clinical practice because isolated observations are collected in an uncontrolled, unsystematic manner and the information gained cannot be generalized to a larger group of patients.[9]

Systematic Reviews and Meta-Analysis

Relying on single trials to make important clinical decisions, especially when the result is a change in practice, is often troublesome. Because the numbers of patients needed to detect small to moderate differences for clinically important outcomes may not be found in single studies, definitive answers can only be obtained by conducting well-designed large trials.

When the information from all relevant trials addressing the same question is combined using well-established, rigorous methodology, the result is a systematic review. Systematic reviews are reviews that incorporate strategies to minimize bias by having clearly formulated research questions, predefined inclusion and exclusion criteria, and explicit methodology to identify, select, and critically appraise studies.[13] These key characteristics of systematic reviews set them apart from traditional narrative reviews. The main differences between narrative and systematic reviews are summarized in Table 84.3.[14]

TABLE 84.3 Differences between narrative and systematic reviews

	Traditional review	Systematic review
Question	Often broad in scope	Focused question
Sources/search	Not usually specified, potentially biased	Comprehensive sources and explicit search strategy
Selection	Rarely specified, potentially biased	Criterion-based selection, uniformly applied
Appraisal	Variable	Rigorous critical appraisal, uniformly applied
Synthesis	Often a qualitative summary	Quantitative when appropriate
Inferences	Sometimes evidence based	Evidence based

Source: Adapted from Cook DJ et al. *Ann Intern Med*. 1997;126(5):376–80.

A systematic review may not necessarily include a meta-analysis, which can be defined as the statistical pooling of data from individual studies to create a single treatment effect estimate (pooled estimates of effects). In a meta-analysis, combining individual studies of small sample size increases statistical power (by increasing the total sample size of the study) and generates more precise effect estimates for that particular intervention under investigation. Usually, meta-analysis is the final step of a systematic review, and should only be performed when the variation of treatment effects between studies is small (low heterogeneity), allowing their pooling into a single estimate.[13]

When properly conducted, systematic reviews and meta-analyses of RCTs are ranked high in the hierarchy of evidence and may serve as the foundation for evidence-based practice guidelines, helping clinicians, researchers, and policy makers with a synthesis of the fast-growing literature in the field.[9]

Nevertheless, like any other research study, particularly one that is observational and retrospective, systematic reviews and meta-analyses can be subjected to systematic (bias) and random (chance) errors due to their own limitations.[15] These intrinsic limitations may originate from poor quality of included articles, heterogeneity between studies, and the presence of publication and outcome reporting biases.[16] Therefore, the validity and applicability of any systematic review depends mainly on the quality of the included studies and on how the review was carried out.[15]

Hierarchy of Research Studies

A hierarchy of research study design constitutes one of the core principles of evidence based medicine. In addition it is necessary to classify the available literature into levels of evidence to allow for clear communication among healthcare providers.

The incorporation of the levels of evidence into pediatric urology practice requires an understanding of what constitutes high- versus low-quality studies. For instance, a case report describing a surgical procedure makes one less certain about the effectiveness of that particular intervention when compared with evidence derived from a meta-analysis of multiple large, high-quality RCTs.[17] To acknowledge these quality issues, which are also linked to the amount of confidence one puts in research results, the Oxford Centre for Evidence-Based Medicine[18] has created a hierarchy of evidence to assist clinicians with their clinical decisions. Consequently, the level of confidence in the results is greatest when systematic error or bias is low.[17]

Several hierarchies of evidence and grading systems exist, and they may vary according to the type of study: therapeutic, prognostic, diagnostic, economic, and decision analyses. In most cases, the level of evidence and grading system adopted from the Oxford Centre for Evidence-Based Medicine has been implemented (Table 84.4).[18] For the purpose of this chapter, levels of evidence for therapy are discussed.

Common Hierarchies of Study Design for Treatment Studies

Therapeutic studies investigate the results of a treatment or intervention. The simplest hierarchy of an evidence system involves only looking at the study design, not the study quality. For instance, studies evaluating a

TABLE 84.4 Levels of evidence for therapeutic studies

Level of evidence	Therapeutic studies: Investigating the results of treatment
Level I	High-quality RCT with statistically significant difference or no statistically significant difference, but narrow confidence intervals
	Systematic review of level I RCTs (and study results were homogeneous)
Level II	Lesser-quality RCT (e.g., <80% follow-up, no blinding, or improper randomization)
	Prospective comparative study
	Systematic review of level II studies or level I studies with inconsistent results
Level III	Case-control study
	Retrospective comparative study
	Systematic review of level III studies
Level IV	Case series
Level V	Expert opinion

therapy, such as a novel surgical procedure or medication, commonly use the following hierarchy of evidence in descending order:

- Meta-analysis and systematic reviews of RCTs
- Randomized controlled trials
- Cohort studies
- Case-control studies
- Case reports
- Narrative reviews and editorials (expert opinions)
- Animal research
- In vitro research

This ranking has an evolutionary order, moving from simple observational methods at the bottom of the list through increasingly sophisticated and statistically refined methodologies at the top. In other words, as the research design becomes more rigorous, the quality of evidence increases, and the chance of bias decreases.[17] The RCT, by nature of randomization, has the ability to reduce selection bias.[19] This is extremely important, as bias can interfere with the outcome of a study, leading to over- or underestimation of treatment effects.[19] Randomization helps to control for both known and unknown prognostic factors in the groups under study, yielding a more accurate estimation of the truth.[19] On the other hand, observational studies are more prone to bias because investigators cannot adjust for all prognostic factors, especially the unknown ones.

Similar grading systems have been proposed. The main difference of their ranking is that they place the *n*-of-1 RCT at the top of the hierarchy of evidence, as displayed in Table 84.5. The reason for that is that the *n*-of-1 RCT provides clinical evidence on treatment outcome for that particular individual, as opposed to general information for the average patient.[20]

The levels of evidence table proposed by the Oxford Centre for Evidence-Based Medicine (Table 84.4) takes into consideration study design and methodological quality of the trials.[18]

High-quality RCTs with a statistically significant difference or no statistically significant difference, but narrow confidence intervals, and systematic reviews of level I RCTs with homogenous study results are classified as level I evidence.[9]

When assessing the quality of a systematic review or meta-analysis, it is necessary to look at the study design and quality of the included trials. Meta-analyses of RCTs combine data from individual studies by pooling them into a single estimate of treatment effect, increasing the sample size, and thereby the study power.[21]

TABLE 84.5 Hierarchy of study design

n-of-1 RCT
Systematic review of RCTs
Single RCTs
Systematic review of observational studies addressing patient-important outcomes
Single observational study addressing patient-important outcomes
Expert opinion

Lower-quality RCTs (e.g., <80% patient follow-up, lack of blinding, or improper randomization), prospective cohort studies, and systematic reviews of level II studies or level I studies with heterogeneous results are considered to be level II evidence. The prospective cohort study includes two groups of patients, one that received the intervention of interest and one that did not. Both groups are followed over time, and the outcomes are assessed and compared. Due to its prospective nature, data collection and follow-up are complete and accurate.[21]

Level III evidence includes the case-control study and systematic reviews of level III studies. The case-control study starts with a group that has the outcome of interest and looks back at other similar individuals to see what factors may have been present in the study group that may be associated with the outcome. Case-control studies are retrospective in nature and are prone to bias. Most retrospective studies have potential for bias because missing data and incomplete follow-up are often encountered.[21]

Case series are classified as level IV evidence. Case series are retrospective in nature and have no comparison group. They provide the outcome for only one group in the population, usually those who received the intervention, and the potential for bias is high, especially when there is incomplete data collection or patient follow-up. Because these studies are typically single-center or single-surgeon initiatives, the generalizability of the results is also limited.[9] Results of case series need to be interpreted cautiously.

Although the aforementioned hierarchy of study design and levels of evidence may vary, the premise is similar among the hierarchies, with high-quality RCTs at the top of the lists, followed by observational studies in the middle, and physiologic studies and unsystematic clinical observations at the bottom. Inferences may be very strong if results come from a systematic review of methodologically sound RCTs with homogeneous results.[19] Nevertheless, inferences should be weaker if only a single RCT is being considered, unless it is very large and the investigators have enrolled a diverse patient population.[19] Because observational studies may under- or overestimate treatment effects in an unpredictable manner, their results are far less trustworthy than those of RCTs.[9]

Grades of Recommendation

Assessing the quality of a study in relation to levels of evidence is extremely important when developing grades of recommendation. A grade of recommendation can only be developed after a thorough systematic review of the literature and, in many cases, after discussion with content experts.[22] When developing grades of recommendation, it is extremely important to place more weight on studies that are high on the hierarchy of evidence and have high methodological quality.[22]

In contrast, less weight should be given to studies that are low on the hierarchy of evidence and of lower methodological quality. The GRADE (Grading of Recommendation Assessment, Development, and Evaluation) Working Group suggests a system for grading the quality of the evidence obtained from a thorough systematic review (Table 84.6).[22]

TABLE 84.6 Criteria for assigning the grades of evidence

Types of evidence
Study design
Randomized trial = High quality
Quasi-randomized trial = Moderate quality
Observational study = Low quality
Any other evidence = Very low quality
Decrease grade if
Serious (–1) or very serious (–2) limitation to study quality
Important inconsistency (–1) Some (–1) or major (–2) uncertainty about directness Imprecise or sparse data (–1) High probability of reporting bias (–1)
Increase grade if
Strong evidence of association-significant relative risk of >2 (0.5) based on consistent evidence from two or more observational studies, with no plausible confounders (+1)
Very strong evidence of association-significant relative risk of >5 (0.2) based on direct evidence with no major threats to validity (+2) Evidence of dose–response gradient (+1) All plausible confounders would have reduced the effect (+1)

Source: Adapted from Atkin D et al. *BMJ* 2004;328:1490. Reprinted with permission.

This grading system should be applied to all outcomes of interest. Once the total evidence has been graded, a recommendation for treatment is then made.[22] The GRADE Working Group suggests that four areas should be considered when making a recommendation for treatment:[9]

1. What are the benefits versus the harm? Are there clear benefits to an intervention, or is there more harm as a result?
2. What is the quality of evidence?
3. Are there modifying factors affecting the clinical setting, such as proximity of qualified persons able to carry out the intervention?
4. What is the baseline risk for the potential population being treated?

Once all the factors have been considered, the recommendation should be placed into one of four categories:[22]

- Do it
- Probably do it
- Probably don't do it
- Don't do it

The grades of "do it" or "don't do it" are defined as a judgment that most well-informed people would make, and the grades of "probably do it" and "probably don't do it" are defined as a judgment that the majority of well-informed people would make, but a substantial minority would not.[22] The development of the grades of recommendation based on the GRADE Working Group system gives some one the tools to convey the best-available evidence to patients, as well as to help busy clinicians get connected with the most current evidence in the field.

Although RCTs provide the highest quality of evidence, evidence-based medicine is not the science of RCTs, thus neglecting other study designs. Evidence-based medicine explicitly acknowledges that a large body of what is called "state-of-the-art evidence" is derived from observational studies, mainly because higher-quality evidence is often not available, as is usually the case in many areas of pediatric urology.[23] In our field, few high-quality RCTs have been conducted evaluating existing surgical treatments.[3,23] Therefore, pediatric urologists are frequently forced to look for lower-quality evidence. The practice and application of evidence-based medicine requires an understanding of types of research design and critical evaluation of study methodology.

Nevertheless, this hierarchy is not absolute. If treatment effects are sufficiently large and consistent in observational studies, they may provide more compelling evidence than most small RCTs.[19] At the same time, instances in which results from an RCT contradict consistent results from observational studies reinforce the need for caution.

Observational Studies

As opposed to experiential studies that include random allocation of patients to certain interventions, in observational studies, a group (single cohort = case series) or multiple groups (multiple cohorts) are followed over time and assessed for the development of an outcome. Cohort studies can include historical controls or ideally involve a concurrent selection of controls.[9]

Case-control studies, in which the compared groups are defined based on the outcome, are also included under the umbrella of observational designs. Cohort studies can be prospective or retrospective, whereas a case-control study, by nature of the design, is always retrospective.[9]

Experimental versus Observational Study Design

Ongoing debate exists on whether the results of observational studies are consistent with those derived from RCTs. Clearly, the gold standard for comparing two interventions is an RCT. RCTs are considered experimental studies, whereas nonrandomized studies fall into the observational design category. The purpose of randomization is to balance known and unknown prognostic factors that may influence the outcome. Consequently, if outcome differences are observed in the groups being compared, this difference can be attributed to the intervention under study. Although some techniques exist to deal with known prognostic factors in observational studies, randomization is the only method capable of balancing all prognostic factors in the groups under comparison. Whenever an imbalance in prognostic factors between groups is noted, results will be biased toward one of the interventions under investigation.[9]

If data from RCTs are less prone to bias, should we rely on RCT data only and not trust observational studies? First and most importantly, not all research questions can be answered by a clinical trial or need to be answered by a clinical trial. Evaluating the outcome of multiple prognostic factors and their interaction on an outcome of interest,

for example, the influence of patient age at bladder closure, gender, comorbidities, osteotomies, and type of treatment on bladder exstrophy outcome, cannot be studied with an RCT design. This would require a prospective cohort study involving many centers and for many years. Second, in some situations, an RCT design might be possible but not feasible, for example, when looking at rare outcomes or outcomes that take too long to develop, such as end-stage renal disease in boys with posterior urethral valves. Case-control studies might be more appropriate for those conditions. However, in many cases, RCTs, as well as cohort studies, can be created to answer a specific research question, for example, compare two different surgical techniques for proximal hypospadias. Although RCTs are preferable due to their reduced risk of bias, they also have disadvantages: RCTs can be extremely expensive, and their generalizability is often limited because they are usually performed in large university centers, as opposed to small community-based hospitals. Available resources and surgeons' expertise may differ in both settings; therefore, results based on data from large university centers might not be generalizable to small community hospitals. Furthermore, in RCTs, groups are deliberately balanced to evaluate the effect of a single aspect on the outcome of interest, whereas in the real world, a particular treatment effect may be caused by a combination of factors. Thus, outcomes of an intervention in daily clinical practice (real life) may be different from those reported in RCTs.[9]

Criticisms of observational studies are largely based on the nonrandom allocation of patients to experimental and control groups, thus resulting in biases. Unrecognized confounding factors, which are never accounted for in observational studies, may distort results by over- or underestimating treatment effects. Consequently, these studies have a higher potential of being unsystematic and the recommendations derived from them are much weaker.

There continues to be a debate about the validity of data derived from observational studies. Evidence suggests that results derived from high-quality observational studies yield a magnitude of effect similar to that of RCTs.[24–27] The main features of high-quality observational studies are the use of concurrent controls as opposed to historical controls, a prospective study design whenever possible, the selection of consecutive patients with clearly defined exclusion and inclusion criteria, the blinding of whoever can be blinded whenever possible—similar to RCTs (patient, investigator, outcome assessor, and data analyst), and a high follow-up rate. The balance of known prognostic factors can be achieved during treatment assignment and during study analysis by using techniques such as matching and stratification, which will adjust for differences in baseline characteristics. However, randomization remains the only method capable of achieving balance between unknown prognostic factors.

Study Guide Questions

CHAPTER 4

1. Which of the following ultrasound probes would be most appropriate to image the kidney of a large 14-year-old boy?
   a. 3 mHz
   b. 5 mHz
   c. 7.5 mHz
   d. 10 mHz
   e. Any of the above
   Answer: a. The lower the millihertz of the probe, the better the tissue penetrance that is obtained. In order to image the kidneys in a large 14-year-old, the 3 Mhz probe offers the best tissue penetrance and would be the best choice.
2. An 18-month-old child is seen in the office for an IOUS. During the exam, an overlying rib obscures the child's left kidney and she becomes increasingly agitated and uncooperative. Which of the following positions is optimal to obtain an image of this kidney?
   a. Supine with the probe placed laterally along the axillary line
   b. Left lateral decubitus position
   c. Prone position
   d. The caretaker holding the child and imaging the kidney from the prone position
   e. Supine with the probe anteriorly in an intercostal space
   Answer: d. The prone position is the best position to image a kidney obscured by ribs. In an uncooperative younger child, the comfort of being held by the caregiver will often calm the child down and allow a better exam.
3. A 7-year-old girl is referred to the office for unilateral Grade 1 hydronephrosis. An IOUS is performed that confirms the finding of right hydronephrosis. All the following maneuvers on IOUS would help make the diagnosis of VUR *except* which?
   a. Imaging of the bladder transversely while full
   b. Imaging of the bladder transversely after voiding
   c. Imaging of the bladder parasagittally from the right
   d. Imaging of the bladder parasagittally from the left
   e. Imaging of the kidneys after voiding
   Answer: c. Use of IOUS is helpful in certain situations to delineate unilateral hydronephrosis due to VUR from UPJO. Resolution of hydronephrosis after voiding would favor a diagnosis of VUR, while persistence of unilateral hydronephrosis after voiding would suggest possible UPJO. Likewise, imaging for dilated distal ureters with a full bladder and resolution after voiding would also be suggestive of VUR. This is best done either transversely (ureters located posterior to the bladder) or longitudinally by viewing the ureter from the contralateral parasagittal view of the bladder. Thus, left parasagittal views of the bladder would be used to image the right ureter.
4. A 2-month-old child is seen in the office for evaluation of severe unilateral hydronephrosis. You perform an IOUS. Which of the following findings would be suggestive of a severely obstructed UPJ rather than an MCDK?
   a. An echogenic contralateral kidney
   b. Contiguity of the dilated renal pelvis and dilated calyces
   c. Involution of the kidney on serial follow-up exams
   d. Elongated kidney without reniform shape with multiple cysts
   e. All the above
   Answer: b. The differentiation between a severely obstructed kidney and an MCDK can be challenging. The key differential feature is the contiguity of the dilated renal pelvis with the dilated calyces that is not seen in an MCDK and the lack of involution of the severely obstructed kidney on serial exams. Furthermore, additional features suggestive of an MCDK include an echogenic elongated kidney without reniform shape, multiple noncommunicating cysts, a contralateral echogenic kidney, and perhaps most importantly, involution of the MCDK over time.
5. An IOUS is performed on routine follow-up on a 14-day-old neonate found to have bilateral prenatal hydronephrosis. Examination of the bladder ultrasound demonstrates echogenic material within the bladder lumen. Which of the following is most likely responsible for this finding?
   a. Bladder calculi
   b. Phosphate crystals
   c. Uric acid crystals
   d. Tamm–Horsfall protein
   e. Hypercalcuria
   Answer: d. The echogenic characteristics of a neonate's bladder are usually due to the Tamm–Horsfall protein. The normal urine in older children is echolucent.
6. A 6-year-old girl is seen in the office for evaluation of incontinence and recurrent UTIs. An IOUS is performed and a bladder capacity is calculated. What is the expected bladder capacity of a 6-year-old?
   a. 140 mL
   b. 180 mL
   c. 240 mL
   d. 280 mL
   e. 340 mL
   Answer: c. The formula to estimate the bladder capacity is as follows: Bladder capacity (oz.) = Age (years) + 2. To convert ounces to milliliters, one multiples the

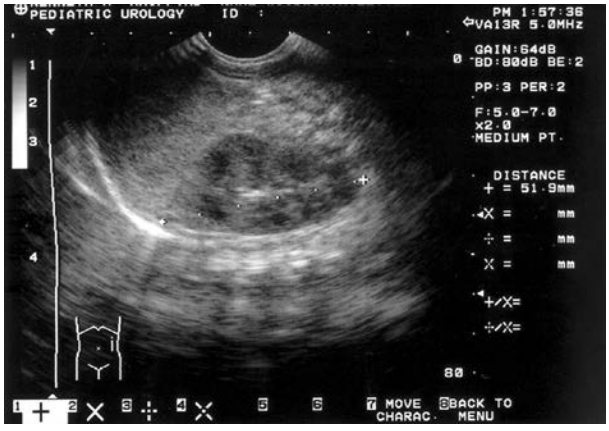
capacity by 30. Thus, a 6-year-old child should have a bladder capacity of 240 mL (or 8 oz.).

7. The following ultrasound is obtained on a 2-week-old neonate as follow-up for prenatally detected right hydronephrosis. Which of the following is the likely diagnosis?

a. Normal right kidney without hydronephrosis
b. Right kidney with SFU Grade 2 hydronephrosis
c. Right kidney with SFU Grade 4 hydronephrosis
d. Right kidney with duplex system and hydronephrosis of upper-pole moiety
e. Right kidney with duplex system and hydronephrosis of lower-pole moiety

Answer: d. This ultrasound image obtained in the office represents an ideal way to follow up on prenatally detected hydronephrosis. This kidney likely has a duplex system, as evidenced by separation of the central echogenic complex (CEC). The upper pole in a duplex system is seen laterally on a sagittal view of the kidney and the lower pole medially. In this case, hydronephrosis is seen in the upper-pole moiety.

8. An IOUS is obtained in the office on a 1-month-old as follow-up for prenatally detected hydronephrosis. The following ultrasound is obtained. What best describes the ultrasound finding?



a. Normal kidney
b. SFU Grade 1 hydronephrosis
c. SFU Grade 2 hydronephrosis
d. SFU Grade 3 hydronephrosis
e. SFU Grade 4 hydronephrosis

Answer: a. This is an image of a normal right kidney. The hypoechoic pockets seen between the renal cortex and renal sinus are prominent renal pyramids typically seen in children. These are not to be confused with hydronephrosis, as there appears to be no connection with the renal pelvis. Furthermore, there is no evidence of dilation within the CEC.

CHAPTER 10

1. Whitish discharge from a newborn girl's vagina is due to
   a. Yeast infection
   b. Strep vaginitis
   c. Maternal estrogens
   d. Ureteral ectopia
   e. Vaginal duplication

   Answer: c
2. The most common cause of paraphimosis is
   a. Chemical irritation
   b. Foreskin retraction without replacement
   c. Yeast infection
   d. Bacterial infection
   e. Diabetes

   Answer: b
3. Meatal stenosis is best diagnosed in the office by
   a. Physical exam
   b. History of voiding problems
   c. VCUG
   d. Observation of urinary stream
   e. Urethral calibration

   Answer: d
4. Urethral prolapse
   a. Usually requires surgery
   b. Occurs more commonly in African American girls
   c. Obstructs bladder outflow
   d. Often recurs
   e. Responds to antibiotics

   Answer: b
5. Labial adhesions
   a. Usually resolve spontaneously
   b. Should usually be separated
   c. Are caused by yeast infections
   d. Are commonly associated with vaginitis
   e. Respond to steroid ointments

   Answer: a
6. Phimosis after a neonatal circumcision
   a. Occurs after circumcision bleeding
   b. Should have the narrowed ring expanded with a hemostat
   c. Is caused by postcircumcision infection
   d. Is often solved by steroid ointment
   e. Is caused by leaving excess inner foreskin

   Answer: e
7. For physiologic foreskin adhesions,
   a. Separation in the office is recommended
   b. 90% of 2-year-old boys' foreskins should be retractable
   c. Smegma buildup leads to infections
   d. Circumcision should follow the first episode of balanitis
   e. Steroid ointment can separate ≥75%

   Answer: e

CHAPTER 13

1. In relation to fertility in the exstrophy male, which of the following statements is true?
   a. Ejaculation is commonly normal.
   b. The bulbocavernosus muscle is normal.
   c. The penile corpora tend to have a narrower girth than in "normal" men.
   d. The testes are structurally normal.
   e. Assisted fertility is always required.

   Answer: d. Typically, men with bladder exstrophy have poor ejaculation; one of the reasons behind this is the absence of a bulbocavernosus muscle. The penile corpora tend to be shorter but broader (wider girth) than normal. Many men do achieve fertility without assistance, but some will need support.
2. In surgery for DSDs, which of the following statements is true?
   a. The clitoral neurovascular bundle is classically ventral.
   b. Genital sensation may be affected.
   c. Intestinal vaginoplasty remains the first choice for reconstruction.
   d. Gonads should always be preserved.
   e. Surgery should be undertaken in early puberty.

   Answer: b. The clitoral neurovascular bundle is dorsal. Intestinal vaginoplasty is major complex reconstructive surgery, and other options should be explored and discussed. Many patients do well with dilation (especially in the absence of previous surgical scarring). The risk of preserving gonads is difficult to quantify. Gonads containing Y chromosomal material in a female phenotype are generally removed for fear of malignant change. The risk varies with diagnosis (e.g., mixed gonadal dysgenesis up to 50% to complete androgen insensitivity). Unless there is an obstruction causing pain and preventing menstruation, once a child has reached puberty, surgery should be deferred, if possible, until sexual activity is contemplated.
3. Which of the following is true regarding a diagnosis of posterior urethral valves?
   a. It is commonly associated with primary vesicoureteric reflux.
   b. It rarely has issues with fertility.
   c. It may be associated with Potter's facies.
   d. Early antenatal diagnosis confers a good prognosis.
   e. Bladder function normally stabilizes in early childhood.

   Answer: c. The vesicoureteric reflux is secondary to obstruction. These men commonly have issues with fertility; this may be due to poor ejaculation or alkalinized or abnormally aggluted semen. As a general rule, earlier diagnosis correlates with worse obstruction, and therefore is associated with a poor outcome. Bladder function may continue to deteriorate well into adult life.
4. In the follow-up of cystoplasty patients, which of the following statements is true?
   a. Bladder stones can be prevented with Mitrofanoff drainage.
   b. Annual cystoscopy is recommended for all.
   c. Subclinical metabolic acidosis should always be treated.
   d. Hematuria can be safely dismissed as catheter trauma.
   e. Gastrocystoplasty has a higher malignant risk than other bowel segments.

   Answer: e. The risk of bladder stones appears to increase with drainage through a Mitrofanoff channel—the theory being that dependent drainage is more effective at clearing mucus and debris. Annual cystoscopy is a poor screening method, but prompt and thorough investigation (including a cystoscopy) of symptoms (e.g., hematuria, pain, and unusual UTIs) is appropriate. Metabolic acidosis needs to be monitored if the bicarbonate is the only derangement and is mild; then no treatment is needed. However, if the chloride is high or there is any sign of symptoms, replacement is indicated.

CHAPTER 14

1. All the following conditions are felt to have a genetic predisposition *except*
   a. Wilms' tumor
   b. Vesicoureteral reflux
   c. Adrenogenital syndrome
   d. Ureteral duplication
   e. Bicornuate uterus

   Answer: e. Bicornuate uterus

CHAPTER 15

1. Adrenal cortical development in human embryogenesis is noted by the eighth week of gestation and is comprised of which of the following?
   a. Fetal zone, zona glomerulosa, and zona fasciculata
   b. Primitive zona glomerulosa, fasciculata, and reticularis
   c. Fetal zone and adrenal cortical cells
   d. Primitive neural crest cells interspersed with primitive adrenocortical cells

   Answer: c. Fetal zone and adrenal cortical cells

CHAPTER 17

1. In hereditary syndromes, which statement is not true?
   a. MEN type 1 is connected with inactivation of a gene on chromosome 11q.
   b. Li–Faumeni syndrome is related to inactivating mutations of TP53.
   c. ACC is linked with abnormalities in 11p15.
   d. Beckwith–Wiedemann syndrome is associated with the WT1 gene.

   Answer: d. Beckwith–Wiedemann is associated with the WT2 gene, abnormalities in 11q15. It is linked with Wilms' tumor, neuroblastoma, hepatoblastoma, and macroglossia.
2. Unilateral APAs do which of the following?
   a. Occur with increased frequency in girls
   b. Occur with equal rates between boys and girls

c. Tend to occur in older children
d. Occur with more frequency in boys

Answer: a. Although uncommon, unilateral APAs have been described in children as young as 3.5 years and affect girls more frequently than boys.

3. All the statements regarding primary hyperaldosteronism are correct *except* which of the following?
   a. Patients present with hypertension and/or hypokalemia, whereas those with secondary hyperaldosteronism do not.
   b. It will lead to a state of excess mineralocorticoid with high PRA.
   c. It may be caused by APA, idiopathic bilateral hyperplasia, or GRA.
   d. Adrenicortical hyperplasia is the most common cause in children.

   Answer: b. Primary aldosteronism will lead to a state of mineralocorticoid excess with *low* PRA.
4. In virilizing tumors, virilization is due to hypersecretion of adrenal androgens, including all *except* which of the following?
   a. DHEAS
   b. DHEA
   c. 11-Deoxycortisol
   d. Δ5-Androstenediol
   e. Δ4-Androstenedione

   Answer: c. Virilization is due to hypersecretion of adrenal androgens, including DHEA and DHEAS, Δ5-androstenediol, and Δ4-androstenedione, all of which may be converted to testosterone and 5α-dihydrotestosterone.
5. All the following conditions are associated with increased plasma catecholamine levels *except*
   a. Neuroblastoma
   b. Pheochromocytoma
   c. Hepatoblastoma
   d. Fever
   e. Stress
   f. Eating

   Answer: c. Norepinephrine and epinephrine are not specific to pheochromocytomas, as they are produced by the sympathoneuronal and sympathomedullary systems. Increased plasma catecholamine levels may be produced by a variety of conditions, including emotional stress, physical activity, eating, fever, and tumor secretion from pheochromocytomas and neuroblastomas.
6. The best investigation for pheochromocytomas is
   a. MIBG
   b. CT
   c. MRI
   d. Ultrasound

   Answer: a. Pheochromocytomas can be imaged with CT, MRI after ^{131}I- or ^{123}I-labeled MIBG. If an initial abdominal CT or MRI is positive, whole-body MIBG should be performed to confirm the diagnosis.

CHAPTER 20

1. There are three sets of kidneys that develop in mammals during embryogenesis. Which of these primitive kidneys do not function during development?
   a. Pronephros
   b. Mesonephros
   c. Metanephric mass
   d. None of the above
   e. All the above

   Answer: a
2. ARPKD is a rare inherited disorder with the abnormal renal configuration due to which of the following?
   a. Abnormal branching of the collecting duct and cyst formation in other parts of the renal tubules
   b. Abnormal formation of the distal convoluted tubule
   c. Enlargement of the collecting ducts
   d. Early obstruction of the tubules from ureteral obstruction potassium administration

   Answer: a

CHAPTER 30

1. The evaluation to define whether a UPJ obstruction exists has included all *except* which of the following studies?
   a. Intravenous pyelogram
   b. MAG-3 lasix renogram
   c. Renal and bladder ultrasound with resistive indices
   d. Antegrade perfusion study (Whitaker)
   e. MR urography with gadolinium

   Answer: c. Although there is not a gold standard that is agreed on in which to define a UPJ obstruction, all the above studies except a renal and bladder ultrasound provide some degree of functional assessment of the kidney. An ultrasound report should not state that the findings are consistent with a UPJ obstruction, but should report the degree of pelvicaliectasis that is present within a kidney.
2. Which surgical repair is most likely to succeed if there is a long segment of ureteral stenosis?
   a. Dismembered pyeloplasty
   b. Endopyelotomy
   c. Laparoscopic Anderson–Hynes pyeloplasty
   d. Spiral flap (Culp–DeWeerd) pyeloplasty
   e. Davis intubated ureterectomy

   Answer: d. Culp and DeWeerd's spiral flap is created from the redundant renal pelvis, transposed inferiorly, and then used to repair the defect at the UPJ. Such a flap is able to bridge the gap between the pelvis and healthy ureter over a distance of several centimeters.
3. Key steps in performing a dismembered pyeloplasty include all *except* which of the following?
   a. Placing a Penrose drain adjacent to the repair
   b. Excising as much redundant pelvis as possible
   c. Placing a feeding tube into the ureter during the suturing of the anastomosis
   d. Ensuring that a tension-free anastomosis exists
   e. Spatulating the ureter on the lateral margin at an adequate distance

   Answer: b. There is no clinical evidence that excessive reduction of the redundant pelvis is required to ensure a patent repair after pyeloplasty. The proximal ureter should be affixed to the most dependent portion of the renal pelvis, which then obviates concerns regarding redundancy.
4. Surgical options in the repair of a failed pyeloplasty include all *except* which of the following?

a. Endopyelotomy
b. Redo pyeloplasty
c. Transureteroureterostomy
d. Nephrectomy
e. Ureterocalicostomy

Answer: c. Depending on the clinical scenario, the presence of a missed crossing vessel, the functional status of the affected kidney, and the degree of hydronephrosis, each of the options above may be considered except transureteroureterostomy. That option is not appropriate due to the proximal ureteral location of stenosis.

5. Endopyelotomy is associated with the greatest likelihood for success in all *except* which of the following scenarios?
   a. Lack of a lower-pole crossing renal vessel
   b. Preserved renal function in the affected kidney
   c. Mild to moderate hydronephrosis
   d. Case of failed previous pyeloplasty
   e. Primary treatment for UPJ obstruction

   Answer: d. Endopyelotomy carries a long-term success rate, as high as 94%, as a secondary treatment for UPJ obstruction after previously failed pyeloplasty. Decreased renal function, severe hydronephrosis, and a lower-pole crossing vessel are known to decrease the likelihood of success in primary treatment cases.
6. Which of the following is an advantage gained with robotic assistance compared with pure laparoscopy?
   a. Two-dimensional visualization in high definition
   b. Ability to perform laparoscopic surgery via a camera port and a single additional port
   c. Dampening of tremor
   d. Decreased analgesia requirement in the postoperative period
   e. Shorter length of postoperative hospitalization

   Answer: c. The clear advantages of robotic-assisted laparoscopy over traditional laparoscopy include three-dimensional visualization (now in high definition), articulating instruments with greater degrees of freedom, and dampening of tremor. No comparable difference has been demonstrated in any postoperative parameters.
7. Appropriate postnatal radiographic imaging of an infant with prenatally detected MCDK has included all *except* which of the following studies?
   a. Voiding cystourethrography
   b. Renal and bladder ultrasound
   c. MAG-3 lasix renogram
   d. Dimercaptosuccinic acid (DMSA) renal scan
   e. MR urography

   Answer: e. In the past, it was important to identify those patients with reflux who had a solitary functioning kidney. An ultrasound has been the predominant modality to define an MCDK, and either a MAG-3 lasix renogram or a DMSA scan will demonstrate no uptake in the MCDK. There is no role for MR urography in this situation to characterize an MCDK.

CHAPTER 34

1. Following blunt abdominal trauma, patients presenting with a history of hematuria disproportionate to the severity of trauma are most likely to have a
   a. Renal tumor
   b. Renal lithiasis
   c. Myoglobinuria
   d. Congenital anomaly
   e. Immature thoracic cage

   Answer: d
2. Delayed hemorrhage occurring 2 weeks following a grade 3 renal fracture should be managed by repeat CT scan and
   a. Observation
   b. Cystoscopy
   c. Epsilon aminocaproic acid (Amicar)
   d. Angiography with selective angiographic embolization
   e. Renal exploration

   Answer: d
3. Three days after selective embolization of a segmental renal artery for persistent bleeding following a grade 4 renal fracture, the patient has a persistent ileus, fever of 40°C, and continued left flank pain. He is currently on broad-spectrum antibiotics. Physical examination reveals no signs of peritoneal localization. The next step is to obtain blood and urine cultures and
   a. Continue observation
   b. Change antibiotics
   c. Obtain a repeat CT scan
   d. Perform aspiration and culture of perinephric hematoma or urinoma
   e. Perform an exploratory laparotomy

   Answer: a
4. A 6-year-old boy has persistent hypertension 12 weeks following a grade 4 left renal fracture. CT angiography reveals a left upper-pole AV fistula with complete resolution of the previous existing left perinephric hematoma and urinoma. Extensive subcapsular fibrosis has developed surrounding the entire left kidney. The right kidney is within normal limits. A DMSA scan reveals 30% differential function of the left kidney and 70% differential function of the right kidney. The serum creatinine and renal clearance are normal. The next step is to continue antihypertensive medications and
   a. Observe
   b. Obtain selective renal vein renins from the upper- and lower-pole vessels of the left kidney
   c. Perform angioinfarction of the left upper-pole AV fistula
   d. Perform a left upper-pole partial nephrectomy and decortication of the perinephric fibrosis
   e. Perform a left nephrectomy

   Answer: c
5. A 15-year-old boy presents with a 22-caliber gunshot wound to the left flank. Evaluation reveals an entrance wound posterior to the left anterior axillary line; no exit wound is seen. Vital signs are stable, and the patient has no signs of peritoneal irritation. A CT scan reveals a grade 2 left renal injury. The right kidney is within normal limits. No air is noted in the peritoneal cavity, and no associated organ injuries are noted. The distal ureters are intact bilaterally. Your next step is to initiate intravenous antibiotics and
   a. Observation
   b. Intravenous indigo carmine and local exploration of the wound

c. Exploratory laparatomy alone
d. Retroperitoneal exploration and renorrhaphy alone
e. Exploratory laparatomy, retroperitoneal exploration, and renorrhaphy

Answer: a

6. A 4-year-old girl presents with a grade 3 renal injury following blunt renal trauma. A CT scan reveals a large perinephric urinoma, no devitalized renal fragments, and distal ureters intact bilaterally. There are no associated intra-abdominal injuries. The next step is admission to the hospital and
   a. Observation
   b. Cystoscopy and placement of a double-J stent
   c. Percutanous nephrostomy
   d. Percutanous tube placement into the urinoma
   e. Exploratory laparatomy

   Answer: a
7. A 12-year-old boy with a history of a pedestrian motor vehicle accident 2 hours ago is clinically stable. A triphasic CT evaluation reveals a grade 3 left renal fracture with a 2 cm devitalized left lower-pole fragment. Extravasation of contrast is seen lateral to the left kidney. No distal left ureter is visible. The right kidney is within normal limits. The right distal ureter is visible. No other intra-abdominal injuries are noted. The next step is
   a. Observation
   b. Exploratory laparatomy
   c. Cystoscopy and retrograde pyelogram
   d. Percutaneous drainage of the urinoma
   e. Percutanous nephrostomy tube placement

   Answer: c
8. A 3-year-old girl sustained an isolated grade 4 left renal trauma following a high-speed motor vehicle accident. The initial CT scan and a CT scan 3 days posttrauma revealed a large left urinoma with a left upper-pole fragment widely separated from the kidney contrast seen in the distal left ureter. The right kidney is normal. Do to persistent ileus, the patient undergoes placement of a 5 French double-J stent on the third posttraumatic day. Six days posttrauma the patient has continued ileus and left flank pain. A CT scan reveals persistent urinoma. The next step is
   a. Cystoscopy and placement of an 8 French double-J stent
   b. Placement of a percutanous drain into the urinoma
   c. Placement of a percutanous nephrostomy tube
   d. Angiography and angioinfarction of the left upper pole
   e. Retroperitoneal exploration and renorrhaphy

   Answer: c

CHAPTER 36

1. Which of the following are involved in the outgrowth of the ureteral bud?
   a. GDNF
   b. Renin–angiotensin system
   c. PAX2
   d. Sonic hedgehog
   e. All the above

   Answer: a, b, c

CHAPTER 38

1. Ureteral triplication
   a. Can be easily diagnosed prenatally
   b. Is associated with a pathognomonic constellation of symptoms
   c. Usually mandates urgent lower urinary tract reconstruction
   d. Is bilateral in most cases
   e. Is often associated with other systemic or urologic anomalies

   Answer: e
2. Which of the following midureteral surgical techniques is most likely to result in ureteral stricture?
   a. Renal mobilization
   b. Ureteral stent
   c. Removal of periureteral adventitia
   d. Perianastomotic drains
   e. Spatulation of both proximal and distal ureteral segments

   Answer: c
3. Retrocaval ureter is most often associated with
   a. Persistence of the supracardinal vein
   b. Situs inversus
   c. Hematuria
   d. The left ureter
   e. Medial ureteral deviation

   Answer: e

CHAPTER 44

1. The most important surgical goal of ureteral reimplantation is the reestablishment of a flap valve mechanism that requires a ratio of ureteral tunnel length to ureteral diameter of
   a. 3:1
   b. 5:1
   c. 10:1
   d. 1:1
   e. 2:1

   Answer: b
2. During the modified Politano–Leadbetter repair, where is the new ureteral hiatus placed in relation to the original hiatus?
   a. Inferior and medial
   b. Superior
   c. Lateral
   d. Superior and medial
   e. Medial

   Answer: d
3. The appropriate evaluation and treatment of asymptomatic hydronephrosis present after open ureteral reimplantation includes
   a. Diuretic renography and ureteral stent placement
   b. Ureteral stent placement
   c. Percutaneous nephrostomy placement
   d. Observation
   e. Repeat reimplantation

   Answer: d
4. The major drawback to the cross-trigonal reimplantation technique is

a. Frequent stenosis of the ureteral orifice
b. Excessive "kinking" of the ureter after repair
c. Insufficient muscular backing
d. Difficulty in accessing the ureter during endoscopy
e. Increased chance of ureteral devascularization
Answer: d

5. Postoperative urinary retention most commonly occurs following which open technique?
a. Modified Politano–Leadbetter
b. Gil-Vernet
c. Lich–Gregoir
d. Glenn–Anderson
e. Cohen cross-trigonal
Answer: c

6. When choosing open repair techniques, which factor supports the use of the Glenn–Anderson approach?
a. Lateral displacement of the ureters
b. Stenotic ureteral orifices
c. Large, wide trigone
d. Numerous preoperative UTIs
e. Presence of bladder–bowel dysfunction
Answer: a

CHAPTER 49

1. The bladder develops from
a. The urogenital sinus
b. The mesoderm of the anterior abdominal wall
c. The endoderm
d. The ureteral buds
e. All the above

2. Place the following events in correct chronological order:
a. Pronephros involutes
b. Urorectal septum descends
c. Proximal urethra forms
d. Müllerian ducts form
e. Wolffian ducts form

1. a, b, c, d, e
2. a, b, e, c, d
3. a, b, c, e, d
4. a, d, c, b, e
5. a, e, b, c, d

CHAPTER 69

1. The fetal gonads begin to differentiate into either a testis or an ovary at approximately which week of gestation?
a. Week 3
b. Week 6
c. Week 9
d. Week 12
e. Week 15
Answer: b

2. Testicular descent from the abdominal cavity through the inguinal canal and into the scrotum may be influenced by all *except* which of the following?
a. Gubernacular guidance
b. Increased intra-abdominal pressure
c. Local hormonal factors
d. The processus vaginalis
e. Completed development of the vas deferens
Answer: e

3. Which of the following is a remnant of the Müllerian duct system?
a. Appendix testis
b. Epoopheron
c. Gartner's duct
d. b and e
e. All the above
Answer: a

CHAPTER 75

1. What hormone is most directly responsible for the development of the external male genitalia?
a. Testosterone
b. Estrogen
c. Mullerian inhibiting substance
d. Dihydrotestosterone
e. Growth hormone
Answer: d

2. The etiology of penile necrosis is likely which of the following?
a. Use of electrocautery with clamp devices
b. Use of electrocautery during freehand sleeve circumcision
c. Use of Dermabond and other skin glues for circumcision closure
d. Postcircumcision hematoma development
e. Local anesthetic use during circumcision
Answer: a

3. When considering a Nesbit placation, the anatomical location of the nerve fibers that course along the penis is which of the following?
a. Six o'clock
b. Three o'clock
c. Twelve o'clock
d. Nine o'clock
e. Two o'clock
Answer: c

4. What is considered an abnormal stretch penile length in a newborn?
a. Less than 1 cm
b. Less than 1.5 cm
c. Less than 2 cm
d. Less than 2.5 cm
e. No normal value exists
Answer: c

5. What is the recommended intial management of high-flow priapism in the pediatric population?
a. Angiographic embolization of arteriovenous fistulization
b. Observation and compression
c. Irrigation and injection of alpha-adrenergic agonists
d. Irrigation and injection of alpha-adrenergic antagonists
e. Winter's shunt
Answer: b

6. In patients with an ectopic scrotum, what additional testing should be performed?
   a. Renal ultrasound
   b. VCUG
   c. MRI abdomen and pelvis
   d. Serum testosterone
   e. Urinalysis
   Answer: a
7. In counseling adolescents about varicocele, which of the following statistics are correct regarding the incidence of varicocele in the population and the incidence of infertility in men who have varicocele:
   a. 50%:50%
   b. 40%:90%
   c. 40%:15%
   d. 40%:40%
   e. 15%:40%
   Answer: e
8. In determining the need for surgical intervention in an adolescent with varicocele, which of the following testicular size discrepancies has been traditionally used as an indicator for the need for varicocelectomy?
   a. 30%
   b. 40%
   c. 20%
   d. 15%
   e. 50%
   Answer: c
9. After varicocelectomy, what percentage of patients will experience testicular "catch-up growth"?
   a. 80%
   b. 20%
   c. 50%
   d. 100%
   e. 90%
   Answer: a
10. The predominant histopathological finding in adolescents undergoing varicocelectomy is which of the following?
   a. Sertoli cell hyperplasia
   b. Hyalinization of the testicle
   c. Leydig cell atrophy
   d. Leydig cell hypertrophy
   e. No abnormality
   Answer: c
11. How are neonatal/adolescent testicular torsion classified?
   a. Intravaginal/extravaginal
   b. Intravaginal/intravaginal
   c. Extravaginal/intravaginal
   d. Extravaginal/extravaginal
   e. Random pattern
   Answer: c
12. What is the embryological origin of the appendix testis?
   a. Wolffian duct remnant
   b. Mullerian duct remnant
   c. Ureteric bud remnant
   d. Gonadal ridge remnant
   e. Testicular remnant
   Answer: b
13. Bilateral abscence of the vas deferens can indicate which genetic condition?
   a. von Hippel–Lindau
   b. Fragile X syndrome
   c. Tuberous sclerosis
   d. Cystic fibrosis
   e. VACTERL
   Answer: d
14. Multiple epididymal cysts in a young male patient indicate the need for what other imaging study due to its possible association with a genetic condition?
   a. Spine MRI
   b. VCUG
   c. Renal ultrasound
   d. electroencephalogram (EEG)
   e. Dimercaptosuccinic acid scan
   Answer: c
15. Which of the following shunts for priapism has the highest risk of long-term erectile dysfunction?
   a. Winter's
   b. Ebbehoj
   c. Al-Ghorab
   d. Grayhack
   e. None of the above
   Answer: d

Index

  extravesical techniques, 716–17
    Lich–Grégoir repair, 716–17
  historical background, 708
  indications, 708
  intravesical techniques, 709–15
    Cohen's cross-trigonal repair, 711–15
    exposure/initial dissection, 709–10
    Gil-Vernet repair, 715
    Glenn–Anderson repair, 715
    Politano–Leadbetter repair, 710–11
  minimally invasive approaches, 721
    extravesical laparoscopic ureteral reimplantation, 723–5
    intravesical laparoscopic ureteral reimplantation, 709–15
  postoperative evaluation, 717–18
  presurgical techniques, 709
    cystoscopy, 709
    positioning, 709
  results, 718
  ureterovesical junction, 716–17
  urinary tract infection in, 729
  voiding dysfunction, 724–5
V-flap umbilical stoma, *985*
videourodynamics, 857, 960, 1101, *1101*
viral cystitis, 222–3
virilizing adrenal tumors, 1393–4
voiding cystourethrography (VCUG), 45–6
  bladder, 780
  bladder augmentation, 784
  bladder diverticulum, 783–4
  bladder rupture, 785–6
  megaureter, 786
  open bladder neck, *783*
  posterior urethral valves, 767
  prune belly syndrome, 419
  small bladder capacity, 1077
  urachus, 778
  ureter, 777
  urinary ascites, *129*
voiding reflex, 813
von Hippel–Lindau disease, 7, 306
von Recklinghausen's disease, *see* neurofibromatosis type 1
von Willebrand disease, 29, **30**
von Willebrand factor (vWF), 29
  ristocetin cofactor (vWFRCo), 29
VQZ skin-slap technique, 970, *985*
vulvitis, 164
vulvovaginitis, 175, 220, 227–8
  nonspecific, 228

W

WAGR syndrome, **236**, *527*, *536–537*
Wallace technique for ureterointestinal anastomosis, 958
weak bladder outlet
  fascial sling, 887, *889–890*
  suture placement, 886, *887*
Weigert–Meyer law, 627
Whitaker test, **496**
Williams syndrome, 1080
Wilms' tumor, 85–6, 250, 331, 430–1, 497–512
  epidemiology, 497–8

biology and genetics, 498–9
genetics, 232
histopathology, 499–51
horseshoe kidney and, 289, 305
in multicystic dysplastic kidney, 341
presentation, preoperative evaluation and staging, 501–3
rhabdomyosarcoma and, 970
staging, **502**
surgery, 503, 521–3
intravascular invasion, *555*
lymph node sampling, *555*
nephrectomy, 557–82
partial nephrectomy, 557–8
pathology specimen, *553*
patient preparation, *554*
surgical outcome, *554*
surgical principles, 554–5
tumor spillage and rupture, 555–6
treatment and outcome, 532–8
International Society of Pediatric Oncology, 1013
late effects of, 538–9
partial nephrectomy in unilateral tumors, 536–7
preoperative chemotherapy vs immediate nephrectomy, 538–9
bilateral disease, 537–8
inoperable tumor, 536
vascular extension, 535–536
UK Children's Cancer Study Group, 1006
Wilson's disease, 436–7
Wolffian duct system, defects of, 1287–8
agenesis, 1287
anomalies of epididymal attachment, 1287–1288
epididymal cysts, 1287
Wolffian duct, fate of, 1287
Wolffian remnants, 626
Wolman's disease, 301

X

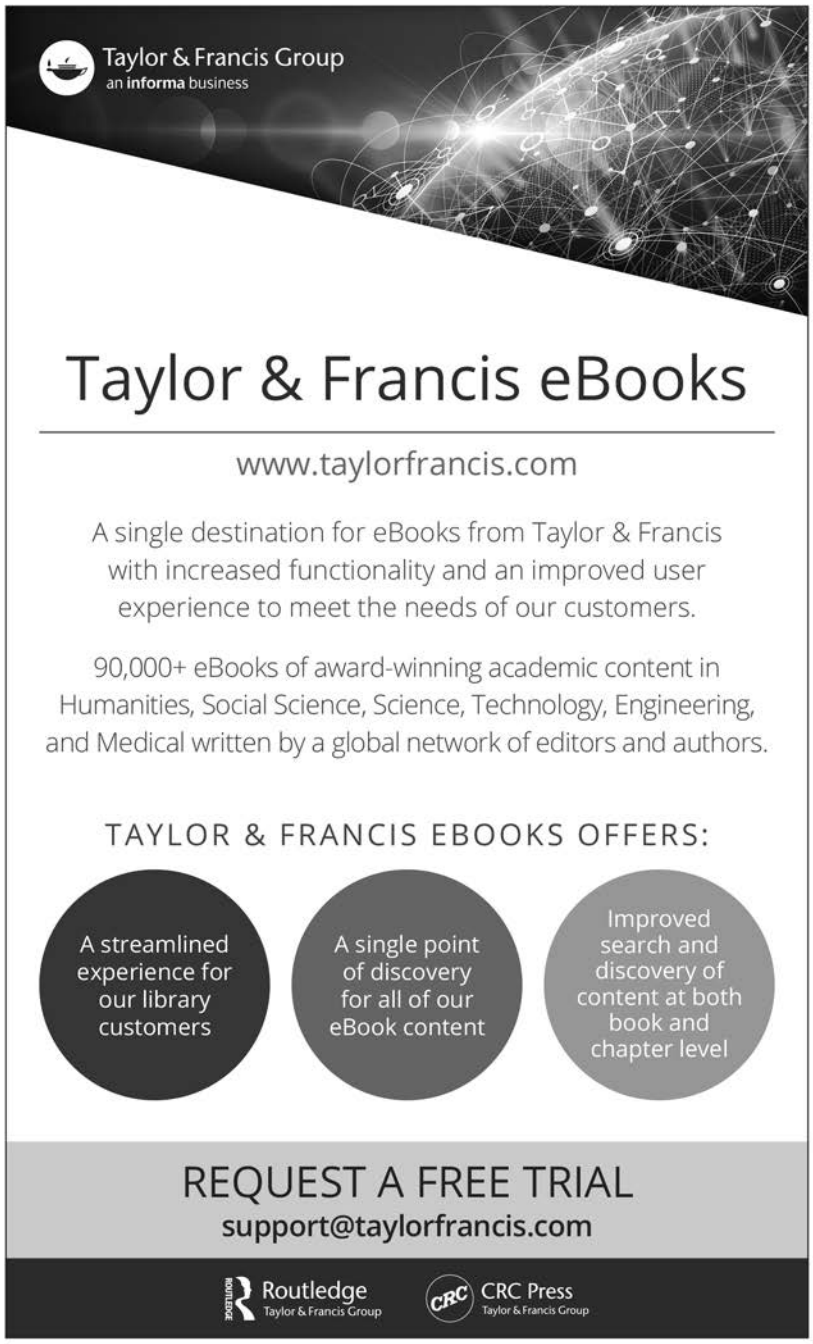
xanthinuria, 432
xanthogranulomatous pyelonephritis, 190, 475
xenotransplantation, 1377
XY gonadal dysgenesis, 1175

Y

Young–Dees–Leadbetter (YDL) bladder neck
reconstruction, 852–3, *852–3*, 865, 1029–31, *1030*
variations, 894–5
Arap's staged bladder reconstruction, *899*
indicators for success, 901–3
Koff's, 895, *897*
Koyle's Thiersch–Duplay tube-tubulization, 895
Mitchell's, 895, *188*
Mollard's, 894–5, *8*
Young–Dees–Leadbetter (YDL) procedure, 893–896, *894–899*
yo-yo reflux, *632*, 633–4
Y-ureterostomy, 954

Z

Zellweger syndrome, **394**



Taylor & Francis Group
an informa business
Taylor & Francis eBooks
www.taylorfrancis.com
A single destination for eBooks from Taylor & Francis with increased functionality and an improved user experience to meet the needs of our customers.
90,000+ eBooks of award-winning academic content in Humanities, Social Science, Science, Technology, Engineering, and Medical written by a global network of editors and authors.
TAYLOR & FRANCIS EBOOKS OFFERS:
A streamlined experience for our library customers
A single point of discovery for all of our eBook content
Improved search and discovery of content at both book and chapter level
